We assume that the distribution function is given by f at $t=-\infty$, that is, at the infinite past. It is assumed to be in equilibrium, that is, $(\mathscr{H}f)=0$. The perturbation (2.1) is inserted adiabatically at $t=-\infty(F(-\infty)=0)$. The distribution function $f'(t)$ obeys the equation

$$\frac{\partial f'(t)}{\partial t}=(\mathscr{H},f')+(\mathscr{H}'(t),f)\,. \tag{2.4}$$

Since we take the linear approximation, we put

$$f'(t)=f+\Delta f$$

and replace (2.4) by

$$\frac{\partial\Delta f}{\partial t}=(\mathscr{H},\Delta f)-F(t)(A,f)\,. \tag{2.5}$$

The solution is easily found to be

$$\Delta f(t)=-\int_{-\infty}^{t}e^{i(t-t')L}(A,f)\,F(t')\,dt' \tag{2.6}$$

where the operator L is defined by the operation4)

$$iLg\equiv(\mathscr{H},g)\,. \tag{2.7}$$

Therefore, the change $\Delta B(t)$ of a dynamical quantity B is statistically given by

$$\begin{aligned}\Delta B(t)&=\int\Delta f(t)\cdot B(p,q)\,d\Gamma\\&=-\int d\Gamma\int_{-\infty}^{t}\left\{e^{i(t-t')L}(A,f)\right\}\cdot F(t')B\,dt'\\&=-\int d\Gamma\int_{-\infty}^{t}(A,f)B(t-t')F(t')\,dt'\,,\end{aligned} \tag{2.8}$$

$d\Gamma$ being the volume element of the phase space. The last expression is obtained from the second remembering that the transformation $\exp(iLt)$ is the natural motion which conserves the measure of the phase space and that $B(t)$ means the dynamical motion of the phase function $B(p,q)$ which follows the equation

$$\dot{B}(p,q)=(B,\mathscr{H})\,.$$

This corresponds to the Heisenberg equation of motion in quantum-mechanics. Eq. (2.8) means that the response $\Delta B(t)$ is a superposition of the effects of pulses $F(t')\,dt'$, $-\infty<t'<t$. The response for an unit pulse will be called the ***response function*** or the ***after-effect function*** $\phi_{AB}(t)$. From Eq. (2.8) we find at once that it is given by

$$\phi_{BA}(t)=-\int d\Gamma(A,f)\,B(t) \tag{2.9}$$

which describes the response ΔB at the time t after the pulse. The response $\Delta B(t)$, (2.8), is written as

$$\Delta B(t)=\int_{-\infty}^{t}\phi_{BA}(t-t')\,F(t')\,dt'\,. \tag{2.10}$$

The above consideration applies even when the initial distribution is very sharp, as far the perturbation is weak enough. But our aim is rather to apply this for a macroscopic system, in which case the statistical average itself acquires a realistic meaning. If A and B are both macroscopic quantities, we may think the ensemble average $\Delta B(t)$ is what we actually observe, because a macroscopic system can be conceived to consist of smaller systems so that observed value of ΔB is a sum of a number of components and has only very small relative fluctuation.

Let us now turn to quantum mechanics. he distribution function in phase space is ow replaced by the density matrix ρ. The itial ensemble which represents statistically e initial state of the system is specified by he density matrix ρ satisfying $[\mathscr{H},\rho]=0$, hereas the motion of the ensemble under he perturbation (2.1) is represented by $\rho'(t)$, hich obeys the equation,

$$\frac{d}{dt}\rho'(t)=\frac{1}{i\hbar}[\mathscr{H}+\mathscr{H}'(t),\rho'(t)]. \qquad (2.11)$$

With the initial condition

$$\rho'(-\infty)=\rho,$$

we expand $\rho'(t)$ as

$$\rho'(t)=\rho+\Delta\rho(t).$$

The same procedure as we used for (2.5) leads us at once to

$$\Delta\rho(t)=-\frac{1}{i\hbar}\int_{-\infty}^{t}\exp(-i(t-t')\mathscr{H}/\hbar)[A,\rho]\times\exp(i(t-t')\mathscr{H}/\hbar)F(t')\,dt'. \qquad (2.12)$$

Incidentally, we note that it is sometimes very convenient to introduce the operator $a^\times$ operating on another operator b by following definition, i.e.,

$$a^\times b=[a,b], \qquad (2.13)$$

for which one find the rule,

$$e^{a^\times}b=e^a b e^{-a}. \qquad (2.14)$$

With this notation, Eq. (2.11) and (2.12) can be written as

$$\rho'(t)=\frac{1}{i\hbar}(\mathscr{H}^\times+\mathscr{H}'(t)^\times)\rho'(t) \qquad (2.15)$$

$$\Delta\rho(t)=-\frac{1}{i\hbar}\int_{-\infty}^{t}\exp(-i(t-t')\mathscr{H}^\times/\hbar)\times[A,\rho]F(t')\,dt' \qquad (2.16)$$

This will make clear the similarity of Eqs. 2.6) and (2.12).

The response $\Delta B(t)$ of the quantity B is statistically

$$\begin{aligned}\Delta B(t)&=\mathrm{Tr}\,\Delta\rho(t)B\\&=-\frac{1}{i\hbar}\mathrm{Tr}\int_{-\infty}^{t}\exp(-i(t-t')\mathscr{H}/\hbar)\\&\quad\times[A,\rho]\exp(i(t-t')\mathscr{H}/\hbar)BF(t')\,dt'\\&=-\frac{1}{i\hbar}\mathrm{Tr}\int_{-\infty}^{t}[A,\rho]B(t-t')F(t')\,dt'\end{aligned} \qquad (2.17)$$

where $B(t)$ is the Heisenberg representation of B following the equation

$$\dot{B}(t)=\frac{1}{i\hbar}[B(t),\mathscr{H}],\ B(0)=B. \qquad (2.18)$$

Eq. (2.17) corresponds to Eq. (2.8)

The response function or the after-effect function is now

$$\phi_{BA}(t)=-\frac{1}{i\hbar}\mathrm{Tr}\,[A,\rho]B(t) \qquad (2.19)$$

corresponding to Eq. (2.9). We naturally have Eq. (2.10) for (2.17) with the use of response function (2.19). If the force is periodic, i.e.,

$$F(t)=F_0\cos\omega t,$$

the response $\Delta B(t)$ will be conveniently written as

$$\Delta B(t)=\mathrm{Re}\,\chi_{BA}(\omega)F_0e^{i\omega t} \qquad (2.20)$$

with the complex admittance $\chi_{BA}(\omega)$, for which we have from Eq. (2.10)

$$\chi_{BA}(\omega)=\int_0^\infty\phi_{BA}(t)e^{-i\omega t}\,dt, \qquad (2.21)$$

or more exactly

$$\chi_{BA}(\omega)=\lim_{\varepsilon\to0+}\int_0^\infty\phi_{BA}(t)e^{-i\omega t-\varepsilon t}\,dt.$$

We summarize the above by the theorem:

Theorem 1. *The linear response of a physical quantity B to an external force F(t) is represented by Eq. (2.10) as the superposition of after-effects. The after-effect function or the response function is given by*

$$\begin{aligned}\phi_{BA}(t)&=\int d\Gamma(f,A)B(t)\quad\text{(classical)}\quad(2.22a)\\&=\frac{1}{i\hbar}\mathrm{Tr}[\rho,A]B(t)\quad\text{(quantal)}.\quad(2.22b)\end{aligned}$$

The admittance $\chi_{BA}(\omega)$ is given by

$$\chi_{BA}(\omega)=\lim_{\varepsilon\to0+}\int_0^\infty e^{-i\omega t-\varepsilon t}\,dt\int d\Gamma(f,A)B(t)\quad\text{(classical)}\quad(2.23a)$$

$$=\lim_{\varepsilon\to0+}\int_0^\infty e^{-i\omega t-\varepsilon t}\,dt\frac{1}{i\hbar}\mathrm{Tr}[\rho,A]B(t).\quad\text{(quantal)}\quad(2.23b)$$

Eqs. (2.22) may be written as

$$\begin{aligned}\phi_{BA}(t)&=\int d\Gamma f(A,B(t))\quad\text{(classical)}\quad(2.24a)\\&=\frac{1}{i\hbar}\mathrm{Tr}\,\rho[A,B(t)]\quad\text{(quantal)}\quad(2.24b)\end{aligned}$$

which are sometimes more convenient. One must however be careful about the boundary conditions of f or ρ, which may, however, be replaced by a suitable potential under certain circumstances.

As we mentioned before, there is no difficulty in classical cases to interprete the response thus obtained as the average which approximates closely the actual observation for large systems. In quantum-mechanical cases, however, we must note that there exists a certain difficulty. ΔB as given by Eq. (2.17) is the quantum-mechanical expectation of the first order change of B at the time t. This means that we prepare at $t=-\infty$ an ensemble of systems which corresponds to the statistical operator ρ. At a certain time t, we pick up a number of systems and observe B. The average of the observed values will be $\Delta B(t)$. We shall not follow these systems after this observation. At a later time point t', we choose different systems which have not been observed before. This is the way to follow the time change $\Delta B(t)$ to avoid the quantum-mechanical disturbance of observation process.

For the most of practical applications, we are rather interested in a continuous observation of a particular system, which is however macroscopic. The use of ensemble average for the actual observation will be justified by the same argument we made for the classical case. But the quantum-mechanical disturbance of observation is another thing. We may, however, expect for most of macroscopic quantities which we observe this disturbance can be neglected. This is a condition for macroscopic observations. Unfortunately, exact conditions for the existence of such quantities are not known.

Thus we shall rather introduce without proof the assumption that the identification of the statistically calculated $\Delta B(t)$ with the actully observed time variation is legitimate at least for those macroscopic quantities we shall be concerned with. We should howev make reservation that this assumption ma not be necessary for the identification of th admittance calculated by Eq. (2.23b) wit what will be actually observed, because th observation of admittance, for example, th refractivity and absorption in optical problem is not the observation of the response fun tion itself. As a matter of fact, Eq. (2.23 is equivalent to the well known dispersio formula of Heisenberg and Kramers[12] plu the absorption calculated by time-depende perturbation method.[7] The dispersion formul represents the oscillation of expectation val of dipole moments if the formula is applie to optical problems. This is not directl observed. We observe the refraction measuring the number of photons passe through the material. The logical relatio between this and that is not clear enough but the most common apologize is the use o correspondence principle. Any further analysis of this delicate problem is not our main purpose in this paper so we shall leave it for a future occasion.

Before concluding this section, we remark that the method employed here is also applicable to higher approximations than the linear. For this purpose we note Eq. (2.5) can be used for successive approximation, namely

$$\frac{\partial \Delta_k f}{\partial t}=(\mathscr{H},\ \Delta_k f)-F(t')(A,\ \Delta_{k-1} f)\,, \tag{2.25}$$

where $\Delta_k f$ means the k-th term of the expansion

$$f'(t)=f+\Delta_1 f+\Delta_2 f+\cdots\,. \tag{2.26}$$

The solution of Eq. (2.25) has the same from as Eq. (2.6), f being replaced by $\Delta_{k-1}f\,(t')$. Therefore we obtain the complete solution of Eq. (2.4) as

$$\begin{aligned} f'(t)=f+\sum_{k=1}^{\infty}(-)^k\int_{-\infty}^{t}\int_{-\infty}^{t_1}\cdots\int_{-\infty}^{t_{k-1}} e^{iL(t-t_1)}\Big(A,\ e^{iL(t_1-t_2)}(A,\ \cdots e^{iL(t_{k-1}-t_k)}(A,\ f))\cdots\Big) \\ \times F(t_1)\,F(t_2)\cdots F(t_k)\,dt_1\cdots dt_k \\ =f+\sum_{k=1}^{\infty}(-)^k\int_{-\infty}^{t}\int_{-\infty}^{t_1}\cdots\int_{-\infty}^{t_{k-1}} e^{iLt}\Big(A(t_1),\ (A(t_2),\cdots(A(t_k),\ f)\cdots\Big)F(t_1)\cdots F(t_k)dt_1\cdots dt_k\,. \end{aligned}$$

(2.27

where $A(t)$ is defined by

$$A(t)=A(p_t,\ q_t)\,,\quad p_{t=0}=p\,,\quad q_{t=0}=q\,.$$

ie same expression is obtained for quantum-mechanical case, namely

$$\rho'(t)=\rho+\sum_{k=1}^{\infty}\left(-\frac{1}{i\hbar}\right)^{k}\int_{-\infty}^{t}\int_{-\infty}^{t_1}\int_{-\infty}^{t_{k-1}}\exp(-it\mathscr{H}^{\times}/\hbar)\,A(t_1)^{\times}A(t_2)^{\times}\cdots A(t_k)^{\times}\rho F(t_1)\cdots F(t_k)\,dt_1\cdots dt_k \tag{2.28}$$

nere the cross means the commutator operation with the operation on its right hand side ee Eqs. (2.13) and (2.14)). These solutions allow us to write down the expression of re-onses in higher approximation. For instance, the second order change of B at the time can be written as

$$\Delta_2 B(t)=\left(\frac{1}{i\hbar}\right)^2 \mathrm{Tr}\int_{-\infty}^{t}\int_{-\infty}^{t_1}[A(t_1-t_2)[A,\rho]]\,B(t_1-t_2)F(t_1)F(t_2)dt_1dt_2 \tag{2.29}$$

he corresponding classical formula is similar so that it is omitted here.

3. Relaxation Function and Other Useful Formulae for Canonical Ensemble

In the following we consider quantum-echanical problems, because the classical mit is easily obtained from quantum-echanical formulae by replacing $[\ ,\ ]/i\hbar$ by oission bracket or by making $\hbar\to 0$.

First let us observe the behavior of the esponse function $\phi_{BA}(t)$ in the limit $t\to\infty$. t may approach to a limiting value or may ot approach to any definite value. If it oes, we must have

$$\lim_{t\to\infty}\phi_{BA}(t)=0 \text{ (if the limit exists).} \tag{3.1}$$

This is evident from Abel's theorem

$$\lim_{t\to\infty}\phi_{BA}(t)=\lim_{\varepsilon\to 0+}\varepsilon\int_0^{\infty}\phi_{BA}(t)\,e^{-\varepsilon t}\,dt \tag{3.2}$$

vhich holds if the left hand side exists. The ight hand side is zero unless $\phi_{BA}(t)$ has a inite Fourier-amplitude at zero frequency. If $_{BA}(t)$ has finite Fourier components for a set f discrete frequencies, $\phi_{BA}(t)$ will oscillate ndefinitely and does not have any limit. But, or calculation of admittance we have the onvergence factor $e^{-\varepsilon t}$ so that we may even n this case regard the relation (3.1) to hold. f $\phi_{BA}(t)$ is expressed by a Fourier integral vith continuous Fourier spectrum, Eq. (3.1) s generally true. This corresponds to actual ases of large systems, because the com-licated interaction within the system is lways enough to split the energy levels into structure so fine that the observation can ot discriminate. The error in the observa-ion of frequency certainly introduces an verage which allows us to replace the riginally discrete Fourier spectrum by con-inuous spectrum. Classically this corresponds to ellimination of long Poincaré cycles.

If the perturbation is applied continuously from $t=-\infty$ up to $t=0$ and is cut off at $t=0$, then the response ΔB will relax following the formula

$$\begin{aligned}\Delta B(t)&=\int_{-\infty}^{0}\phi_{BA}(t-t')dt'F\\&=F\int_t^{\infty}\phi_{BA}(t')dt',\qquad t>0\,.\end{aligned} \tag{3.3}$$

Therefore, the function

$$\Phi_{BA}(t)=\lim_{\varepsilon\to 0+}\int_t^{\infty}\phi_{BA}(t')\,e^{-\varepsilon t'}\,dt' \tag{3.4}$$

describes the relaxation of ΔB after removal of the outer disturbance. This will be called the relaxation function.

Here, for later reference we note the theorem:

Theorem 2. *The admittance $\chi_{BA}(\omega)$ can be calculated by the following formulae;*

$$\begin{aligned}\chi_{BA}(\omega)&=\lim_{\varepsilon\to 0+}\int_0^{\infty}\phi_{BA}(t)\,e^{-i\omega t-\varepsilon t}\,dt\\&=\lim_{\varepsilon\to 0+}\frac{1}{i\omega+\varepsilon}\left\{\phi_{BA}(0)+\int_0^{\infty}\dot{\phi}_{BA}(t)\,e^{-i\omega t-\varepsilon t}dt\right\}\\&=\Phi_{BA}(0)-i\omega\int_0^{\infty}\Phi_{BA}(t)\,e^{-i\omega t}\,dt\,.\end{aligned} \tag{3.5}$$

These transformations are rather evident.

The expression of $\phi_{BA}(t)$ has already been given by Eq. (2.22). We note here that other functions $\phi_{BA}(t)$ and $\Phi_{BA}(t)$ have convenient transform if the statistical ensemble is assumed to be *canonical*. For this purpose, we observe the identity

$$\begin{aligned}&[A,\exp(-\beta\mathscr{H})]\\&\quad=\exp(-\beta\mathscr{H})\int_0^{\beta}\exp(\lambda\mathscr{H})[\mathscr{H},A]\\&\qquad\qquad\times\exp(-\lambda\mathscr{H})\,d\lambda\end{aligned}$$

$$= \frac{\hbar}{i} \exp(-\beta \mathscr{H}) \int_0^S \exp(\lambda \mathscr{H})\, \dot{A} \times \exp(-\lambda \mathscr{H})\, d\lambda$$

$$= \frac{\hbar}{i} \exp(-\beta \mathscr{H}) \int_0^\beta \dot{A}(-i\hbar\lambda)\, d\lambda \tag{3.6}$$

or

$$[\rho_\beta, A] = i\hbar \int_0^\beta \rho_\beta \dot{A}(-i\hbar\lambda)\, d\lambda \tag{3.7}$$

which is easily seen by writing the expression in matrix form in the representation diagonalizing $\mathscr{H}$.

Let us now assume that the system we observe is statistically represented by the canonical density matrix,

$$\rho = \exp(-\beta(\mathscr{H} - \Psi)), \quad \beta = 1/kT,$$
$$\exp(-\beta\Psi) = \mathrm{Tr} \exp(-\beta\mathscr{H}). \tag{3.8}$$

By Eq. (2.22b) we have

$$\begin{aligned}\phi_{BA}(t) &= \frac{1}{i\hbar} \mathrm{Tr}\, [\rho, A] B(t) \\ &= \int_0^\beta \mathrm{Tr}\, \rho \dot{A}(-i\hbar\lambda) B(t)\, d\lambda \\ &= -\int_0^\beta \mathrm{Tr}\, \rho A(-i\hbar\lambda) \dot{B}(t)\, d\lambda \end{aligned} \tag{3.9}$$

and also

$$\begin{aligned}\dot{\phi}_{BA}(t) &= \frac{1}{i\hbar} \mathrm{Tr}\, [\rho, A] \dot{B}(t) \\ &= \frac{1}{i\hbar} \mathrm{Tr}\, \rho [A, \dot{B}(t)] = \frac{-1}{i\hbar} \mathrm{Tr}\, \rho [\dot{A}, B(t)] \\ &= \int_0^\beta \mathrm{Tr}\, \rho \dot{A}(-i\hbar\lambda) \dot{B}(t)\, d\lambda \end{aligned} \tag{3.10}$$

One may use any of these expressions depending on the nature of the quantities A and B. This will be illustrated later by examples.

With the aid of Eq. (3.9), the relaxation is transformed into

$$\Phi_{BA}(t) = \frac{i}{\hbar} \int_t^\infty \mathrm{Tr}\, \rho [B(t'), A]\, dt' \tag{3.11a}$$

$$= \int_0^\beta \mathrm{Tr}\, \rho A(-i\hbar\lambda) B(t) d\lambda - \beta \mathrm{Tr} \rho A^0 B^0 \tag{3.11b}$$

where A^0 and B^0 are the diagonal parts of A B with respect to $\mathscr{H}$. The second term on the right hand side of Eq. (3.11) is the limit

$$\begin{aligned}&\lim_{t\to\infty} \int_0^\beta \mathrm{Tr}\, \rho A(-i\hbar\lambda) B(t)\, d\lambda \\ &= \lim_{t\to\infty} \frac{1}{t} \int_0^t dt \int_0^\beta \mathrm{Tr}\, \rho A(-i\hbar\lambda) B(t)\, d\lambda \\ &= \beta\, \mathrm{Tr}\, \rho A^0 B^0 \end{aligned} \tag{3.12}$$

because this limit process selects the zer frequency component of $B(t)$. The limit the first expression, if it exists, must be equ to the last.

We may also define the function

$$\Phi^e{}_{BA}(t) = \int_0^\beta \mathrm{Tr}\, \rho A(-i\hbar\lambda)(B - B(t)) \tag{3.1}$$

which we shall call the *excitation* function convenience, because this describes the i crease of $\Delta B(t)$ when a constant force applied from $t=0$. Thus

$$\lim_{t\to\infty} \Phi^e{}_{BA}(t) = \Phi_{BA}(0). \tag{3.14}$$

In particular, for $t=0$, we have from Eq (3.11) and Eq. (3.5)

$$\begin{aligned}\chi_{BA}(0) &= \Phi_{BA}(0) = \Phi^e{}_{BA}(\infty) \\ &= \int_0^\beta \mathrm{Tr}\, \rho A(-i\hbar\lambda) B d\lambda - \beta\, \mathrm{Tr}\, \rho A^0 B^0 \\ &= \int_0^\beta \mathrm{Tr}\, \rho (A(-i\hbar\lambda) - A^0)(B - B^0)\, d\lambda \end{aligned} \tag{3.15}$$

where $\chi_{BA}(0)$ is the static admittance.

Eq. (3.15) is a little embarrassing, since the isothermal admittance, $\chi_{BA}{}^T$, is

$$\chi_{BA}{}^T = \int_0^\beta \mathrm{Tr}\, \rho (A(-i\hbar\lambda) - \overline{A})(B - \overline{B})\, d\lambda \tag{3.16}$$

where $\overline{A}$ and $\overline{B}$ and the equilibrium expectations of A and B in thermal equilibrium with $F=0$.

Eq. (3.16) is obtained by using the expansion

$$\exp\{-\beta(\mathscr{H} - FA\} = \exp(-\beta\mathscr{H})\{1 + \int_0^\beta A(-i\hbar\lambda) d\lambda F + 0(F^2)\}$$

for the expression

$$\Delta B = \frac{\mathrm{Tr} \exp\{-\beta(\mathscr{H} - FA)\} B}{\mathrm{Tr} \exp\{-\beta(\mathscr{H} - FA)\}} - \frac{\mathrm{Tr} \exp(-\beta\mathscr{H}) B}{\mathrm{Tr} \exp(-\beta\mathscr{H})}$$

$\chi_{BA}{}^T$ is defined by

$$\chi_{BA}{}^T = \Delta B / F.$$

Expressions (3.15) and (3.16) are different unless

$$\mathrm{Tr}\, \rho A^0 B^0 = \overline{A}\, \overline{B} = \mathrm{Tr}\, \rho A \cdot \mathrm{Tr}\, \rho B. \tag{3.17}$$

This will not however hold without certain restrictions imposed on A and B. In fact, $\chi_{BA}(0)$ as given by Eq. (3.15) is the static admittance of an isolated system on which the force F is inserted adiabatically. On the other hand $\chi_{BA}{}^T$, Eq. (3.16), is isothermal, hat gives the response when the system is in thermal contact with the heat reservoir. Thus they need not be equal.

But, there are situations in which the difference is quite negligible. For instance, suppose a magnetic system is magnetized by external field. If the magnetic energy is only a very small fraction of the total energy, the magnetization process treated by Eq. (3.15) is practically isothermal. This means that, if the heat capacities associated with A and B are only a small fraction of total heat capacity, the equality (3.17) must be practically satisfied.

It is noted here that this is concerned with the ergodic property of the system. Khinchin[13] has shown that the ergodicity for a quantity A, namely

$$\langle A\rangle=\lim_{t\to\infty}\frac{1}{t}\int_0^t A(t)\,dt \tag{3.18}$$

must hold if the autocorrelation of A satisfies the relation

$$\lim_{t\to\infty}\langle A(0)A(t)\rangle=\langle A\rangle^2\,. \tag{3.19}$$

Here $\langle A\rangle$ means the phase average of a phase function $A(p, q)$ over a microcanonical ensemble. The ergodicity of A, (3.18), means that the time average of A starting from any point P on the ergodic surface approaches to $\langle A\rangle$ independent of the initial point P. This will hold on the assumption of (3.19) for almost all of P except a set of measure zero. This Khintchin's theorem can be reversed. It can be proved that the correlation function $\langle A(0)A(t)\rangle$ satisfies Eq. (3.19) if (3.18) holds uniformly.

In classical limit, (3.11b) in replaced by

$$\Phi_{BA}(t)=\beta\{\langle A(0)B(t)\rangle-\langle A^0B^0\rangle\}\,, \tag{3.20}$$

where $\langle\ \ \rangle$ means the phase average, and A^0 means the invariant part of $A(p_{t},, q_t)$ with respect to the natural motion. Eq. (3.16) becomes classically

$$\chi_{BA}{}^T=\beta\langle(A-\langle A\rangle)(B-\langle B\rangle)\rangle\,. \tag{3.21}$$

In general we must expect

$$\begin{aligned}\Phi_{BA}(0)&=\Phi_{BA}{}^e(\infty)=\chi_{BA}(0)\\&=\beta\langle(A-\mathrm{A}^0)(B-B^0)\rangle\doteqdot\chi_{BA}{}^T\,.\end{aligned} \tag{3.22}$$

The left hand side is the static admittance for an isolated system. This means that

$$\lim_{t\to\infty}\langle A(0)(B(t)\rangle\doteqdot\langle A\rangle\langle B\rangle \tag{3.23}$$

and hence that the ergodicity (3.18) does not hold. This is quite true as one would easily understand by the example of magnetization process of an ideal magnetic system. The isothermal and adiabatic susceptibilities are different, the later being zero.

However, our aim is to apply the whole theory to realistic systems which contain various interactions. As we have mentioned before, we should expect that

$$\chi_{BA}(0)=\chi_{BA}{}^T \tag{3.24}$$

will hold if the total system is large enough compared to the degrees of freedom associated with the observed quantities A and B.

For a very large system, the canonical distribution is almost equivalent to a microcanonical distribution, the relative fluctuation being very small. The ensemble average in Eqs. (3.20), etc., can be regarded as that over an ergodic surface. Therefore, Eq. (3.24) must hold if the quantities A, B, and $A(0)B(t)$ are ergodic, namely

$$\begin{aligned}\langle A\rangle&=\lim_{t\to\infty}\frac{1}{t}\int_0^t A(t)\,dt\,,\\ \langle B\rangle&=\lim_{t\to\infty}\frac{1}{t}\int_0^t B(t)\,dt\,,\\ \langle A(0)\,B(t)\rangle&=\lim_{t'\to\infty}\frac{1}{t'}\int_0^{t'}\langle A(t')B(t'+t)\rangle\,dt'\end{aligned} \tag{3.25}$$

Here the right hand sides of the equations are primarily determined by the location of the initial point of time average, but they do not depend on that. That is the assertion of ergodicity.

If the requirement of ergodicity, (3.25), is fulfilled, we shall have

$$\begin{aligned}&\lim_{t\to\infty}\langle A(0)\,B(t)\rangle\\&=\lim_{t\to\infty}\lim_{t'\to\infty}\frac{1}{t'}\int_0^{t'}\langle A(t')B(t'+t)\rangle\,dt'\\&=\lim_{t\to\infty}\frac{1}{tt'}\int_0^t\int_0^{t'}\langle A(t')\,B(t'+t)\rangle\,dt'dt\\&=\langle\langle A\rangle\langle B\rangle\rangle=\langle A\rangle\langle B\rangle\,.\end{aligned} \tag{3.26}$$

Thus Eq. (3.22) holds.

The above arguments apply to quantum-mechanical cases with small modifications that the function $\int_0^\beta\langle A(-i\hbar\lambda)\,B(t)\rangle\,d\lambda$ enters in place of the correlation function.

Let us consider a magnetic system for illustration. The system, M, of the magnetic units are embedded in another large system,

R, with a certain interaction between M and R. The total system S we consider is $M+R$. If the heat capacity of R is large compared with M, R is a sort of heat bath for M. If we treat only M, assuming a canonical distribution and ignore the interaction between M and R, the relaxation function calculated by (3.11) describes only the internal process inside the subsystem M. The magnetic susceptibility, for instance, obtained from this, is adiabatic. For this canonical distribution, the ergodicity such as (3.25) will not hold.

If we consider the interaction and suppose, for instance, that it induces a Markoffian process for the transition of M among its various states, the ergodicity (3.25) will become true; the Markoffian assumption makes it easy to treat the relaxation process. The Markoffian assumption may be adequate if the interaction is weak and satisfies certain conditions which may be required. If such conditions are not satisfied, we are forced to deal directly with the combined system $M+R$. The relaxation function or the response function has to be treated with the complete Hamiltonian for $M+R$. In this case, the ergodicity (3.25) may be approximately true if the subsystem M is small compared to R. A rigorous formulation of mathematical proof of this is not easy, so that we merely anticipate this.

§ 4. Correlation Functions

We have seen in the previous section that the relations function $\Phi_{BA}(t)$ in classical case for canonical ensemble is essentially the correlation function of A and B; namely

$$\Phi_{BA}(t)=\beta\langle A(0)B(t)\rangle-\beta\langle A^0B^0\rangle \quad \text{(classical)} \tag{4.1}$$

where the bracket means the phase average over the canonical distribution. Or, the excitation function is

$$\Phi_{BA}{}^e(t)=\beta\langle A(0)(B-B(t))\rangle\,. \tag{4.2}$$

Other functions, for example, the response functions, are also proportional to certain correlation functions; e.g.

$$\phi_{BA}(t)=-\beta\langle A(0)\dot{B}(t)\rangle\,. \tag{4.3}$$

These are also valid for the microcanonical ensemble provided that the system in question is large.

Now the question arises how the correlation functions are defined in quantum-mechanics. We may define this by

$$\Psi_{BA}(t)=\mathrm{Tr}\,\rho\{A(0)B(t)\}=\mathrm{Tr}\,\rho\{A(t_1)B(t_1+t)\} \tag{4.4}$$

where ρ is the equilibrium density matrix, either canonical or microcanonical. The bracket means the symmetrized product,

$$\{AB\}=\frac{1}{2}(AB+BA)\,.$$

We may call this the time correlation of B and A at the time interval t, although it is not the correlation of two sets of actually observed values of B and A at different time points. The disturbance due to the observation is not taken into account. If the nature of the system and of A and B is such that this disturbance is not serious, which will be true for macrosopic systems and macroscopic observations, the function (4.4) describes the actual correlation. Since ρ is equilibrium density matrix, the time variation of A and B makes a stochastic time series which is stationary in time. For the sake of brevity, we rewrite the relaxation function as

$$\Phi_{BA}(t)=\int_0^\beta \mathrm{Tr}\,\rho(A(-i\hbar\lambda)-A^0)(B-B^0)\,d\lambda \tag{4.5}$$

and in the following we shall deal with quantities A and B which satisfy the condition

$$\mathrm{Tr}\,\rho A=\mathrm{Tr}\,\rho B=0\,, \tag{4.6}$$

which is achieved merely by substracting the invariant part from each of the quantities.

We can show easily that the relaxation function and the correlation function are mutually connected by the following theorem:

Theorem 3. *Let the Fourier transforms of $\Phi_{BA}(t)$ and $\Psi_{BA}(t)$ be*

$$f_{BA}(\omega)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\Phi_{BA}(t)\,e^{-i\omega t}\,dt\,,$$

$$g_{BA}(\omega)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\Psi_{BA}(t)\,e^{-i\omega t}\,dt\,, \tag{4.7}$$

then we have

$$g_{BA}(\omega)=E_\beta(\omega)f_{BA}(\omega) \tag{4.8}$$

where $E_\beta(\omega)$ is the average energy of the oscillator with the frequency ω at temperature $T=1/k\beta$,

$$E_\beta(\omega)=\frac{\hbar\omega}{2}\coth\frac{\beta\hbar\omega}{2}\,. \tag{4.9}$$

Eq. (4.8) is equivalent to

$$\Phi_{BA}(t)=\int_{-\infty}^{\infty}\Gamma(t-t')\Psi_{BA}(t')\,dt' \qquad (4.10)$$

where $\Gamma(t)$ *is defined*

$$\Gamma(t)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\frac{e^{i\omega t}}{E_\beta(\omega)}\,d\omega=\frac{2}{\hbar\pi}\log\coth\frac{\pi}{2\beta\hbar}|t|\,, \qquad (4.11)$$

or to

$$\Psi_{BA}(t)=E_\beta\left(\frac{d}{idt}\right)\Phi_{BA}(t)\,. \qquad (4.12)$$

The easiest way of the proof is to write first the functions $\Phi_{BA}(t)$ and $\Psi_{BA}(t)$ as double series over the quantum states of $\mathscr{H}$ and rearrange the double sum. An alternative method is to assume a function-theoretical conditions, i.e.,

$$\lim_{Ret\to\pm\infty}\operatorname{Tr}\rho AB(t)=0\,, \qquad (4.13)$$

and that $\operatorname{Tr}\rho AB(t)$ is analytic in the domain

$$0\leqq \operatorname{Im} t\leqq\beta\hbar\,.$$

The condition (4.13) is fulfilled if one extends the meaning of the limit process as was discussed in § 2 and § 3. The second condition is equivalent to the existence $\operatorname{Tr}\rho AB$ and $\operatorname{Tr}\rho BA$.

Now Eq. (4.8) is derived as follows. By definition we can write

$$\begin{aligned}f_{BA}(\omega)&=\frac{1}{2\pi}\int_{-\infty}^{\infty}\int_0^\beta\operatorname{Tr}\rho AB(t+i\hbar\lambda)\exp(-i\omega t)d\lambda dt\\&=\frac{1}{2\pi}\int_{-\infty}^{\infty}\int_0^\beta\operatorname{Tr}\rho AB(t+i\hbar\lambda)\\&\qquad\times\exp\{-i\omega(t+i\hbar\lambda)-\lambda\hbar\omega\}\,d\lambda dt\\&=\frac{1}{2\pi}\int_0^\beta d\lambda\exp(-\lambda\hbar\omega)\\&\qquad\times\int_{-\infty+i\hbar\lambda}^{\infty+i\hbar\lambda}\operatorname{Tr}\rho AB(t)\exp(-i\omega t)\,dt\,.\end{aligned}$$

Thus interchanging the order of integration and shifting the path of integration, we obtain by the above-mentioned assumptions

$$f_{BA}(\omega)=\frac{1-\exp(-\beta\hbar\omega)}{\hbar\omega}\times\frac{1}{2\pi}\int_{-\infty}^{\infty}\operatorname{Tr}\rho AB(t)\exp(i\omega t)\,dt\,. \qquad (4.14)$$

Similarly we can show that

$$\int_{-\infty}^{\infty}\operatorname{Tr}\rho AB(t)e^{-i\omega t}\,dt=\exp(\beta\hbar\omega)\int_{-\infty}^{\infty}\operatorname{Tr}\rho B(t)\,A\exp(-i\omega t)\,dt \qquad (4.15)$$

by shifting the integration path to $-i\hbar\beta-\infty$ to $-i\hbar\beta+\infty$. In the above transformations, we took ρ as canonical given by Eq. (3.8).

Eqs. (4.15) gives

$$\int_{-\infty}^{\infty}\operatorname{Tr}\rho AB(t)e^{-i\omega t}\,dt=\frac{2}{1+\exp(-\beta\hbar\omega)}g_{BA}(\omega)\,,$$

so that Eq. (4.14) leads Eq. (4.8).

Eq. (4.10) is easily obtained from (4.8). The kernel $\Gamma(t)$, (4.11) is calculated using the partial fraction expansion of $\tanh z/z$. We note further that it has the property

$$\lim_{\hbar\to 0}\Gamma(t)=\beta\delta(t)\,, \qquad (4.16)$$

which in naturally to be expected.

§ 5. Simple Examples

It will be adequate to insert here simple examples to illustrate the general idea developed in the previous sections. The author has applied this in a previous paper[7] to the problem of magnetic resonance absorption. An uniform magnetic field $\boldsymbol{H}(t)$ is applied to a magnetic system, the total magnetic moment of which is denoted by $\boldsymbol{M}$. The perturbation energy due to $\boldsymbol{H}(t)$ is now

$$\mathscr{H}'(t)=-\boldsymbol{MH}(t)\,. \qquad (5.1)$$

The natural motion of the magnetic moment in the absence of the external field is represented by $\boldsymbol{M}(t)$. Then, the response function $\phi_{\mu\nu}(t)$ for the magnetization in μ-direction when the external field $\boldsymbol{H}(t)$ lies in ν-direction, is by Eq. (2.22).

$$\begin{aligned}\phi_{\mu\nu}(t)&=\frac{i}{\hbar}\langle[M_\mu(t),\ M_\nu]\rangle\\&=\int_0^\beta\langle\dot{M}_\nu(-i\hbar\lambda)M_\mu(t)\rangle d\lambda\,,\end{aligned} \qquad (5.2)$$

and the relaxation function is, by Eq. (3.11),

$$\Phi_{\mu\nu}(t)=\int_0^\beta\langle(M_\nu(-i\hbar\lambda)-M_\nu{}^0)(M_\mu(t)-M_\mu{}^0)\rangle\,d\lambda \qquad (5.3)$$

where $M_\nu{}^0$ and $M_\mu{}^0$ mean the diagonal parts of M_ν and M_μ with respect to the unperturbed Hamiltonian $\mathscr{H}$.

If we consider a system with unit volume, the admittance becomes the magnetic susceptibility. Thus the complex magnetic susceptibility tensor can be expressed either by $\phi_{\mu\nu}(t)$ or $\Phi_{\mu\nu}(t)$. The convenient expression is, by Eq. (3.5)

$$\chi_{\mu\nu}(\omega)=\Phi_{\mu\nu}(0)-i\omega\int_0^\infty\Phi_{\mu\nu}(t)\,e^{-i\omega t}\,dt\,. \qquad (5.4)$$

The static susceptibility is, in particular,

$$\chi_{\mu\nu}(0)=\int_0^\beta \langle (M_\nu(-i\hbar\lambda)-M_\nu{}^0)(M_\mu-M_\mu{}^0)\rangle\, d\lambda \tag{5.5}$$

which is the susceptibility for the isolated system and is not necessarily equal to the isothermal susceptibility,

$$\chi_{\mu\nu}{}^T=\int_0^\beta \langle M_\nu(-i\hbar\lambda)M_\mu\rangle d\lambda-\beta\langle M_\nu\rangle\langle M_\mu\rangle. \tag{5.6}$$

In the expression for $\chi_{\mu\nu}(0)$, the diagonal parts of M_ν and M_μ are substracted. This corresponds to the fact the magnetization in an isolated system proceeds adiabatically, the occupation probabilities of the levels remaining unchanged. On the other hand they are changed in isothermal process for $\chi_{\mu\nu}{}^T$. The difference becomes smaller if the environment is taken into account in greater extent.

In the classical limit, Eq. (5.5) becomes

$$\chi_{\mu\nu}(0)=\frac{1}{kT}\langle (M_\nu-M_\nu{}^0)(M_\mu-M_\mu{}^0)\rangle\,. \tag{5.7}$$

while Eq. (5.6) becomes

$$\chi_{\mu\nu}{}^T=\frac{1}{kT}\langle\, (M_\nu-\langle M_\nu\rangle)(M_\mu-\langle M_\mu\rangle)\,\rangle\,. \tag{5.8}$$

The last expression is first noticed by Kirkwood[14] for the classical theory of dielectric polarization. Eq. (5.7) is its extension to adiabatic susceptibility, and Eq. (5.4) to general complex susceptibility for non-equilibrium states. It is evident that the similar formulae are obtained for dielectric polarizations.

As a second example we shall consider the electric conductivity. For an electric $\boldsymbol{E}(t)$, the perturbation energy is

$$\mathscr{H}'(t)=-\sum_i e_i\boldsymbol{r}_i\boldsymbol{E}(t) \tag{5.7}$$

where e_i is the charge of the i-th particle in the system and $\boldsymbol{r}_i$ its position vector. The response of current in μ-direction when a pulse of electric field is applied in ν-direction at $t=0$ is, by Eq. (2.22) or Eq. (3.9)

$$\begin{aligned}\phi_{\mu\nu}(t)&=\frac{1}{i\hbar}\,\mathrm{Tr}\,[\rho,\,\sum_i e_i\, x_{i\nu}]\sum e_i\,\dot{x}_{i\mu}(t)\\ &=\int_0^\beta \langle\, J_\nu\,(-i\hbar\lambda)\,J_\mu(t)\,\rangle\, d\lambda\end{aligned} \tag{5.10}$$

where

$$J_\mu=\sum e_i\,\dot{x}_{i\mu}$$

is the total current in the system.

If we take the volume of the system as unity, the conductivity tensor $\sigma_{\mu\nu}(\omega)$ for periodic field is given by

$$\sigma_{\mu\nu}(\omega)=\int_0^\infty e^{-i\omega t}\,dt\int_0^\beta d\lambda\,\langle\, J_\nu(-i\hbar\lambda)\,J_\mu(t)\,\rangle\,. \tag{5.11}$$

This is an exact expression for the conductivity. In particular, for the static conductivity we have

$$\sigma_{\mu\nu}=\int_0^\infty\int_0^\beta d\lambda\,\langle\, J_\nu(-i\hbar\lambda)\,J_\mu(t)\,\rangle\,. \tag{5.12}$$

This may be expressed in another form,

$$\sigma_{\mu\nu}=\lim_{s\to0+}\frac{1}{s}\left\{\phi_{\mu\nu}(0)+\int_0^\infty\dot{\phi}_{\mu\nu}(t)\,e^{-st}\,dt\right\} \tag{5.13}$$

where

$$\dot{\phi}_{\mu\nu}(t)=-\frac{1}{i\hbar}\,\mathrm{Tr}\,\rho[J_\nu,\,J_\mu(t)]\,. \tag{5.14}$$

The above expressions of conductivity tensor are, as a matter of fact, what one would obtain by simple application of dispersion formula of Heisenberg and Kramers. But they are more convenient and much clearer for physical interpretation. Nakano[8] has shown that the Grüneisen formula is obtained from (5.11) as the first approximation. We emphasize again that the formulae given in the above are exact although they are admittedly rather abstract and have to be approximated in some way to deduce useful answers for assumed physical models. We can show that the usual method of employing Boltzmann-Bloch type transport equations makes a certain approximation to calculate these exact expressions. But the transport equation can not always be justified since the Markoffian assumption involved is only valid under rather strict conditions for the scattering processes.[1] The exact theory will certainly give a starting point of actual calculations when the traditional methods are not justified. A good example of this is provided by the problem of electronic conduction in strong magnetic field.[11] This will be treated in a forthcoming paper.

§ 6. Symmetry Relations

We note here some symmetry properties of the response and relaxation functions and those of the admittance. Let us consider for convenience the relaxtion function defined by Eq. (3.11), for which we have the theorem:

Theorem 4. *The relaxation function $\Phi_{BA}(t)$ has the following properties;*

1) *$\Phi_{BA}(t)$ is real* (6.1)

2) $\Phi_{BA}(-t)=\Phi_{AB}(t)$ (6.2)

3) *reciprocity law: if a static magnetic field* $\boldsymbol{H}$ *is present, the reversal of the direction of* $\boldsymbol{H}$ *results in*

$$\begin{aligned}\Phi_{BA}(t, \boldsymbol{H}) &= \mathcal{E}_A\mathcal{E}_B\Phi_{BA}(-t, -\boldsymbol{H})\\ &= \mathcal{E}_A\mathcal{E}_B\Phi_{AB}(t, -\boldsymbol{H})\end{aligned} \tag{6.3}$$

where $\mathcal{E}_A$ *or* $\mathcal{E}_B$ *is* $+1$ *or* -1 *according to the quantity* A *or* B *is even or odd with respect to the reversal of time.*

The proof is simple. The complex conjugate of $\Phi_{BA}(t)$ is calculated as follows.

$$\begin{aligned}\overline{\Phi}_{BA}(t) &= \int_0^\beta \mathrm{Tr}\,\rho B(t)\,A(i\hbar\lambda)\,d\lambda\\ &= \int_0^\beta \mathrm{Tr}\,\rho B(t-i\hbar\lambda)\,A\,d\lambda\\ &= \int_0^\beta \mathrm{Tr}\,\rho B(t-i\hbar(\beta-\lambda))\,A\,d\lambda\\ &= \int_0^\beta \mathrm{Tr}\,\rho AB(t+i\hbar\lambda)\,d\lambda = \Phi_{BA}(t)\,.\end{aligned}$$

The transformation from the second to the third line is simply the change of integration variable from λ to $\beta-\lambda$.

Similarly, we may proceed as

$$\begin{aligned}\Phi_{BA}(-t) &= \int_0^\beta \mathrm{Tr}\,\rho AB(-t+i\hbar\lambda)\,d\lambda\\ &= \int_0^\beta \mathrm{Tr}\,\rho A(t-i\hbar\lambda)\,B\,d\lambda\\ &= \int_0^\beta \mathrm{Tr}\,\rho BA(t+i\hbar\lambda)\,d\lambda = \Phi_{BA}(t)\,.\end{aligned}$$

Eq. (6.3) follows from the fact that the simultaneous reversal of t and $\boldsymbol{H}$ changes the q-representation of the Hamiltonian and the wave function to their complex conjugates. A corollary of the theorem is the symmetry of other functions such as $\phi_{BA}(t)=-\dot{\Phi}_{BA}(t)$. This is clear and so is omitted here.

The second corollary is the symmetry of admittance. We write down here the symmetry of the quantity defined by

$$\sigma_{BA}(\omega)=\int_0^\infty \Phi_{BA}(t)\,e^{-i\omega t}\,dt \tag{6.4}$$

for which we have

$$\mathrm{Re}\,\sigma_{BA}(\omega)=\mathrm{Re}\,\sigma_{BA}(-\omega)\,, \tag{6.5}$$

$$\mathrm{Im}\,\sigma_{BA}(\omega)=-\mathrm{Im}\,\sigma_{BA}(-\omega)\,, \tag{6.6}$$

$$\sigma_{BA}(\omega, -\boldsymbol{H})=\mathcal{E}_A\mathcal{E}_B\sigma_{AB}(\omega, \boldsymbol{H})\,. \tag{6.7}$$

Eq. (6.7) is the well-known Onsager's relation.[15] The derivation here made is very simple.

As examples, we note the symmetry of magnetic susceptibility tensor and that of the conductivity tensor. The susceptibility tensor has the symmetry

$$\begin{aligned}\mathrm{Re}\,\chi_{\mu\nu}(\omega, \boldsymbol{H}) &= \mathrm{Re}\,\chi_{\mu\nu}(-\omega, \boldsymbol{H})\\ &= \mathrm{Re}\,\chi_{\nu\mu}(\omega, -\boldsymbol{H})\,,\\ \mathrm{Im}\,\chi_{\mu\nu}(\omega, \boldsymbol{H}) &= -\mathrm{Im}\,\chi_{\mu\nu}(-\omega, \boldsymbol{H})\\ &= \mathrm{Im}\chi_{\nu\mu}(\omega, -\boldsymbol{H})\,.\end{aligned} \tag{6.8}$$

For the conductivity tensor we have the same relations

$$\begin{aligned}\mathrm{Re}\,\sigma_{\mu\nu}(\omega, \boldsymbol{H}) &= \mathrm{Re}\,\sigma_{\mu\nu}(-\omega, \boldsymbol{H})\\ &= \mathrm{Re}\,\sigma_{\nu\mu}(\omega, -\boldsymbol{H})\,,\\ \mathrm{Im}\,\sigma_{\mu\nu}(\omega, \boldsymbol{H}) &= -\mathrm{Im}\,\sigma_{\mu\nu}(-\omega, \boldsymbol{H})\\ &= \mathrm{Im}\,\sigma_{\nu\mu}(\omega, -\boldsymbol{H})\,.\end{aligned} \tag{6.9}$$

Thus, for the change ω to $-\omega$, the real part is even while the imaginary part is odd. For the reversal of $\boldsymbol{H}$, the symmetric part is even and the antisymmetric part is odd.

§ 7. Fluctuation-Dissipation Theorems

We have shown in § 4 that the response and relaxation functions can be expressed by correlation functions. Thus the admittance can also be expressed in terms of correlation functions. This is rather trivial for classical cases, but in quantum mechanics it becomes rather complicated. The relation between the admittance and the Fourier components correlation functions is usually called the fluctuation-dissipation theorem. Thus our aim here is to give this theorem in its complete form.

We treat as a typical example the case of electric conduction. Let us rewrite Eq. (5.11) in terms of the Fourier component of response function $\phi_{\mu\nu}(t)$, i.e.,

$$f_{\mu\nu}(\omega)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\phi_{\mu\nu}(t)\,e^{-i\omega t}\,dt\,. \tag{7.1}$$

Eq. (5.11) is transformed as

$$\begin{aligned}\sigma_{\mu\nu}(\omega) &= \int_0^\infty \phi_{\mu\nu}(t)\,e^{-i\omega t}\,dt\\ &= \int_0^\infty dt\int_{-\infty}^{\infty} d\omega'\,f_{\mu\nu}(\omega')\,e^{i\omega' t-i\omega t}\\ &= \pi f_{\mu\nu}(\omega)+i\int_{-\infty}^{\infty}\frac{f_{\mu\nu}(\omega')}{\omega'-\omega}\,d\omega'\,.\end{aligned} \tag{7.2}$$

Thus we obtain at once

$$\mathrm{Re}\,\sigma^{s}{}_{\mu\nu}(\omega)=\pi f^{s}{}_{\mu\nu}(\omega)\equiv\frac{\pi}{2}\left\{f_{\mu\nu}(\omega)+f_{\nu\mu}(\omega)\right\}$$

$$\operatorname{Im}\sigma^{a}_{\mu\nu}(\omega)=\frac{\pi}{2}f^{a}_{\mu\nu}(\omega)\equiv\frac{\pi}{2i}\Big\{f_{\mu\nu}(\omega)-f_{\nu\mu}(\omega)\Big\} \tag{7.3}$$

$$\operatorname{Im}\sigma^{s}_{\mu\nu}(\omega)=\int_{-\infty}^{\infty}\frac{f^{s}_{\mu\nu}(\omega')}{\omega'-\omega}d\omega'$$

$$\operatorname{Re}\sigma^{a}_{\mu\nu}(\omega)=i\int_{-\infty}^{\infty}\frac{f^{a}_{\mu\nu}(\omega')}{\omega'-\omega}d\omega'\ , \tag{7.4}$$

where the superscript s or a means the symmetric or the anti-symmetric part of the tensor. By the theorem 4 one has the symmetry

$$\overline{f_{\mu\nu}}(\omega)=f_{\nu\mu}(\omega)\ , \tag{7.5}$$

which shows $f^{s}_{\mu\nu}(\omega)$ is real while $f^{a}_{\mu\nu}(\omega)$ is purely imaginary. Eqs. (7.3) and (7.4) give the well-known Kramers-Kronig relation. Note that it holds for each of the symmetric and antisymmetric parts separately.

Now let us introduce the correlation function of current components,

$$\Psi_{\mu\nu}(t)=\operatorname{Tr}\rho\{j_{r}(0)\,j_{\mu}(t)\}\ , \tag{7.6}$$

which describes the correlation of spontaneous current fluctuating in equilibrium. We can show the following theorem:

Theorem 5. *The conductivity tensor $\sigma_{\mu\nu}(\omega)$ is connected with correlation function of current components, (7.6), by the following relations:*

$$E_{\beta}(\omega)\operatorname{Re}\sigma^{s}_{\mu\nu}(\omega)=\pi g^{s}_{\mu\nu}(\omega)$$
$$=\int_{0}^{\infty}\Psi^{s}_{\mu\nu}(t)\cos\omega t\,dt \tag{7.7a}$$

$$E_{\beta}(\omega)\operatorname{Im}\sigma^{a}_{\mu\nu}(\omega)=\frac{\pi}{i}g^{a}_{\mu\nu}(\omega)$$
$$=-\int_{0}^{\infty}\Psi^{a}_{\mu\nu}(t)\sin\omega t\,dt \tag{7.7b}$$

$$\Psi^{s}_{\mu\nu}(t)=\frac{2}{\pi}\int_{0}^{\infty}E_{\beta}(\omega)\operatorname{Re}\sigma^{s}_{\mu\nu}(\omega)\cos\omega t\,d\omega \tag{7.8a}$$

$$\Psi^{a}_{\mu\nu}(t)=-\frac{2}{\pi}\int_{0}^{\infty}E_{\beta}(\omega)\operatorname{Im}\sigma^{a}_{\mu\nu}(\omega)\sin\omega t\,d\omega\ , \tag{7.8b}$$

and

$$\operatorname{Im}\sigma^{s}_{\mu\nu}(\omega)=\int_{-\infty}^{\infty}\frac{1}{E_{\beta}(\omega')}\cdot\frac{g^{s}_{\mu\nu}(\omega')}{\omega'-\omega}d\omega'$$
$$=-2\int_{0}^{\infty}\Gamma(\tau)\cos\omega\tau\,d\tau\int_{\tau}^{\infty}\Psi^{s}_{\mu\nu}(t)\sin\omega t\,dt$$
$$-2\int_{0}^{\infty}\Gamma(\tau)\sin\omega\tau\,d\tau\int_{0}^{\tau}\Psi^{s}_{\mu\nu}(t)\cos\omega t\,dt \tag{7.9a}$$

$$\operatorname{Re}\sigma^{a}_{\mu\nu}(\omega)=-\frac{1}{i}\int_{-\infty}^{\infty}\frac{1}{E_{\beta}(\omega')}\frac{g^{a}_{\mu\nu}(\omega')}{\omega'-\omega}d\omega'$$
$$=2\int_{0}^{\infty}\Gamma(\tau)\cos\omega\tau\,d\tau\int_{\tau}^{\infty}\Psi^{a}_{\mu\nu}(t)\cos\omega t\,dt$$
$$-2\int_{0}^{\infty}\Gamma(\tau)\sin\omega\tau\,d\tau\int_{0}^{\tau}\Psi^{a}_{\mu\nu}(t)\sin\omega t\,dt \tag{7.9b}$$

$$\Psi^{s}_{\mu\nu}(t)=\frac{2}{\pi}\int_{0}^{\infty}\operatorname{Im}\sigma^{s}_{\mu\nu}(\omega)\operatorname{Re}\Delta(\omega,t)\,d\omega \tag{7.10a}$$

$$\Psi^{a}_{\mu\nu}(t)=\frac{2}{\pi}\int_{0}^{\infty}\operatorname{Re}\sigma^{a}_{\mu\nu}(\omega)\operatorname{Im}\Delta(\omega,t)\,d\omega\ , \tag{7.10b}$$

where the kernel $\Delta(\omega,t)$ is defined by

$$\Delta(\omega,t)=\frac{1}{\pi}\int_{-\infty}^{\infty}\frac{du}{u-\omega}E_{\beta}(u)e^{iut}\ . \tag{7.11}$$

These expressions reduce, in classical limit, to

$$\operatorname{Re}\sigma_{\mu\nu}(\omega)=\int_{0}^{\infty}\Psi_{\mu\nu}(t)\cos\omega t\,dt$$
$$\operatorname{Im}\sigma_{\mu\nu}(\omega)=-\int_{0}^{\infty}\Psi_{\mu\nu}(t)\sin\omega t\,dt \tag{7.12}$$

First we note that the symmetry of $\Psi_{\mu\nu}(t)$ is the same as that we have for $\phi_{\mu\nu}(t)$ (Theorem 4). Eqs. (7.7) and the first parts of (7.9a) and (7.9b) are obvious from Eq. (4.8). Eq. (7.8a, b) is simply the inverse of Eq. (7.7a, b). We need some calculation to derive (7.9) and (7.10) but the details are omitted here. Only we note for the convenience of reference that the function (7.11) can be transformed to

$$\operatorname{Re}\Delta(\omega,t)=-E_{\beta}(\omega)\sin\omega t\cdot\operatorname{sign}t$$
$$+\frac{1}{\pi\beta}\sum_{n=1}^{\infty}\frac{(n\pi)^{2}\exp(-2n\pi|t|/\beta\hbar)}{(n\pi)^{2}+(\beta\hbar\omega)^{2}/4} \tag{7.13a}$$

$$\operatorname{Im}\Delta(\omega,t)=E_{\beta}(\omega)\cos\omega t\cdot\operatorname{sign}t$$
$$-\frac{1}{\pi\beta}\sum_{n=1}^{\infty}\frac{(n\pi/2)\beta\hbar\omega\exp(-2n\pi|t|/\beta\hbar)}{(n\pi)^{2}+(\beta\hbar\omega)^{2}/4}\operatorname{sign}t\ . \tag{7.13b}$$

An useful corollary of the theorem is the expression of static conductivity $\sigma_{\mu\nu}(0)$. We have the formulae;

$$\sigma^{s}_{\mu\nu}(0)=\beta\int_{0}^{\infty}\Psi^{s}_{\mu\nu}(t)\,dt\equiv\frac{\beta}{2}\int_{-\infty}^{\infty}\Psi^{s}_{\mu\nu}(t)\,dt \tag{7.14}$$

$$\sigma^{a}_{\mu\nu}(0)=2\int\Gamma(\tau)\,d\tau\int_{\tau}^{\infty}\Psi^{a}_{\mu\nu}(t)\,dt$$
$$=2\int_{0}^{\infty}\Psi^{a}_{\mu\nu}(t)\int_{0}^{t}\Gamma(\tau)\,d\tau\ . \tag{7.15}$$

Thus the symmetric part of the static conductivity is calculated either as the integration of the response function or as that of the correlation function. The situation is more complicated for the antisymmetric part. If one wishes to use the correlation function instead of the response function, one has to be careful about a quantum effect which appears as $\Gamma(\tau)$ in Eq. (7.15).

Another remark is that, even at finite frequencies, the symmetric part is easily obtained if the correlation function is known. This is, of particular interest, for instance, in the case of magnetic problem[7]. For a linearly polarized radiation, the absorption is determined by the imaginary part of susceptibility tensor, for which we have from Eq. (5.4)

$$\chi''_{xx}(\omega) = -\mathrm{Im}\,\chi_{xx} = \frac{\omega}{2E_\beta(\omega)}\int_{-\infty}^{\infty}\langle\{M_x(0)M_x(t)\}\rangle\cos\omega t\,dt\,. \tag{7.16}$$

The corresponding expression for conduction is (7.7a) itself, i.e.,

$$\sigma_{xx}(\omega) = \frac{1}{2E_\beta(\omega)}\int_{-\infty}^{\infty}\langle\{J_x(0)J_x(t)\}\rangle\cos\omega t\,dt \tag{7.17}$$

The last equation is the well-known Niquist's theorem[16]. If the fluctuating current is expanded into the Fourier components, Eq. (7.17) reduces to

$$\sigma_{xx}(\omega) = \frac{\pi}{E_\beta(\omega)}\langle|J_x(\omega)|^2\rangle\,. \tag{7.18}$$

§ 8. Sum Rules

It is interesting that the exact expressions of admittance derived in the above give proof of certain general laws. The simplest example of this is the well-known sum-rule of oscillator strength. This is generalized in the following way.

We consider the expression (6.4), from which we obtain

$$\frac{1}{\pi}\int_{-\infty}^{\infty}\sigma_{BA}(\omega)\,d\omega = 2\int_0^{\infty}\Phi_{BA}(t)\,\delta(t)\,dt = \Phi_{BA}(0)\cdot \tag{8.1}$$

and

$$\lim_{\omega\to\infty} i\omega\,\sigma_{BA}(\omega) = \Phi_{BA}(0) \tag{8.2}$$

by Abel's theorem if the left hand side does exist.

Let us now apply this for electric conduction. By Eq. (5.10) one can write

$$\phi_{\mu\nu}(t) = \frac{1}{i\hbar}\mathrm{Tr}\,\rho\left[\sum e_i x_{i\nu},\ \sum e_j \dot{x}_{j\mu}(t)\right] \tag{8.3}$$

If the Hamiltonian $\mathscr{H}$ has the general form

$$\mathscr{H} = \sum_i\left[p_{i\nu} - \frac{e_i}{c}A_\nu(\boldsymbol{r}_i)\right]^2\Big/2m_i + V(\boldsymbol{r}_1,\cdots\boldsymbol{r}_N),$$

$\boldsymbol{A}$ being the vector potential we have the commutation rule

$$[x_{i\nu},\ \dot{x}_{j\mu}] = \frac{i\hbar}{m_i}\delta_{ij}\,\delta_{\mu\nu} \tag{8.4}$$

which gives

$$\phi_{\mu\nu}(0) = \sum_{i=1}^{N}\frac{e_i{}^2}{m_i}\delta_{\mu\nu} = \sum_r\frac{n_r e_r{}^2}{m_r} \tag{8.5}$$

where r means the species of charge carriers, n_r being the number of carriers of r-th kind.

Eq. (8.3) is derived from Eq. (5.10) by changing the order in the trace operation. One might doubt whether this is justfied or not, pointing out that the operators $x_{i\nu}$ may be singular if one uses the Born-Karman boundary conditions. As a matter of fact this will not affect the validity of the proof, because the commutators are actually regular operators. It might be worth while to see what one has in classical case. Classically we may proceed as (see Eq. (2.22a))

$$\begin{aligned}\phi_{\mu\nu}(t) &= \int d\Gamma(f,\ \sum e_i x_{i\nu})\sum e_j\dot{x}_{j\mu}(t)\\ &= -\int d\Gamma\sum_i e_i\frac{\partial f}{\partial p_{i\nu}}\cdot\sum e_j\dot{x}_{j\mu}(t)\\ &= \int d\Gamma\,f\sum_i\sum_j e_i e_j\frac{\partial}{\partial p_{i\nu}}\dot{x}_{j\mu}(t)\,.\end{aligned} \tag{8.6}$$

Thus we have

$$\begin{aligned}\phi_{\mu\nu}(0) &= \int d\Gamma f\sum_i\sum_j e_i e_j\frac{\partial}{\partial p_{i\nu}}\cdot\frac{1}{m_j}\left\{p_{j\mu} - \frac{e_j}{c}A_\mu(\boldsymbol{r}_j)\right\}\\ &= \int d\Gamma f\sum_i e^2{}_i\,/\,m_i\,\delta_{\mu\nu}\end{aligned} \tag{8.7}$$

This is exactly the same as Eq. (8.5). This does not prove directly the validity of (8.3), but will be enough to make it convincing. As as proof one may introduce a suitable potential to avoid the difficulty of singular operators $x_{i\nu}$, and make it vanish if one wants.

Thus we have proved the sum rule

$$\frac{2}{\pi}\int_0^{\infty}\mathrm{Re}\,\sigma^s{}_{\mu\nu}(\omega)\,d\omega = \sum_r\frac{e^2{}_r n_r}{m_r}\delta_{\mu\nu} \tag{8.8}$$

and

$$\lim_{\omega\to\infty}\omega\,\mathrm{Im}\,\sigma^{s}_{\mu\nu}=-\sum_{r}\frac{e^{2}_{r}n_{r}}{m_{r}}\delta_{\mu\nu} \qquad (8.9)$$

which hold for any system irrespective of the interaction of particles, the temperature, the statistics and even in the presence of magnetic field. This is the most general form of the sum rule.

For a system of electrons, Eqs. (8.8) and (8.9) are written as

$$\frac{2}{\pi}\int_{0}^{\infty}\mathrm{Re}\,\sigma^{s}_{\mu\nu}(\omega)\,d\omega=\frac{ne^{2}}{m}\delta_{\mu\nu} \qquad (8.10)$$

$$\mathrm{Im}\,\sigma^{s}_{\mu\nu}(\omega)\to-\frac{e^{2}n}{m\omega}\delta_{\mu\nu}\quad(\omega\to\infty)\,. \qquad (8.11)$$

Here we should remember that m is the true mass of electrons. The integration of $\sigma(\omega)$ has to be carried over all range of frequencies.

If one considers electrons in a crystal and confines himself to the electrons in a particular band neglecting interband transitions, the sum rule has to be modified to

$$\begin{aligned}&\frac{2}{\pi}\int_{0}^{\infty}\mathrm{Re}\,\sigma^{s}_{\mu\nu}(\omega)\,d\omega\\&=-\lim_{\omega\to\infty}\omega\,\mathrm{Im}\,\sigma^{s}_{\mu\nu}(\omega)\\&=e^{2}\,\mathrm{Tr}\,\{\rho\cdot\partial^{2}E(p)/\partial p_{\nu}\partial p_{\mu}\}\,. \qquad (8.12)\end{aligned}$$

This holds if the electron system is described by the Hamiltonian

$$\mathscr{H}=\sum_{i}E(p_{i})+V(r_{1},\cdots r_{N}) \qquad (8.13)$$

where $E(p)$ is the energy of an electron with the crystal moments p. Also one has to omit the interband elements of the potential V. The theorem (8.12) is wider than that usually given in text books only for the oscillator strength connecting one-electron states.

Another interesting result is obtained from the second expression of (3.5) when applied to conduction problem. This give

$$\begin{aligned}&\frac{1}{\pi}\int_{-\infty}^{\infty}\{i\sigma_{\mu\nu}(\omega)\,\omega-\phi_{\mu\nu}(0)\}d\omega\\&=-\lim_{\omega\to\infty}\omega^{2}\left\{\sigma_{\mu\nu}(\omega)-\frac{\phi_{\mu\nu}(0)}{i\omega}\right\}=\dot{\phi}_{\mu\nu}(0)\end{aligned} \qquad (8.14)$$

The tensor

$$\dot{\phi}_{\mu\nu}(0)=-\frac{i}{\hbar}\,\mathrm{Tr}\,\rho\,[J_{\mu},J_{\nu}] \qquad (8.15)$$

is antisymmetric. Therefore Eq. (8.14) is rewritten as

$$\begin{aligned}&-\frac{1}{\pi}\int_{-\infty}^{\infty}\mathrm{Im}\,\sigma^{a}_{xy}(\omega)\,\omega d\omega\\&=\lim_{\omega\to\infty}\omega^{2}\sigma^{a}_{xy}(\omega)=-\sum_{r}\frac{n_{r}e_{r}^{3}H_{z}}{m_{r}^{2}c}\,. \qquad (8.16)\end{aligned}$$

Both sides of this equation are identically zero unless the system is in a magnetic field (or rotating, in which case $e_{r}H_{z}/m_{r}c$ must be replaced by the angular frequency of the rotation). This is seen from the fact that the velocity of charged particles in magnetic field is

$$v=\frac{1}{m}\left(p-\frac{e}{c}A\right)$$

and the commutation rule is now

$$[v_{x},v_{y}]=-\frac{eH_{z}}{m^{2}c}\frac{\hbar}{i}\,. \qquad (8.17)$$

This gives

$$\frac{i}{\hbar}\,\mathrm{Tr}\,\rho\,[J_{x},J_{y}]=\sum n_{r}e_{r}^{3}H_{z}/m_{r}^{2}c\,, \qquad (8.18)$$

which is the last expression in Eq. (8.16).

In particular, for electrons we have

$$\begin{aligned}\frac{2}{\pi}\int_{0}^{\infty}\mathrm{Im}\,\sigma^{a}_{\mu\nu}(\omega)\omega d\omega&=-\lim_{\omega\to\infty}\omega^{2}\sigma^{a}_{\mu\nu}(\omega)\\&=\frac{ne^{3}}{m^{2}c}H_{z}\,. \qquad (8.19)\end{aligned}$$

This is another type of sum-rule which holds quite generally, but is not usually remarked. Eq. (8.19) may also be written as

$$\sum_{l}\mathrm{Im}\,\langle k|J_{x}|l\rangle\langle l|J_{y}|k\rangle=-\frac{ne^{3}}{2m^{2}c}H_{z} \qquad (8.20)$$

for a system of n electrons.

Similar arguments can also be made for tensors of other kinds. For instance, the magnetic susceptibility tensor satisfies the rules,

$$-\frac{1}{\pi}\int_{-\infty}^{\infty}\mathrm{Im}\,\chi^{s}_{\mu\nu}(\omega)\frac{d\omega}{\omega}=\chi^{s}_{\mu\nu}(0)\,, \qquad (8.21)$$

$$\lim_{\omega\to\infty}\mathrm{Re}\,\chi^{s}_{\mu\nu}(\omega)=0\,, \qquad (8.22)$$

$$\begin{aligned}&\frac{1}{\pi}\int_{-\infty}^{\infty}\mathrm{Re}\,\chi^{a}_{\mu\nu}(\omega)\,d\omega\\&=-\lim_{\omega\to\infty}\omega\,\mathrm{Im}\,\chi^{a}_{\mu\nu}(\omega)=\frac{i}{\hbar}\,\mathrm{Tr}\,\rho[M_{\mu},M_{\nu}]\,.\end{aligned} \qquad (8.23)$$

The relation (8.21) is well-known. This states that the properly weighted integration of absorption intensity for linearly polarized radiation is equal to the static susceptibility. The third relation, (8.23), requires more attention.

If M_μ is written as

$$M_\mu=\sum_i \gamma_i I_{i\mu} \ ,$$

where I_i is the angular momentum associated with the magnetic moment, we have

$$\frac{i}{\hbar}[M_x, M_y]=-\sum \gamma_i^2 I_{iz} \ .$$

Therefore Eq. (8.23) can be written as

$$\frac{1}{2}\int_0^\infty \mathrm{Re}\, \chi^a{}_{xy}(\omega)\, d\omega$$

$$=-\lim_{\omega\to\infty} \omega\, \mathrm{Im}\, \chi^a{}_{xy}(\omega)=-\sum \gamma_i^2 \overline{I}_{iz}=-\sum \gamma_r \overline{M}_{rz} \tag{8.24}$$

where $\overline{M}_{rz}$ means the magnetization due to r-th component in the system.

For circularly polarized radiation, the rate of energy absorption per unit volume is

$$Q=\frac{\omega}{2} H_1^2\{\chi'_{xy}-\chi'_{yx}+\chi''_{xx}+\chi''_{yy}\}$$

H_1 being the amplitude of the magnetic field of radiation. Thus, $\mathrm{Re}\, \chi^a{}_{xy}(\omega)$ is related to the absorption intensity of circular waves. The total integration of the absorption intensity is directly connected with the gyromagnetic ratio γ. This may not be of much value if γ can be measured accurately by sharp resonance. But one has to remember that (8.24) is generally valid even in the presence of strong interaction between magnetic moments. Thus the effects related to the absorption of circular wave may be used for the determination of γ, for instance, for electronic magnetic moments in ferromagnets or paramagnets. This sort of experiments may be considered to corresponds in a sense to those of gyromagnetic effects.

§ 9. Einstein Relations

We note here that the expression of conductivity given by Eq. (5.12) or (7.14) is the most general form of Einstein relation, which connects the conductivity or the mobility with the diffusion constant.

To see this, let us take the simplest example of charged particles which are moving independently. By Eq. (7.14), the conductivity is

$$\sigma^s{}_{\mu\nu}=\frac{ne^2}{kT}\int_0^\infty \langle v_\nu(0)\, v_\mu(t)\rangle\, dt \ , \tag{9.1}$$

if we regard the system to be classical. If we admit

$$\lim_{t\to\infty} \langle v_\nu(0) v_\mu(t)\rangle=\langle v_\nu\rangle\langle v_\mu\rangle=0$$

we can transform the right hand side of Eq. (9.1) as

$$\int_0^\infty \langle v_\nu(0) v_\mu(t)\rangle\, dt$$

$$=\lim_{T\to\infty} \frac{1}{2T}\int_0^T\int_0^T \langle v_\nu(t') v_\mu(t)\rangle\, dt\, dt'$$

$$=\lim_{T\to\infty} \frac{1}{2T}\langle (x_\nu(T)-x_\nu(0))(x_\mu(T)-x_\mu(0))\rangle$$

$$=D_{\mu\nu} \ . \tag{9.2}$$

where $D_{\mu\nu}$ is the diffusion constant defined by the third expression of Eq. (9.2). Eqs. (9.2) and (9.1) give at once

$$\sigma^s{}_{\mu\nu}=e^2 n D_{\mu\nu}/kT \tag{9.3}$$

which is the well known Einstein relation.

For a system of interacting particles, the exact form of Einstein relation is

$$\sigma^s{}_{\mu\nu}=e^2\overline{\Delta n^2} D_{\mu\nu}/kT \tag{9.4a}$$

$$=e^2 D_{\mu\nu}\Big/\left(\frac{\partial\mu}{\partial n}\right)_T \tag{9.4b}$$

where $D_{\mu\nu}$ is the diffusion constant in isothermal conditions, $\overline{\Delta n^2}$ the average fluctuation of particle density, and μ the chemical potential of the particle. This relation gives, for the diffusion constant,

$$D^s{}_{\mu\nu}=\left(\frac{\partial\mu}{\partial n}\right)_T\int_0^\infty dt\int_0^\beta \mathrm{Tr}\, \rho I_\nu(-i\hbar) I_\mu(t) d\lambda$$

$$=\left(\frac{\partial\mu}{\partial n}\right)_T \frac{1}{2}\int_{-\infty}^\infty dt\, \mathrm{Tr}\, \rho\{I_\nu I_\mu(t)\} \tag{9.5}$$

where

$$I_\nu=\sum_i v_{i\nu}$$

is the total particle flow per unit volume. Eq. (9.5) can be used for the calculation of diffusion constant in gases and also condensed phases. This will be discussed further in a forthcoming paper.

It might be worth while to note that Eq. (9.4) indicates at once how the factor $1/kT$ appearing in the expression of electric conductivity, Eq. (7.14) cancels out for degenerate Fermi particles. In this case, $\overline{\Delta n^2}$ is proportional to T, or in other words $(\partial\mu/\partial n)_T$ is a constant of the order of μ_0/n, μ_0 being the Fermi-level at the absolute zero.

Electron-Electron Interaction and Superconductivity. I*

By Ziro MIKURA

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai

(Received January 11, 1957)

It is shown that an electron gas exhibits the Meissner-Ochsenfeld effect if a special type of electron-electron interaction, $e^2s_1\cdot s_2/r$, is assumed and if the motion of an electron is considered to obey Dirac's relativistic equation. (s_1 and s_2 are the spin operators belonging respectively to each interacting electron.) The perturbation method of statistical mechanics, when applied to this system, leads to the London equation though the coefficient is different from London's original one. The theory talks in principle about the feature at the absolute zero of temperature in the sense that the electron-phonon interaction is not taken into account. The penetration depth of the field calculated according to the present model is quantitatively in good agreement with experiment. The known type of electron-electron interaction due to Breit, does not lead to superconductivity even in the relativistic treatment. The proposed interaction is discussed in connection with some experimental facts, i.e. the existance of an impurity effect for the penetration depth and the smaller Knight shift in the superconducting than the normal state.

§ 1. Introduction

A perfectly free electron gas does not exhibit the Meissner-Ochsenfeld effect (M–O effect), and it has long been supposed that introduction of some kind of electron-electron interaction would be able to account for this phenomenon. But no one has ever succeeded to establish a theory substantiating this supposition.

Fröhlich¹⁾ and Bardeen²⁾ proposed a theory of superconductivity based on an indirect electron-electron interaction with phonons as intermediaries. The most prominent success of this theory was the prediction of the isotope effect³⁾. However, the most important feature of a superconductor, i.e. the Meissner-Ochsenfeld effect, has not yet been understood on the basis of this theory. In this connection we should note the work of Schafroth⁴⁾, who showed that Fröhlich's interaction does not lead to the M–O effect as long as the perturbation theory can be used. He showed besides that the Coulomb interaction cannot produce the M–O effect, and stated further that the absence of this effect is confirmed generally for any not explicitly spin-dependent two-body force⁵⁾. On the other hand, Schafroth⁶⁾ has shown in a recent paper that an ideal Bose-Einstein gas exhibits the M–O effect below its condensation temperature. Application of this model to an actual superconducting metal, however, is not easy, since the assembly of conduction electrons in a metal should be considered to be a Fermi gas as confirmed by various kinds of experimental evidence.

Several years ago, the author investigated the magnetic property of a non-interacting electron gas by means of the relativistic theory of an electron by Dirac and the quantum hydrodynamics by Born and Green⁷⁾, and suggested that the M–O effect would occur if one assumes between two electrons such an interaction that makes the antiparallel-spin orientation more favourable than the parallel-spin orientation**. According to this conjecture we are led to introduce an interaction of the form $e^2s_1\cdot s_2/r$, where s_1 and s_2 are the spin operators belonging respectively to each interacting electron and each has eigenvalues ±1/2. Applying the relativistic theory of an electron by Dirac and the perturbation theory in statistical mechanics by Schafroth⁴⁾ and

** Read at the Osaka meeting of the Physical Society of Japan, Nov. 2, 1950 (unpublished).

Nakajima[8)], we show in this paper that a stationary current is established in the system of electrons interacting each other through the above-mentioned interaction under the influence of a magnetic field. Since the electron-phonon interaction is not taken into account, the theory should be considered to hold only at the absolute zero of temperature. The equation connecting current and field has the same form as the London equation, but the coefficient is different from London's. The penetration depth of the field according to the present model is numerically of the same order of magnitude as that according to London, in spite of different appearences, and in good agreement with experiment.

The M–O effect does not occur for the well-known type of electron-electron interaction due to Breit[9)] even if the relativistic theoy is applied.

In § 2 the perturbation theory in statistical mechanics is re-formulated in terms of the Dirac theory of an electron. In § 3 the well-known result that the M–O effect is absent in a free electron gas is confirmed in a relativistic way. The subsequent two sections, §§ 4 and 5, are devoted to the theory of an electron gas with interaction. In § 6 some experimental facts are discussed in the light of the present theory.

§ 2. Notations and Fundamental Equations

(i) Relativistic wave mechanics of an electron

The wave function ψ for the stationar state of a free Dirac electron satisfies

$$(c\boldsymbol{\alpha}\cdot\boldsymbol{p}+mc^2\alpha_m)\psi=\mathcal{E}\psi\ , \qquad (2.$$

where $\boldsymbol{\alpha}(\alpha_x,\ \alpha_y,\ \alpha_z)$ and α_m are the Dirac ope rators and satisfy

$$\alpha_\mu\alpha_\nu+\alpha_\nu\alpha_\mu=2\delta_{\mu\nu} \qquad (\mu,\ \nu=x,\ y,\ z,\ m)\ . \qquad (2.$$

As well known, these α's can be represente by the following four-four matrices:

$$\alpha_x=\begin{pmatrix}0&0&0&1\\0&0&1&0\\0&1&0&0\\1&0&0&0\end{pmatrix},\quad \alpha_y=\begin{pmatrix}0&0&0&-i\\0&0&i&0\\0&-i&0&0\\i&0&0&0\end{pmatrix},$$
$$\alpha_z=\begin{pmatrix}0&0&1&0\\0&0&0&-1\\1&0&0&0\\0&-1&0&0\end{pmatrix},\quad \alpha_m=\begin{pmatrix}1&0&0&0\\0&1&0&0\\0&0&-1&0\\0&0&0&-1\end{pmatrix}. \qquad (2.3$$

The solution $\psi(\boldsymbol{x})$ of (2.1) has four component $\psi(\rho,\ \boldsymbol{x})$ ($\rho=1,\ 2,\ 3,\ 4$), so that (2.1) can be re garded as a set of four simultaneous equa tions for $\psi(\rho,\ \boldsymbol{x})$. The solution of (2.1) cor responding to a given momentum $\boldsymbol{p}=\hbar\boldsymbol{k}$ ca be given by

$$\psi(\boldsymbol{x})=u_k\exp[i\boldsymbol{k}\cdot\boldsymbol{x}]\ , \qquad (2.4$$

where u_k satisfies the equation

$$(c\hbar\boldsymbol{\alpha}\cdot\boldsymbol{k}+mc^2\alpha_m)u_k=\mathcal{E}u_k \qquad (2.5$$

and has four components $u_k(\rho)$. For a give $\boldsymbol{k}$, (2.5) has four independent solutions. typical set of these solutions is:

$$\left.\begin{array}{cccc}
u_k^{(1)} & u_k^{(2)} & u_k^{(3)} & u_k^{(4)} \\
\hline
1 & 0 & \dfrac{-c\hbar k_z}{mc^2+\mathcal{E}_k} & \dfrac{-c\hbar k_x+ic\hbar k_y}{mc^2+\mathcal{E}_k} \\
0 & 1 & \dfrac{-c\hbar k_x-ic\hbar k_y}{mc^2+\mathcal{E}_k} & \dfrac{c\hbar k_z}{mc^2+\mathcal{E}_k} \\
\dfrac{c\hbar k_z}{mc^2+\mathcal{E}_k} & \dfrac{c\hbar k_x-ic\hbar k_y}{mc^2+\mathcal{E}_k} & 1 & 0 \\
\dfrac{c\hbar k_x+ic\hbar k_y}{mc^2+\mathcal{E}_k} & \dfrac{-c\hbar k_z}{mc^2+\mathcal{E}_k} & 0 & 1
\end{array}\right\}\times D_k\ , \qquad (2.6$$

$$\mathcal{E}_k=(m^2c^4+c^2\hbar^2k^2)^{1/2}\ , \qquad D_k=(mc^2+\mathcal{E}_k)^{1/2}/(2\mathcal{E}_k)^{1/2}\ .$$

The eigenvalue $\mathcal{E}$ in (2.5) should be $\mathcal{E}_k$ for $u_k^{(1)}$ and $u_k^{(2)}$, and $-\mathcal{E}_k$ for $u_k^{(3)}$ and $u_k^{(4)}$, i.e. $\mathcal{E}_k^{(1)}=\mathcal{E}_k^{(2)}=\mathcal{E}_k$ and $\mathcal{E}_k^{(3)}=\mathcal{E}_k^{(4)}=-\mathcal{E}_k$. We call the eigenstates $u_k^{(1)}$ and $u_k^{(2)}$ the positive-energy states, and $u_k^{(3)}$ and $u_k^{(4)}$ the negative-energy states. The normalization is

$$\textstyle\sum_{\rho=1}^4 u_k^{(s)*}(\rho)u_k^{(t)}(\rho)\equiv(\boldsymbol{k}s|\boldsymbol{k}t)=\delta_{st}\ , \qquad (2.7$$

as easily confirmed by using the identity

$$\frac{mc^2+\mathcal{E}_k}{2\mathcal{E}_k}+\frac{c^2\hbar^2k^2}{2\mathcal{E}_k(mc^2+\mathcal{E}_k)}=1\ . \qquad (2.8$$

The velocity of an electron in the Dira

theory is given by

$$v=c\boldsymbol{\alpha}\ . \tag{2.9}$$

The wave equation for an electron in a magnetic field $\boldsymbol{A}$ is

$$(c\boldsymbol{\alpha}\cdot\boldsymbol{p}-e\boldsymbol{\alpha}\cdot\boldsymbol{A}+mc^2\alpha_m)\psi=\mathcal{E}\psi\ . \tag{2.10}$$

Note that the expression (2.9) represents the velocity not only for a free electron but also for an electron in a field. This forms a striking contrast to the non-relativistic case, in which the velocity explicitly depends on $\boldsymbol{A}$ and is given by the equation

$$v=(\boldsymbol{p}/m)+(e\boldsymbol{A}/mc)\ .$$

The Dirac relativistic electron has the spin angular momentum $\boldsymbol{s}\hbar$. $\boldsymbol{s}$ is called the spin operator and defined by

$$\boldsymbol{s}=\boldsymbol{\sigma}/2\ , \tag{2.11}$$

where $\boldsymbol{\sigma}$ is the spin matrix to be defined in terms of $\boldsymbol{\alpha}$ by the equations

$$\sigma_x=-i\alpha_y\alpha_z\ ,\quad \sigma_y=-i\alpha_z\alpha_x\ ,\quad \sigma_z=-i\alpha_x\alpha_y\ .$$

In the representation in which α's are expressed in the form (2.3), σ_z is diagonal and its eigenvalues are ±1.

In later sections we need the explicit values of matrix elements of the following types

$$\left.\begin{aligned}(\boldsymbol{k}'s'|\boldsymbol{k}''s'')&\equiv u_{\boldsymbol{k}'}{}^{(s')*}1u_{\boldsymbol{k}''}{}^{(s'')}\ ,\\ (\boldsymbol{k}'s'|\sigma_\mu|\boldsymbol{k}''s'')&\equiv u_{\boldsymbol{k}'}{}^{(s')*}\sigma_\mu u_{\boldsymbol{k}''}{}^{(s'')}\ ,\\ (\boldsymbol{k}'s'|\alpha_\mu|\boldsymbol{k}''s'')&\equiv u_{\boldsymbol{k}'}{}^{(s')*}\alpha_\mu u_{\boldsymbol{k}''}{}^{(s'')}\ ,\end{aligned}\right\}$$

$$(\mu=x,\ y,\ z;\ \ s',\ s''=1,\ 2,\ 3,\ 4.)$$

for $\boldsymbol{k}'=\boldsymbol{k}-\frac{1}{2}\boldsymbol{q}$ and $\boldsymbol{k}''=\boldsymbol{k}+\frac{1}{2}\boldsymbol{q}$. They are listed in Table II of the Appendix.

(ii) *Perturbation expansion in statistical mechanics*

A brief account of the perturbative expansion theorem in statistical mechanics is given. We follow the formulation developed by Nakajima[8]. The Hamiltonian is assumed to be composed of two parts, namely, the unperturbed H_0 and the perturbation H_I and thus to be given by

$$H=H_0+H_I\ . \tag{2.12}$$

For the canonical distribution the free energy of the system is

$$F=-\beta^{-1}\ln \mathrm{Tr}\,(\exp[-\beta H])\ , \tag{2.13}$$

where $\beta=(kT)^{-1}$. According to Nakajima we have the following expansion:

$$F=F_0+F_1+F_2+F_3+\cdots\ ,$$

$$\begin{aligned}&F_0=\text{Free energy of the unperturbed system},\\ &F_1=\langle H_I\rangle_\beta\ ,\\ &F_2=\frac{1}{2}\beta\langle H_I\rangle_\beta{}^2-\frac{1}{2}\int_0^\beta d\lambda_1\langle H_I(\lambda_1\rangle H_I\rangle_\beta\ ,\\ &F_3=\frac{1}{3}\beta^2\langle H_I\rangle_\beta{}^3-\frac{1}{2}\beta\langle H_I\rangle_\beta\int_0^\beta d\lambda_1\langle H_I(\lambda_1)H_I\rangle_\beta\\ &\qquad+\frac{1}{3}\int_0^\beta d\lambda_1\int_0^{\lambda_1}d\lambda_2\langle H_I(\lambda_1)H_I(\lambda_2)H_I\rangle_\beta\ ,\\ &\cdots\cdots\cdots\ ,\end{aligned} \tag{2.14}$$

where

$$H_I(\lambda_i)=\exp[\lambda_i H_0]H_I\exp[-\lambda_i H_0]\ , \tag{2.15}$$

$$\langle Q\rangle_\beta=\mathrm{Tr}\,(Q\exp[-\beta H_0])/\mathrm{Tr}\,(\exp[-\beta H_0])\ . \tag{2.16}$$

$\langle Q\rangle_\beta$ is the expectation value of Q with respect to the unperturbed canonical distribution.

(iii) *Second quantization*

We consider a system of N Dirac electrons and impose on the wave functions a periodic boundary condition with periodic volume V. The formalism of second quantization is used, and the wave function is expanded in terms of the eigenfunctions of the Dirac equation for a free electron which are given by (2.4) and (2.6). Thus we write

$$\left.\begin{aligned}\psi(\boldsymbol{x})&=V^{-1/2}\textstyle\sum_k\sum_s a_k{}^{(s)}u_k{}^{(s)}\exp[i\boldsymbol{k}\cdot\boldsymbol{x}]\ ,\\ \psi^*(\boldsymbol{x})&=V^{-1/2}\textstyle\sum_k\sum_s a_k{}^{(s)*}u_k{}^{(s)*}\exp[-i\boldsymbol{k}\cdot\boldsymbol{x}]\ ,\end{aligned}\right\} \tag{2.17}$$

where $a_k{}^{(s)}$ and $a_k{}^{(s)*}$ are the usual destruction and creation operators satisfying

$$\left.\begin{aligned}&[a_k{}^{(s)*},\ a_l{}^{(t)}]_+=\delta_{kl}\delta_{st}\ ,\\ &[a_k{}^{(s)},\ a_l{}^{(t)}]_+=[a_k{}^{(s)*},\ a_l{}^{(t)*}]_+=0\ ,\\ &a_k{}^{(s)*}a_k{}^{(s)}=n_k{}^{(s)}\ .\end{aligned}\right\} \tag{2.18}$$

According to statistical mechanics we see

$$\begin{aligned}\langle a_k{}^{(s)*}a_k{}^{(s)}\rangle_\beta&\equiv\langle n_k{}^{(s)}\rangle_\beta\equiv f_k{}^{(s)}\\ &=(\exp[\beta(\mathcal{E}_k{}^{(s)}-\eta)]+1)^{-1}\ ,\end{aligned} \tag{2.19}$$

where

$$\mathcal{E}_k{}^{(s)}=\begin{cases}\ \ \mathcal{E}_k\ , & s=1,\ 2,\\ -\mathcal{E}_k\ , & s=3,\ 4,\end{cases} \tag{2.20}$$

and η is determined by means of the equation

$$\textstyle\sum_k\sum_s^+ f_k{}^{(s)}=N\ . \tag{2.21}$$

$\sum_s^+$ stands for $\sum_{s=1,2}$. Note that $f_k{}^{(1)}=f_k{}^{(2)}$ and $f_k{}^{(3)}=f_k{}^{(4)}$, and that the latter is very nearly equal to 1 at ordinary temperatures. It is advantageous to use different notations for the distribution function in the positive- and negative-energy regions:

$$f_k \equiv f_k^{(1)} = f_k^{(2)}\ , \qquad g_k \equiv f_k^{(3)} = f_k^{(4)}\ . \quad (2.22)$$

Corresponding to the velocity of an electron expressed by (2.9), the current density is

$$\boldsymbol{j} = ce\psi^*\boldsymbol{\alpha}\psi\ , \quad (2.23)$$

which is compared with the non-relativistic expression

$$\boldsymbol{j} = -(ie\hbar/2m)(\psi^*\nabla\psi - \nabla\psi^*\psi) - (e^2/mc^2)\psi^*\psi\boldsymbol{A}\ . \quad (2.24)$$

Let the Hamiltonian be

$$H = H_0 + H_A + H'\ , \quad (2.25)$$

where

$$H_0 = c\int\psi^*(\boldsymbol{\alpha}\cdot\boldsymbol{p} + mc\alpha_m)\psi d^3\boldsymbol{x}\ , \quad (2.26)$$

$$H_A = -e\int\psi^*\boldsymbol{\alpha}\cdot\boldsymbol{A}\psi d^3\boldsymbol{x}\ , \quad (2.27)$$

and H' represents the electron-electron, electron-phonon and other interactions independent of the field $\boldsymbol{A}$. It is clear that the current density (2.3) can be obtained as the functional derivative of H with respect to $\boldsymbol{A}$:

$$j_\mu(\boldsymbol{x}) = -c\delta H/\delta A_\mu(\boldsymbol{x})\ .$$

The mean current density is then the functional derivative of the free energy:

$$\begin{aligned} J_\mu(\boldsymbol{x}) &= \mathrm{Tr}(j_\mu(\boldsymbol{x})\exp[-\beta H])/\mathrm{Tr}(\exp[-\beta H]) \\ &= -c\delta F/\delta A_\mu(\boldsymbol{x})\ . \end{aligned} \quad (2.28)$$

This expression was derived by Nakajima[8] in the non-relativistic case and the derivation in the relativistic case is much the same. Since, however, this current involves the infinite contribution from the vacuum, the actual current can be obtained by subtracting this contribution. Let F° be the free energy of the vacuum, then the mean current density should be written as

$$J_\mu(\boldsymbol{x}) = -c\delta\Phi/\delta A_\mu(\boldsymbol{x})\ , \quad (2.29)$$

instead of (2.28), in terms of the corrected free energy

$$\Phi = F - F^\circ\ .$$

(iv) *Criterion for the occurrence of the Meissner-Ochsenfeld effect*

According to Schafroth[4] the mean current density $J_\mu(\boldsymbol{x})$ in a weak magnetic field $\boldsymbol{A}(\boldsymbol{x})$ (in an arbitrary gauge) can be expressed by the equation

$$J_\mu(\boldsymbol{x}) = \sum\nolimits_\nu\int d^3\boldsymbol{x}'K_{\mu\nu}(\boldsymbol{x}-\boldsymbol{x}')A_\nu(\boldsymbol{x}')\ .$$

Its Fourier transform is

$$J_\mu(\boldsymbol{q}) = \sum\nolimits_\nu K_{\mu\nu}(\boldsymbol{q})A_\nu(\boldsymbol{q})\ . \quad (2.30$$

Assuming an isotropic system, gauge invariance and continuity of current require $K_{\mu\nu}(\boldsymbol{q}$ to take the form

$$K_{\mu\nu}(\boldsymbol{q}) = (q^2\delta_{\mu\nu} - q_\mu q_\nu)K(q)\ . \quad (2.31$$

The M–O effect is established when $K(q)$ ha a pole of order q^{-2} at the origin, that is, whe it has the form

$$K(q) = -K_0 q^{-2} + K_r(q^2) \quad (2.32$$

with K_0, a positive constant, and $K_r(q^2)$, regular function of q^2. Substituting (2.31) an (2.32) in (2.30) and going back to the ordinar space we have the London equation

$$\mathrm{curl}\,\boldsymbol{J}(\boldsymbol{x}) = -K_0\boldsymbol{B}(\boldsymbol{x})\ , \qquad \boldsymbol{B}(\boldsymbol{x}) = \mathrm{curl}\,\boldsymbol{A}(\boldsymbol{x})\ , \quad (2.33$$

apart from an ordinarily negligible correctio term related to $K_r(q^2)$.

§ 3. Absence of the Meissner-Ochsenfel Effect in a Free Electron Gas

It is shown that the M–O effect cannot b established in a free electron gas even if th motion of an electron is dealt with in th relativistic theory. It is a well establishe fact in the non-relativistic case, and at firs sight it appears trivial in the relativistic theor as well. But, as the calculations in this section will show, the manner in which the M– effect disappears in the relativistic case is ver instructive and suggestive, and enables on to presume a type of electron-electron interaction which is able to produce the M– effect. Before entering the actual calculatio we should point out an important differenc between the relativistic and non-relativisti cases. The curent density in the former cas is expressed by a single term while that i the latter consists of two terms, as indicate by eqs. (2.23) and (2.24). It is a well-know fact that the vanishing of the M–O effec in the non-relativistic theory is due to th exact cancellation of the contributions fro these two terms in (2.24) (apart from highe order effects involving Landau's diamagnetism). This sort of cancellation cannot occu in the relativistic case, because the expressio for current in the field contains only a singl term in this case. This does not mean, however, that the relativistic treatment of a fre electron gas leads to the M–O effect. Th object of this section is to make this poin clear.

The Hamiltonian for a free electron gas in the magnetic field takes the form

$$H = H_0 + H_A\,,$$

$$H_0 = \sum_k \sum_s \mathcal{E}_k{}^{(s)} a_k{}^{(s)*} a_k{}^{(s)}\,, \tag{3.1}$$

$$H_A = -eV^{-1}\int d^3x \sum_k \sum_q \sum_{s's''} (\boldsymbol{k}'s'|\boldsymbol{\alpha}|\boldsymbol{k}''s'')\boldsymbol{A}(x) \times a_{k'}{}^{(s')*} a_{k''}{}^{(s'')} \exp[i\boldsymbol{q}\cdot\boldsymbol{x}]\,, \tag{3,2}$$

where $\boldsymbol{k}' = \boldsymbol{k} - \frac{1}{2}\boldsymbol{q}$ and $\boldsymbol{k}'' = \boldsymbol{k} + \frac{1}{2}\boldsymbol{q}$ as before[*]. It follows immediately from (2.26) and (2.27) if (2.17) is substituted in $\psi(\boldsymbol{x})$.

We need to calculate the free energy to the second order of H_A in order to get the current linear in $\boldsymbol{A}$. Putting $H_I = H_A$ and avoiding higher order terms in (2.14) we have

$$F = F_0 + F_1 + F_2\,, \tag{3.3}$$

$$F_1 = \langle H_A \rangle_\beta = -eV^{-1} \sum_k \sum_s \int d^3\boldsymbol{x} (\boldsymbol{k}s|\boldsymbol{\alpha}|\boldsymbol{k}s)\cdot \boldsymbol{A}(\boldsymbol{x}) \langle a_k{}^{(s)*} a_k{}^{(s)} \rangle_\beta\,, \tag{3.4}$$

$$\begin{aligned} F_2 = \frac{1}{2}\beta\langle H_A\rangle_\beta{}^2 - \frac{1}{2} e^2 V^{-2} \sum_k \sum_q \sum_{s's''} \int_0^\beta d\lambda \exp[\lambda(\mathcal{E}_{k'}{}^{(s')} - \mathcal{E}_{k''}{}^{(s'')})] \\ \times \iint d^3\boldsymbol{x} d^3\boldsymbol{x}' (\boldsymbol{k}'s'|\boldsymbol{\alpha}|\boldsymbol{k}''s'')\cdot\boldsymbol{A}(\boldsymbol{x}) (\boldsymbol{k}''s''|\boldsymbol{\alpha}|\boldsymbol{k}'s')\cdot\boldsymbol{A}(\boldsymbol{x}') \\ \times \langle a_{k'}{}^{(s')*} a_{k''}{}^{(s'')} a_{k''}{}^{(s'')*} a_{k'}{}^{(s')} \rangle_\beta \exp[i\boldsymbol{q}\cdot(\boldsymbol{x}-\boldsymbol{x}')]\,. \end{aligned} \tag{3.5}$$

It is first noted that F_0 and F_1 do not contribute to the current. Since it is evident for F_0, we need only to show it for F_1. It can easily be shown that the summation with respect to s in (3.4) yields an odd function of $\boldsymbol{k}$, use being made of the explicit values for the matrix elements of $\boldsymbol{\alpha}$ given in the Appendix. In consequence, the right-hand side of (3.4) should vanish when the summation over $\boldsymbol{k}$ is performed. This happens in the respective contributions from the positive- and negative-energy states separately. It is concluded therefrom that the F_1-contribution of the vacuum and thus the corrected first-order free energy Φ_1 also vanish. F_2 is then the only term which might lead to a non-vanishing current.

Making use of (2.18) and (2.19) we find

$$\int_0^\beta d\lambda \langle a_{k'}{}^{(s')*} a_{k''}{}^{(s'')} a_{k''}{}^{(s'')*} a_{k'}{}^{(s')} \rangle_\beta \exp[\lambda(\mathcal{E}_{k'}{}^{(s')} - \mathcal{E}_{k''}{}^{(s'')})] = -\frac{f_{k'}{}^{(s')} - f_{k''}{}^{(s'')}}{\mathcal{E}_{k'}{}^{(s')} - \mathcal{E}_{k''}{}^{(s'')}}\,. \tag{3.6}$$

Substituting (3.6) in (3.5) gives

$$F_2 = \frac{e^2}{2V^2} \sum_k \sum_q \sum_{s's''} P(\boldsymbol{k}, \boldsymbol{q}, s', s'') \frac{f_{k'}{}^{(s')} - f_{k''}{}^{(s'')}}{\mathcal{E}_{k'}{}^{(s')} - \mathcal{E}_{k''}{}^{(s'')}}\,, \tag{3.7}$$

where

$$P(\boldsymbol{k}, \boldsymbol{q}, s', s'') = \iint d^3\boldsymbol{x} d^3\boldsymbol{x}' (\boldsymbol{k}'s'|\boldsymbol{\alpha}|\boldsymbol{k}''s'')\cdot\boldsymbol{A}(\boldsymbol{x}) (\boldsymbol{k}''s''|\boldsymbol{\alpha}|\boldsymbol{k}'s')\cdot\boldsymbol{A}(\boldsymbol{x}') \exp[i\boldsymbol{q}\cdot(\boldsymbol{x}-\boldsymbol{x}')]\,. \tag{3.8}$$

According to the definition of the vacuum its F_2-contribution is obtained by setting $f_k{}^{(1)} = f_k{}^{(2)} = 0$ and $f_k{}^{(3)} = f_k{}^{(4)} = 1$ in (3.7):

$$F_2{}^\circ = -\frac{e^2}{2V} \sum_k \sum_q \left\{ \sum_{s'}^+ \sum_{s''}^- P(\boldsymbol{k}, \boldsymbol{q}, s', s'') \frac{1}{\mathcal{E}_{k'} + \mathcal{E}_{k''}} + \sum_{s'}^- \sum_{s''}^+ P(\boldsymbol{k}, \boldsymbol{q}, s', s'') \frac{1}{\mathcal{E}_{k'} + \mathcal{E}_{k''}} \right\}\,, \tag{3.9}$$

where $\sum_s^+$ and $\sum_s^-$ mean the summations on $s = 1, 2$ and $3, 4$ respectively. Subtraction of (3.9) from (3.7) gives

$$\begin{aligned} \Phi_2 = \frac{e^2}{2V} \sum_k \sum_q \Bigg\{ \sum_{s'}^+ \sum_{s''}^+ P(\boldsymbol{k}, \boldsymbol{q}, s', s'') \frac{f_{k'}{}^{(s')} - f_{k''}{}^{(s'')}}{\mathcal{E}_{k'} - \mathcal{E}_{k''}} + \sum_{s'}^+ \sum_{s''}^- P(\boldsymbol{k}, \boldsymbol{q}, s', s'') \frac{f_{k'}{}^{(s')} + 1 - f_{k''}{}^{(s'')}}{\mathcal{E}_{k'} + \mathcal{E}_{k''}} \\ + \sum_{s'}^- \sum_{s''}^+ P(\boldsymbol{k}, \boldsymbol{q}, s', s'') \frac{f_{k''}{}^{(s'')} + 1 - f_{k'}{}^{(s')}}{\mathcal{E}_{k'} + \mathcal{E}_{k''}} - \sum_{s'}^- \sum_{s''}^- P(\boldsymbol{k}, \boldsymbol{q}, s', s'') \frac{f_{k'}{}^{(s')} - f_{k''}{}^{(s'')}}{\mathcal{E}_{k'} - \mathcal{E}_{k''}} \Bigg\}\,. \end{aligned} \tag{3.10}$$

---

[*] Hereinafter all singly and doubly primed wave numbers should be understood in an analogous way.

At ordinary temperatures we may put $f_k^{(3)}=f_k^{(4)}=g_k=1$ with complete accuracy, and then (3.10) becomes

$$\Phi_2=\frac{e^2}{2V^2}\Sigma_k\Sigma_q\Big\{\Sigma^+_{s'}\Sigma^+_{s''}P(\boldsymbol{k},\boldsymbol{q},s',s'')\frac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}}$$
$$+\Sigma^+_{s'}\Sigma^-_{s''}P(\boldsymbol{k},\boldsymbol{q},s',s'')\frac{f_{k'}}{\mathcal{E}_{k'}+\mathcal{E}_{k''}}+\Sigma^-_{s'}\Sigma^+_{s''}P(\boldsymbol{k},\boldsymbol{q},s',s'')\frac{f_{k''}}{\mathcal{E}_{k'}+\mathcal{E}_{k''}}\Big\}. \tag{3.11}$$

An important fact is that the corrected second-order free energy (3.11) can be obtained by putting $f_k^{(3)}=f_k^{(4)}=g_k=0$ in the corresponding uncorrected expression (3.7).

Substituting (3.11) in (2.29) we find, for the mean current density in the Fourier space,

$$J_\mu(\boldsymbol{q})=-\frac{ce^2}{V}\Sigma_\nu\Sigma_k\Sigma^+_{s'}\Sigma^+_{s''}(\boldsymbol{k}'s'|\alpha_\mu|\boldsymbol{k}''s'')(\boldsymbol{k}''s''|\alpha_\nu|\boldsymbol{k}'s')A_\nu(\boldsymbol{q})\frac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}}$$
$$-\frac{ce^2}{V}\Sigma_\nu\Sigma_k\Sigma^+_{s'}\Sigma^-_{s''}(\boldsymbol{k}'s'|\alpha_\mu|\boldsymbol{k}''s'')(\boldsymbol{k}''s''|\alpha_\nu|\boldsymbol{k}'s')A_\nu(\boldsymbol{q})\frac{f_{k'}}{\mathcal{E}_{k'}+\mathcal{E}_{k''}}$$
$$-\frac{ce^2}{V}\Sigma_\nu\Sigma_k\Sigma^-_{s'}\Sigma^+_{s''}(\boldsymbol{k}'s'|\alpha_\mu|\boldsymbol{k}''s'')(\boldsymbol{k}''s''|\alpha_\nu|\boldsymbol{k}'s')A_\nu(\boldsymbol{q})\frac{f_{k''}}{\mathcal{E}_{k'}+\mathcal{E}_{k''}}. \tag{3.12}$$

As we are only concerned here with the Meissner-Ochsenfeld effect and not with other magnetic effects generally small compared with it, it is sufficient to calculate the right-hand side of (3.12) in the limit of small q as discussed by Schafroth[4].

We now consider successively each term in (3.12). In the first term, $s'\neq s''$ does not contribute in the limit $q\to 0$ as easily confirmed making use of the explicit values of $(\boldsymbol{k}'s'|\alpha_\mu|\boldsymbol{k}''s'$ in the Appendix. For $s'=s''$ we have easily, for $q\to 0$,

$$-\frac{2c^3e^2\hbar^2}{V}\Sigma_\nu\Sigma_k\frac{k_\mu k_\nu}{\mathcal{E}_k^2}\frac{\partial f_k}{\partial\mathcal{E}_k}A_\nu(\boldsymbol{q}). \tag{3.13}$$

The summand for $\nu\neq\mu$ vanishes after the summation over $\boldsymbol{k}$ because it is an odd function with respect to k_μ and k_ν. When the summation over $\boldsymbol{k}$ is replaced by integration, it is easy to show for $\nu=\mu$, by integration by parts,

$$-\frac{2c^3e^2\hbar^2}{V}\Sigma_k\frac{k_\mu^2}{\mathcal{E}_k^2}\frac{\partial f_k}{\partial\mathcal{E}_k}A_\mu(\boldsymbol{q})=\frac{2ce^2}{V}A_\mu(\boldsymbol{q})\Sigma_k\frac{f_k}{\mathcal{E}_k}\Big(1-\frac{c^2\hbar^2k_\mu^2}{\mathcal{E}_k^2}\Big). \tag{3.14}$$

We now consider the second term in (3.12). As the matrix elements of α_μ listed in Table II of the Appendix are not symmetrical in μ, the calculations are difficult to be carried out without specifying μ. Taking $\mu=x$ and applying the values in Table II together with (A.2) and (A.3) of the Appendix, we have for $q\to 0$

$$-\frac{2ce^2}{V}A_x(\boldsymbol{q})\Big\{\Sigma_k(1-N_kk_x^2+iN_kk_xk_y)(1-N_kk_x^2-iN_kk_xk_y)\frac{f_k}{2\mathcal{E}_k}+\Sigma_kN_k^2k_z^2k_x^2\frac{f_k}{2\mathcal{E}_k}\Big\}. \tag{3.15}$$

In this expression, the first term in { } comes from 1⇄4 and 2⇄3 and the second from 1⇄3 and 2⇄4*. In both terms the non-vanishing contributions have only come from the case $\nu=\mu=x$. The expression (3.15) can be further simplified by applying (2.8) and considering the definition of N_k in (A.2). One finds

$$(1-N_kk_x^2+iN_kk_xk_y)(1-N_kk_x^2-iN_kk_xk_y)$$
$$=1-\frac{2c^2\hbar^2k_x^2}{\mathcal{E}_k(mc^2+\mathcal{E}_k)}-\frac{c^4\hbar^4(k_x^4+k_x^2k_y^2)}{\mathcal{E}_k^2(mc^2+\mathcal{E}_k)^2}=1-\frac{c^2\hbar^2k_x^2}{\mathcal{E}_k^2}-\frac{c^4\hbar^4k_z^2k_y^2}{\mathcal{E}_k^2(mc^2+\mathcal{E}_k)}.$$

According to this, (3.15) becomes

---

* We mean the scattering $s'=1$, $s''=4$ or $s'=4$, $s''=1$ by simply writting 1⇄4 or 4⇄1.

$$-\frac{ce^2}{V}A_x(\boldsymbol{q})\sum_k \frac{f_k}{\mathcal{E}_k}\left(1-\frac{c^2\hbar^2k_x^2}{\mathcal{E}_k^2}\right). \tag{3.16}$$

We have similar results for $\mu=y$ and z.

Now consider the third term in (3.12). It is an easy matter to show that its contribution is equal to that of the second term. This is guaranteed by the relation

$$\sum_{s'}^{-}\sum_{s''}^{+}(\boldsymbol{k}'s'|\alpha_\mu|\boldsymbol{k}''s'')(\boldsymbol{k}''s''|\alpha_\mu|\boldsymbol{k}'s')\frac{f_{k''}}{\mathcal{E}_{k'}+\mathcal{E}_{k''}}=\sum_{s'}^{+}\sum_{s''}^{-}(\boldsymbol{k}'s'|\alpha_\mu|\boldsymbol{k}''s'')(\boldsymbol{k}''s''|\alpha_\mu|\boldsymbol{k}'s')\frac{f_{k'}}{\mathcal{E}_{k'}+\mathcal{E}_{k''}},$$

which holds for any μ in the limit $q\rightarrow 0$. See Table II in the Appendix.

The sum of the second and third terms is thus equal to just twice the value given by (3.16) with x replaced by μ:

$$-\frac{2ce^2}{V}A_\mu(q)\sum_k \frac{f_k}{\mathcal{E}_k}\left(1-\frac{c^2\hbar^2k_\mu^2}{\mathcal{E}_k^2}\right). \tag{3.17}$$

The right-hand side of (3.12), which is the sum of (3.14) and (3.17), has then to vanish in the limit $q\rightarrow 0$, and this means

$$J_\mu(\boldsymbol{q})=0$$

in the same limit. This is the same result that obtained according to the usual non-relativistic theory, and means the absence of the M–O effect in a free electron gas. Note that the result is relativistically exact as we have not used any non-relativistic approximation. We should note further that the contribution in the first term of (3.12) comes from the virtual transitions between the electronic states with spins parallel while the main contribution in the second and third terms comes from those between the states with spins antiparallel to each other. Considering that the latter contribution is diamagnetic, we can presume that a spin-dependent electron-electron interaction can produce a diamagnetic current if it favours the antiparallel spin orientation of interacting electrons. This is just the conclusion reached in the earlier argument* by the author on the same reason as mentioned here.

§ 4. A Special Type of Electron-Electron Interaction which Produces the Meissner-Ochsenfeld Effect

As suggested in § 1 and at the end of § 3 we introduce a special type of electron-electron interaction of the form**

$$U_M=e^2\boldsymbol{s}_1\cdot\boldsymbol{s}_2/r\,, \tag{4.1}$$

where $\boldsymbol{s}_1$ and $\boldsymbol{s}_2$ are the spin angular momenta belonging respectively to each interacting electron, measured in the unit $\hbar$. They are related to the spin matrices $\boldsymbol{\sigma}_1$ and $\boldsymbol{\sigma}_2$ by eq. (2.11). r is a distance between interacting electrons. Choice is made of the special form (4.1) according to the following considerations. Firstly, we require the scalar product of the spin angular momenta as a factor, in order to secure the property that the interaction lowers the energy of the state with antiparallel spin orientation. Secondly, the r^{-1}-dependence is introduced to obtain the required singularity of the kernel $K(q)$ in (2.31), as discussed there. Finally, the analogy with the magnetic interaction

$$e^2\boldsymbol{\alpha}_1\cdot\boldsymbol{\alpha}_2/r \tag{4.2}$$

is considered. This is the Coulomb interaction multiplied by the product of velocities measured in the unit of the light velocity c, the universal unit of velocity. The proposed expression (4.1) has a resemblance to this in the sense that it is the Coulomb interaction multiplied by the product of spin angular momenta measured in $\hbar$, the universal unit of angular momentum. We shall show in this section that the interaction (4.1) brings upon the Meissner-Ochsenfeld effect of the correct order of magnitude.

---

* Footnote on p. 587.

** This interaction is not Lorentz invariant. It is to be considered as a part of some Lorentz invariant interaction.

Write the Hamiltonian of the system in a magnetic field as

$$H=H_0+H_I\ , \qquad H_I=H_A+H_M\ . \tag{4.3}$$

Here H_A is given by (3.2) and H_M by

$$H_M=\frac{\pi e^2}{2V}\sum_{kl}\sum_q\sum_{s's''t't''}\frac{(\boldsymbol{k}'s'|\boldsymbol{\sigma}|\boldsymbol{k}''s'')\cdot(\boldsymbol{l}''t''|\boldsymbol{\sigma}|\boldsymbol{l}'t')}{q^2}a_{k'}^{(s')*}a_{k''}^{(s'')}a_{l''}^{(t'')*}a_{l'}^{(t')}\ . \tag{4.4}$$

For convenience $\boldsymbol{\sigma}$ is used in place of $\boldsymbol{s}$.

The free energy should be calculated to the first order of H_M and to the second order of H_A. The expansion theorem (2.14) gives

$$F=F_0+F_1+F_2+F_3\ ,$$

$$F_1=\langle H_A\rangle_\beta+\langle H_M\rangle_\beta\ , \tag{4.5}$$

$$F_2=\frac{1}{2}\beta(\langle H_A\rangle_\beta+\langle H_M\rangle_\beta)^2-\frac{1}{2}\int_0^\beta d\lambda\langle(H_A(\lambda)+H_M(\lambda))(H_A+H_M)\rangle_\beta\ , \tag{4.6}$$

$$\begin{aligned}F_3=&\frac{1}{3}\beta^2(\langle H_A\rangle_\beta+\langle H_M\rangle_\beta)^3-\frac{1}{2}\beta(\langle H_A\rangle_\beta+\langle H_M\rangle_\beta)\int_0^\beta d\lambda\langle(H_A(\lambda)+H_M(\lambda))(H_A+H_M)\rangle_\beta\\&+\frac{1}{3}\int_0^\beta d\lambda_1\int_0^{\lambda_1}d\lambda_2\langle(H_A(\lambda_1)+H_M(\lambda_1))(H_A(\lambda_2)+H_M(\lambda_2))(H_A+H_M)\rangle_\beta\ .\end{aligned} \tag{4.7}$$

In the above equations $\langle H_A\rangle_\beta$ should vanish as discussed in § 3. After dropping all the terms independent of $\boldsymbol{A}$ as well as those equal to zero, we are left with

$$F_m=-\frac{1}{2}\int_0^\beta d\lambda\langle H_A(\lambda)H_A\rangle_\beta-\frac{1}{2}\beta\langle H_M\rangle_\beta\int_0^\lambda d\lambda\langle H_A(\lambda)H_A\rangle_\beta+\frac{1}{3}\int_0^\beta d\lambda_1\int_0^{\lambda_1}d\lambda_2{\sum}'_P\langle H_M(\lambda_1)H_A(\lambda_2)H_A\rangle_\beta\ , \tag{4.8}$$

where $\sum'_P$ means the summation over all different permutations of suffixes to H. We have here dropped terms of orders H_M^2, H_M^3 and H_A^3 as we are not concerned with these higher order terms. As concerns the first term on the right-hand side of (4.8), we have already developed a detailed discussion in § 3 and have shown that it has nothing to do with the M-O effect. We are thus left with

$$F_M=-\frac{1}{2}\beta\langle H_M\rangle_\beta\int_0^\lambda d\lambda\langle H_A(\lambda)H_A\rangle_\beta+\frac{1}{3}\int_0^\beta d\lambda_1\int_0^{\lambda_1}d\lambda_2{\sum}'_P\langle H_M(\lambda_1)H_A(\lambda_2)H_A\rangle_\beta\ . \tag{4.9}^*$$

It is convenient to write

$$F_M=F_{M0}+F_{M1}+F_{M2}+F_{M3}\ , \tag{4.10}$$

where F_{M0} stands for the first term in (4.9), and F_{M1}, F_{M2} and F_{M3} correspond to the permutations MAA, AMA and AAM respectively in the second term. Using (2.15), (3.2) and (4.4) and performing integrations with respect to λ_1 and λ_2 in the last three terms give

---

* The first term on the right-hand side vanishes for the particular interaction (4.1) because $\langle H_M\rangle_\beta$ vanishes in this case. This term is formally included here in order to apply in § 5 the expression for the current derived in this section also to the case where this term does not vanish. We should note that the corrected free energy corresponding to this term does not vanish in the general case where the statistical average of the perturbative Hamiltonian due to interaction does not disappear.

$$
\begin{aligned}
F_M &= F_{M0}+\sum_{\xi=1}^{3}F_{M\xi}\\
&= \frac{\pi e^4}{6V^3}\sum_q\sum_{kl}\sum_{s's''t't''}\sum_\xi Q_\xi\left(\frac{1}{q^2}-\frac{1}{|\boldsymbol{k}-\boldsymbol{l}|^2}\right)(\boldsymbol{k}'s'|\boldsymbol{\sigma}|\boldsymbol{k}''s'')\cdot(\boldsymbol{l}''t''|\boldsymbol{\sigma}|\boldsymbol{l}'t')\\
&\quad\times\iint d^3x d^3x'(\boldsymbol{k}''s''|\boldsymbol{\alpha}|\boldsymbol{k}'s')\cdot\boldsymbol{A}(\boldsymbol{x})(\boldsymbol{l}'t'|\boldsymbol{\alpha}|\boldsymbol{l}''t'')\cdot\boldsymbol{A}(\boldsymbol{x}')\exp\left[i\boldsymbol{q}\cdot(\boldsymbol{x}-\boldsymbol{x}')\right]+F_{M0}+F_{MR}\;, \qquad (4.11)
\end{aligned}
$$

where

Q_1 &= \left\{\frac{\exp[-\beta(\delta_1+\delta_2)]-1}{\delta_1(\delta_1+\delta_2)}-\frac{\exp[-\beta\delta_2]-1}{\delta_1\delta_2}+\frac{\exp[-\beta(\delta_1+\delta_2)]-1}{\delta_2(\delta_1+\delta_2)}-\frac{\exp[-\beta\delta_1]-1}{\delta_1\delta_2}\right\}\\
&\quad\times\langle a_{k'}^{(s')*}a_{k''}^{(s'')}a_{l''}^{(t'')*}a_{l'}^{(t')}a_{k''}^{(s'')*}a_{k'}^{(s')}a_{l'}^{(t')*}a_{l''}^{(t'')}\rangle_\beta \qquad (4.12)
\end{aligned}
$$

with

$$
\delta_1=\mathcal{E}_{k''}^{(s'')}-\mathcal{E}_{k'}^{(s')}\;,\qquad \delta_2=\mathcal{E}_{l'}^{(t')}-\mathcal{E}_{l''}^{(t'')}\;, \qquad (4.13)
$$

$$
\begin{aligned}
Q_2 &= \left\{\frac{\exp[-\beta\delta_1]-1}{\delta_1(\delta_1+\delta_2)}+\frac{\exp[\beta\delta_2]-1}{\delta_2(\delta_1+\delta_2)}+\frac{\exp[-\beta\delta_2]-1}{\delta_2(\delta_1+\delta_2)}+\frac{\exp[\beta\delta_1]-1}{\delta_1(\delta_1+\delta_2)}\right\}\\
&\quad\times\langle a_{l'}^{(t')*}a_{l''}^{(t'')}a_{k'}^{(s')*}a_{k''}^{(s'')}a_{l''}^{(t'')*}a_{l'}^{(t')}a_{k''}^{(s'')*}a_{k'}^{(s')}\rangle_\beta\;, \qquad (4.14)
\end{aligned}
$$

$$
\begin{aligned}
Q_3 &= \left\{\frac{\exp[\beta(\delta_1+\delta_2)]-1}{\delta_2(\delta_1+\delta_2)}-\frac{\exp[\beta\delta_1]-1}{\delta_1\delta_2}+\frac{\exp[\beta(\delta_1+\delta_2)]-1}{\delta_1(\delta_1+\delta_2)}-\frac{\exp[\beta\delta_2]-1}{\delta_1\delta_2}\right\}\\
&\quad\times\langle a_{k''}^{(s'')*}a_{k'}^{(s')}a_{l'}^{(t')*}a_{l''}^{(t'')}a_{k'}^{(t')*}a_{k''}^{(s'')}a_{l''}^{(t'')*}a_{l'}^{(t')}\rangle_\beta\;. \qquad (4.15)
\end{aligned}
$$

F_{MR} concerns those processes, in which H_M scatters electrons initially in $\boldsymbol{k}'$- and $\boldsymbol{l}''$-states into $\boldsymbol{l}''$- and $\boldsymbol{k}'$-states respectively, initial and final states of the system being thus identical. F_{MR} contributes a regular term to the kernel $K(q)$ at $q=0$ and has nothing to do with the M-O effect. F_{M0} also yields no required singularity in the kernel, as clearly seen from the appearence. The $1/|\boldsymbol{k}-\boldsymbol{l}|^2$ term, reqular in q, can be shown to vanish in the limit $q\to0$ when combined with the last two terms, F_{M0} and F_{MR}, as required by gauge invariance*. Making use of the definition (2.16) and of the invariance property of the trace of a product with respect to the cyclic change in the order of factors, gives the following equations:

$$
\begin{aligned}
&\langle a_{k'}^{(s')*}a_{k''}^{(s'')}a_{l''}^{(t'')*}a_{l'}^{(t')}a_{k''}^{(s'')*}a_{k'}^{(s')}a_{l'}^{(t')*}a_{l''}^{(t'')}\rangle_\beta\\
&\quad=\exp[\beta\delta_2]\langle a_{l'}^{(t')*}a_{l''}^{(t'')}a_{k'}^{(s')*}a_{k''}^{(s'')}a_{l''}^{(t'')*}a_{l'}^{(t')}a_{k''}^{(s'')*}a_{k'}^{(s')}\rangle_\beta\\
&\quad=\exp[\beta(\delta_1+\delta_2)]\langle a_{k''}^{(s'')*}a_{k'}^{(s')}a_{l'}^{(t')*}a_{l''}^{(t'')}a_{k'}^{(s')*}a_{k''}^{(s'')}a_{l''}^{(t'')*}a_{l'}^{(t')}\rangle_\beta\;. \qquad (4.16)
\end{aligned}
$$

With this one obtains

$$
\begin{aligned}
\sum_{\xi=1}^{3}Q_\xi &= 3\left\{\frac{\exp[-\beta(\delta_1+\delta_2)]-1}{\delta_1(\delta_1+\delta_2)}+\frac{\exp[-\beta(\delta_1+\delta_2)]-1}{\delta_2(\delta_1+\delta_2)}-\frac{\exp[-\beta\delta_1]-1}{\delta_1\delta_2}-\frac{\exp[-\beta\delta_2]-1}{\delta_1\delta_2}\right\}\\
&\quad\times f_{k'}^{(s')}(1-f_{k''}^{(s'')})f_{l''}^{(t'')}(1-f_{l'}^{(t')})\\
&= 3\frac{(\exp[-\beta\delta_1]-1)(\exp[-\beta\delta_2]-1)}{\delta_1\delta_2}f_{k'}^{(s')}(1-f_{k''}^{(s'')})f_{l''}^{(t'')}(1-f_{l'}^{(t')})\\
&= 3\frac{f_{k'}^{(s')}-f_{k''}^{(s'')}}{\mathcal{E}_{k'}^{(s')}-\mathcal{E}_{k''}^{(s'')}}\frac{f_{l'}^{(t')}-f_{l''}^{(t'')}}{\mathcal{E}_{l'}^{(t')}-\mathcal{E}_{l''}^{(t'')}}\;. \qquad (4.17)
\end{aligned}
$$

Substituting this in (4.11) gives

$$
\begin{aligned}
F_M &= \frac{\pi e^4}{2V^3}\sum_q\sum_{kl}\sum_{s's''t't''}\frac{(\boldsymbol{k}'s'|\boldsymbol{\sigma}|\boldsymbol{k}''s'')\cdot(\boldsymbol{l}''t''|\boldsymbol{\sigma}|\boldsymbol{l}'t')}{q^2}\frac{f_{k'}^{(s')}-f_{k''}^{(s'')}}{\mathcal{E}_{k'}^{(s')}-\mathcal{E}_{k''}^{(s'')}}\frac{f_{l'}^{(t')}-f_{l''}^{(t'')}}{\mathcal{E}_{l'}^{(t')}-\mathcal{E}_{l''}^{(t'')}}\\
&\quad\times\iint d^3x d^3x'(\boldsymbol{k}''s''|\boldsymbol{\alpha}|\boldsymbol{k}'s')\cdot\boldsymbol{A}(\boldsymbol{x})(\boldsymbol{l}'t'|\boldsymbol{\alpha}|\boldsymbol{l}''t'')\cdot\boldsymbol{A}(\boldsymbol{x}')\exp\left[i\boldsymbol{q}\cdot(\boldsymbol{x}-\boldsymbol{x}')\right]\;. \qquad (4.18)
\end{aligned}
$$

To obtain the corrected free energy Φ_M, we should take all $f^{(3)}$'s and $f^{(4)}$'s in (4.18) as equal to 0 as explained in § 3*. Write, for convenience,

---

* See Schafroth[4].

$$R_{\mu\nu}{}^{ij}(\boldsymbol{k}, \boldsymbol{l}, \boldsymbol{q}, s', s'', t', t'') = (\boldsymbol{k}'s'|\sigma_i|\boldsymbol{k}''s'')(\boldsymbol{l}''t''|\sigma_j|\boldsymbol{l}'t')(\boldsymbol{k}''s''|\alpha_\mu|\boldsymbol{k}'s')(\boldsymbol{l}'t'|\alpha_\nu|\boldsymbol{l}''t'') , \tag{4.19}$$

then, by applying (2.28) to the corrected free energy Φ_M and taking the Fourier transform, one gets the mean current density in the form

$$J_\mu(\boldsymbol{q}) = \sum_\nu K_{\mu\nu}(\boldsymbol{q}) A_\nu(\boldsymbol{q}) ,$$

$$\begin{aligned} K_{\mu\nu}(\boldsymbol{q}) = -\frac{\pi c e^4}{V^2}\frac{1}{q^2}\sum_{kl}\sum_j \Big\{ & \sum^+_{s's''}\sum^+_{t't''} R_{\mu\nu}{}^{jj}\frac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}}\frac{f_{l'}-f_{l''}}{\mathcal{E}_{l'}-\mathcal{E}_{l''}} \\ & + \sum^+_{s's''t''}\sum^-_{t'} R_{\mu\nu}{}^{jj}\frac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}}\frac{f_{l''}}{\mathcal{E}_{l'}+\mathcal{E}_{l''}} + \sum^+_{s's''t'}\sum^-_{t''} R_{\mu\nu}{}^{jj}\frac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}}\frac{f_{l'}}{\mathcal{E}_{l'}+\mathcal{E}_{l''}} \\ & + \sum^+_{s''t't''}\sum^-_{s'} R_{\mu\nu}{}^{jj}\frac{f_{k''}}{\mathcal{E}_{k'}+\mathcal{E}_{k''}}\frac{f_{l'}-f_{l''}}{\mathcal{E}_{l'}-\mathcal{E}_{l''}} + \sum^+_{s't't''}\sum^-_{s''} R_{\mu\nu}{}^{jj}\frac{f_{k'}}{\mathcal{E}_{k'}+\mathcal{E}_{k''}}\frac{f_{l'}-f_{l''}}{\mathcal{E}_{l'}-\mathcal{E}_{l''}} \\ & + \sum^+_{s''t''}\sum^-_{s't'} R_{\mu\nu}{}^{jj}\frac{f_{k''}}{\mathcal{E}_{k'}+\mathcal{E}_{k''}}\frac{f_{l''}}{\mathcal{E}_{l'}+\mathcal{E}_{l''}} + \sum^+_{s''t'}\sum^-_{s't''} R_{\mu\nu}{}^{jj}\frac{f_{k''}}{\mathcal{E}_{k'}+\mathcal{E}_{k''}}\frac{f_{l'}}{\mathcal{E}_{l'}+\mathcal{E}_{l''}} \\ & + \sum^+_{s't''}\sum^-_{s''t'} R_{\mu\nu}{}^{jj}\frac{f_{k'}}{\mathcal{E}_{k'}+\mathcal{E}_{k''}}\frac{f_{l''}}{\mathcal{E}_{l'}+\mathcal{E}_{l''}} + \sum^+_{s't'}\sum^-_{s''t''} R_{\mu\nu}{}^{jj}\frac{f_{k'}}{\mathcal{E}_{k'}+\mathcal{E}_{k''}}\frac{f_{l'}}{\mathcal{E}_{l'}+\mathcal{E}_{l''}} \Big\} , \end{aligned} \tag{4.20}$$

where $R_{\mu\nu}{}^{jj}$ is the abbreviation of (4.19) for $i=j$. Note that $R_{\mu\nu}{}^{jj}$ is a function of s', s'', t' and t''. For the sake of convenience we write

$$K_{\mu\nu}(\boldsymbol{q}) = -\frac{\pi c e^4}{V^2}\frac{1}{q^2}\sum_{\xi=1}^{9} \Lambda_{\mu\nu}{}^{\xi} , \tag{4.21}$$

where $\Lambda_{\mu\nu}{}^1$, $\Lambda_{\mu\nu}{}^2$, $\cdots$, and $\Lambda_{\mu\nu}{}^9$ stand for the first, second, $\cdots$, and nineth terms respectively on the right-hand side of (4.20) apart from a trivial factor $-\pi c e^4/(Vq)^2$.

In order to study the M–O effect it is sufficient to look for the values of $\Lambda_{\mu\nu}{}^\xi$'s to the order of q^2 in the limit of small q. The calculations are elaborate but can be performed in a straight-forward way by applying the explicit values of matrix elements listed in Table II of the Appendix. We should note that the evaluation of $K_{\mu\nu}(q)$ can be restricted to a single case $\mu=\nu=x$ because the values for the other cases can readily be obtained according to the symmetry property of the kernel as mentioned in § 2, (iv).

In the first place, we consider $\Lambda_{xx}{}^1$ in which all the virtual transitions involved are those between positive-energy states. It is sufficient in this section to use approximate values correct to the first order of q_μ for all the matrix elements. Note that $(f_{k'}-f_{k''})/(\mathcal{E}_{k'}-\mathcal{E}_{k''})$ is an even function of $\boldsymbol{k}$, then one obtains

$$\begin{aligned} \Lambda_{xx}{}^1 = \sum_j & \Big\{ \sum_\pm \sum_k \sum^+_{s's''} (\boldsymbol{k}'s'|\sigma_j|\boldsymbol{k}''s'')_\pm (\boldsymbol{k}''s''|\alpha_x|\boldsymbol{k}'s')_\pm \frac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}} \Big\} \\ & \times \Big\{ \sum_\pm \sum_l \sum^+_{t't''} (\boldsymbol{l}''t''|\sigma_j|\boldsymbol{l}'t')_\pm (\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')_\pm \frac{f_{l'}-f_{l''}}{\mathcal{E}_{l'}-\mathcal{E}_{l''}} \Big\} , \end{aligned} \tag{4,22}$$

where the (+) or (−) symbol attached to the matrix element means that the expression designates its even or odd part as a function of $\boldsymbol{k}$, and $\sum_\pm$ means the summation on both pairs of double signs. Applying the list in the Appendix together with (A.2) and (A.3) we have the following results which are correct to the first order of q_μ:

$$\begin{aligned} & \sum_\pm \sum_k \sum^+_{s'=s''} (\boldsymbol{k}'s'|\sigma_j|\boldsymbol{k}''s'')_\pm (\boldsymbol{k}''s''|\alpha_x|\boldsymbol{k}'s')_\pm \frac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}} \\ & = \begin{cases} i\sum_k \{N_k k_z k_x(-K_k q_y + 2L_k k_y \boldsymbol{k}\cdot\boldsymbol{q}) + K_k N_k k_x(k_z q_y - k_y q_z)\} \dfrac{\partial f_k}{\partial \mathcal{E}_k} = 0 , & j=x , \\ i\sum_k K_k N_k (k_x{}^2 + N_k k_y{}^2 k_z{}^2) q_z \dfrac{\partial f_k}{\partial \mathcal{E}_k} , & j=y , \\ -i\sum_k K_k \{1 - 2N_k k_y{}^2 + N_k{}^2 k_y{}^2 (k_x{}^2 + k_y{}^2)\} q_y \dfrac{\partial f_k}{\partial \mathcal{E}_k} , & j=z , \end{cases} \end{aligned} \tag{4.23}$$

---

* This procedure corresponds to the subtraction from (4.18) of the sum of the free energies belonging to those cases where either $\boldsymbol{k}$- or $\boldsymbol{l}$- or both electrons belong to the vacuum.

$$\sum_{\pm}\sum_k\sum^{+}_{s'\neq s''}(\boldsymbol{k}'s'|\sigma_j|\boldsymbol{k}''s'')_{\pm}(\boldsymbol{k}''s''|\alpha_x|\boldsymbol{k}'s')_{\pm}\frac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}}$$

$$=\begin{cases} i\sum_k N_k k_y k_x(K_k q_z-2L_k k_z\boldsymbol{k}\cdot\boldsymbol{q})\dfrac{\partial f_k}{\partial\mathcal{E}_k}=0\,, & j=x\,,\\ i\sum_k K_k\{1-N_k(k_x^2+2k_z^2)+N_k^2k_z^2(k_x^2+k_z^2)\}q_z\dfrac{\partial f_k}{\partial\mathcal{E}_k}\,, & j=y\,,\\ -i\sum_k K_k N_k^2k_y^2k_z^2q_y\dfrac{\partial f_k}{\partial\mathcal{E}_k}\,, & j=z\,,\end{cases} \tag{4.24}$$

where $\sum^{+}_{s'=s''}$ means the summation on pairs, (1, 1) and (2, 2), and $\sum^{+}_{s'\neq s''}$ the summation on pairs, (1, 2) and (2, 1). Combining (4.23) and (4.24) gives

$$\sum_{\pm}\sum_k\sum^{+}_{s's''}(\boldsymbol{k}'s'|\sigma_j|\boldsymbol{k}''s'')_{\pm}(\boldsymbol{k}''s''|\alpha_x|\boldsymbol{k}'s')_{\pm}\frac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}}$$

$$=\begin{cases} 0\,, & j=y\,,\\ iq_z\sum_k K_k(1-2N_kk_z^2+N_k^2k^2k_z^2)\dfrac{\partial f_k}{\partial\mathcal{E}_k}\,, & j=y\,,\\ -iq_y\sum_k K_k(1-2N_kk_y^2+N_k^2k^2k_y^2)\dfrac{\partial f_k}{\partial\mathcal{E}_k}\,, & j=z\,,\end{cases}$$

$$=\begin{cases} 0\,, & j=x\,,\\ iq_z\sum_k K_kI_k\dfrac{\partial f_k}{\partial\mathcal{E}_k}\,, & j=y\,,\\ -iq_y\sum_k K_kI_k\dfrac{\partial f_k}{\partial\mathcal{E}_k}\,, & j=z\,,\end{cases} \tag{4.25}$$

where

$$I_k\equiv1-\frac{2}{3}N_kk^2+\frac{1}{3}N_k^2k^4=1-\frac{1}{3}\frac{c^2\hbar^2k^2}{\mathcal{E}_k^2}\,. \tag{4.26}$$

Inserting (4.25) into the first brackets on the right-hand side of (4.22) and applying the same expression with $\boldsymbol{l}$ and $-\boldsymbol{q}$ to the second brackets, we get

$$\Lambda_{xx}{}^1=(q_y^2+q_z^2)\sum_kK_kI_k\frac{\partial f_k}{\partial\mathcal{E}_k}\sum_lK_lI_l\frac{\partial f_l}{\partial\mathcal{E}_l}=(q_y^2+q_z^2)\Bigl(\sum_kK_kI_k\frac{\partial f_k}{\partial\mathcal{E}_k}\Bigr)^2 \tag{4.27}$$

Note that the second term in the last expression of (4.26) is a small quantity usually negligible compared to 1 for the conduction electrons in a metal. This is clearly seen from the estimate

$$2c^2\hbar^2k^2/\mathcal{E}_k^2\sim(v/c)^2\lesssim10^{-4}\,. \tag{4.28}$$

It is also obvious that this term should be interpreted as the usual relativistic correction.

We now proceed to the discussion of the next four terms, $\Lambda_{xx}{}^2\sim\Lambda_{xx}{}^5$, in (4.21). They all involve two kinds of virtual processes, of which one scatters the electron between positive-energy states and the other between positive- and negative-energy states. The details of calculation will be described only for the second term, $\Lambda_{xx}{}^2$, because from this result those for the other three can be easily derived and shown to equal it.

Note that

$$\Lambda_{xx}{}^2=\sum_j\Bigl\{\sum_{\pm}\sum_k\sum^{+}_{s's''}(\boldsymbol{k}'s'|\sigma_j|\boldsymbol{k}''s'')_{\pm}(\boldsymbol{k}''s''|\alpha_x|\boldsymbol{k}'s')_{\pm}\frac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}}\Bigr\}$$
$$\times\Bigl\{\sum\sum^{+}_{t''}\sum^{-}_{t'}(\boldsymbol{l}''t''|\sigma_j|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')\frac{f_l}{\mathcal{E}_{l'}+\mathcal{E}_{l''}}\Bigr\}\,. \tag{4.29}$$

The first brackets have already been dealt with, so the second alone are to be worked out.

The second brackets can be divided into two parts:

$$\begin{aligned}
&\Sigma_l \Sigma^+_{t''} \Sigma^-_{t'} (\boldsymbol{l}'t''|\sigma_j|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')\,\frac{f_{l''}}{\varepsilon_{l'}+\varepsilon_{l''}} \\
&= \frac{1}{2}\Sigma_\pm \Sigma_l \Sigma^+_{t''} \Sigma^-_{t'} (\boldsymbol{l}'t''|\sigma_j|\boldsymbol{l}'t')_\pm (\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')_\pm \frac{f_{l'}+f_{l''}}{\varepsilon_{l'}+\varepsilon_{l''}} \\
&+ \frac{1}{2}\Sigma_\pm \Sigma_l \Sigma^+_{t''} \Sigma^-_{t'} (\boldsymbol{l}'t''|\sigma_j|\boldsymbol{l}'t')_\pm (\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')_\mp \frac{f_{l''}-f_{l'}}{\varepsilon_{l'}+\varepsilon_{l''}}\,.
\end{aligned} \tag{4.30}$$

As the first brackets in (4.29) have no zeroth order term of q_μ, calculations in the first order of q_μ are sufficient for the second brackets. We are then allowed to use the following approximations:

$$\frac{f_{l'}+f_{l''}}{\varepsilon_{l'}+\varepsilon_{l''}}=\frac{f_l}{\varepsilon_l}; \qquad \frac{f_{l''}-f_{l'}}{\varepsilon_{l'}+\varepsilon_{l''}}=\frac{c^2\hbar^2}{2\varepsilon_l}\frac{\partial f_l}{\partial \varepsilon_l}\boldsymbol{l}\cdot\boldsymbol{q}=\frac{1}{2}K_l{}^2\frac{\partial f_l}{\partial \varepsilon_l}\boldsymbol{l}\cdot\boldsymbol{q}\,, \tag{4.31}$$

in which the neglected terms are those of the second and higher orders of q_μ.

Making use again of the explicit values in Table II of the Appendix for treating the right-hand side of (4.30) we have

$$\Sigma_l \Sigma_{(t'',t')=(1,3),\,(2,4)} (\boldsymbol{l}''t''|\sigma_j|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')\,\frac{f_{l''}}{\varepsilon_{l'}+\varepsilon_{l''}}
=\begin{cases} 0\,, & j=x\,, \\ -\dfrac{1}{2}\,iq_z\Sigma_l K_l{}^3 N_l l_x{}^2 l_z{}^2\dfrac{\partial f_l}{\partial\varepsilon_l}\,, & j=y\,, \\ 0\,, & j=z\,. \end{cases} \tag{4.32}$$

In the derivation of this result, it proves that the contribution from the first term on the right-hand side of (4.30) vanishes on account of the cancellation of those terms due to $(t'', t')=(1, 3)$ and $(2, 4)$ respectively. Similarly we obtain

$$\Sigma_l \Sigma_{(t'',t')=(1,4),\,(2,3)} (\boldsymbol{l}''t''|\sigma_j|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')\,\frac{f_{l''}}{\varepsilon_{l'}+\varepsilon_{l''}}
=\begin{cases} 0\,, & j=x\,, \\ -\dfrac{1}{2}iq_z\Sigma_l K_l{}^3(1-N_l l_x{}^2)l_z{}^2\dfrac{\partial f_l}{\partial\varepsilon_l}\,, & j=y\,, \\ \dfrac{1}{2}\,iq_y\Sigma_l K_l{}^3 l_y{}^2\dfrac{\partial f_l}{\partial\varepsilon_l}\,, & j=z\,. \end{cases} \tag{4.33}$$

Only the second term in (4.30) gives again non-vanishing contributions. Combining (4.32) and (4.33) results in

$$\Sigma_l \Sigma^+_{t''} \Sigma^-_{t'} (\boldsymbol{l}''t''|\sigma_j|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')\,\frac{f_{l'}}{\varepsilon_{l'}+\varepsilon_{l''}}
=\begin{cases} 0\,, & j=x\,, \\ -\dfrac{1}{2}iq_z\Sigma_l K_l{}^3 l_z{}^2\dfrac{\partial f_l}{\partial\varepsilon_l}\,, & j=y\,, \\ \dfrac{1}{2}\,iq_y\Sigma_l K_l{}^3 l_y{}^2\dfrac{\partial f_l}{\partial\varepsilon_l}\,, & j=z\,. \end{cases} \tag{4.34}$$

Substituting (4.25) and (4.34) in (4.29), with $l_z{}^2$ or $l_y{}^2$ in (4.34) replaced by $l^2/3$, gives

$$\Lambda_{xx}{}^2=\frac{1}{6}(q_y{}^2+q_z{}^2)\Sigma_{kl}K_k I_k K_l{}^3 l^2\frac{\partial f_k}{\partial\varepsilon_k}\frac{\partial f_l}{\partial\varepsilon_l}\,. \tag{4.35}$$

It is shown that the same result can be obtained for Λ_{xx}^3, Λ_{xx}^4 and Λ_{xx}^5. To show this for Λ_{xx}^3, note that this term is obtained if one interchanges t' with t'' and $f_{l'}$ with $f_{l''}$ in (4.30) and uses this result for the second factor on the right-hand side of (4.29). On the other hand, it is easily seen with the use of the table in the Appendix that the left-hand sides of (4.32) and (4.33) and, in consequence, that of (4.30) retain their original values for the simultaneous interchanges $t' \rightleftarrows t''$ and $f_{l'} \rightleftarrows f_{l''}$. This means that Λ_{xx}^3 can also be given by the right-hand side of (4.35). The same is true for Λ_{xx}^4 and Λ_{xx}^5, because they are obtained respectively merely by interchanging $\boldsymbol{k}$ and $\boldsymbol{l}$ in the expressions for Λ_{xx}^2 and Λ_{xx}^3.

We now proceed to the evaluation of the last four terms, $\Lambda_{xx}^6 \sim \Lambda_{xx}^9$. The virtual transitions involved are all those between positive- and negative-energy states. Applying (4.34) we readily obtain

$$\begin{aligned}\Lambda_{xx}^6 = \Sigma_j \Big\{ & \Sigma_k \Sigma_{s''}^{+} \Sigma_{s'}^{-} (\boldsymbol{k}'s'|\sigma_j|\boldsymbol{k}''s'')(\boldsymbol{k}''s''|\alpha_x|\boldsymbol{k}'s') \frac{f_{k''}}{\mathcal{E}_{k'}+\mathcal{E}_{k''}} \Big\} \\ \times \Big\{ & \Sigma_l \Sigma_{t''}^{+} \Sigma_{t'}^{-} (\boldsymbol{l}''t''|\sigma_j|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'') \frac{f_{l''}}{\mathcal{E}_{l'}+\mathcal{E}_{l''}} \Big\} \\ = & -\frac{1}{36}(q_y^2+q_z^2)\Sigma_{kl} K_k^3 K_l^3 k^2 l^2 \frac{\partial f_k}{\partial \mathcal{E}_k}\frac{\partial f_l}{\partial \mathcal{E}_l} \,. \end{aligned} \tag{4.36}$$

All the four terms $\Lambda_{xx}^6 \sim \Lambda_{xx}^9$ have the same contribution, as obvious from the argument developed in the discussion of the preceding terms.

Introducing (4.27), (4.35) and (4.36) into (4.21) with consideration of $\Lambda_{xx}^2 = \Lambda_{xx}^3 = \Lambda_{xx}^4 = \Lambda_{xx}^5$ and $\Lambda_{xx}^6 = \Lambda_{xx}^7 = \Lambda_{xx}^8 = \Lambda_{xx}^9$, we have

$$K_{xx}(\boldsymbol{q}) = (q_y^2+q_z^2) K_M(q) \,, \tag{4.37}$$

$$\begin{aligned} K_M(q) = -\frac{\pi c e^4}{V^2}\frac{1}{q^2}\Big\{ & \Big(\Sigma_k K_k I_k \frac{\partial f_k}{\partial \mathcal{E}_k}\Big)^2 \\ & + \frac{1}{3}\Sigma_{kl} K_k K_l (K_k^2 I_l k^2 + K_l^2 I_k l^2) \frac{\partial f_k}{\partial \mathcal{E}_k}\frac{\partial f_l}{\partial \mathcal{E}_l} - \frac{1}{9}\Big(\Sigma_k K_k^3 k^2 \frac{\partial f_k}{\partial \mathcal{E}_k}\Big)^2 \Big\} \,. \end{aligned} \tag{4.38}$$

According to the general discussion of the kernel described in § 2, (iv), we have by inspection, as the final result,

$$K_{\mu\nu}(\boldsymbol{q}) = (q^2 \delta_{\mu\nu} - q_\mu q_\nu) K_M(q) \,, \tag{4.39}$$

with $K_M(q)$ given by (4.33). The result obtained here is exact in the sense that our treatment does not involve any approximation to be allowed only for $(v/c)^2 \ll 1$. The second and third terms in the curly brackets of (4.38) provide respectively at most the first and second order relativistic corrections, in the ordinary sense, to the first term. These correction terms are, of course, of little importance for the conduction electrons in a metal as $(v/c)^2 \ll 1$ for these electrons. It might be argued that these terms could be discarded from the beginning by reason of their little importance in order to dispense with laborious calculations. In this connection, however, we should note that similar terms involving virtual transitions between positive- and negative-energy states are sometimes of the same importance as those involving only transitions among positive-energy states. It was the case, for instance, for a free electron gas discussed in § 3. Another example of such a case is that of the magnetic interaction which will be discussed in § 5. Thus, we have no right without calculation to regard those terms as small corrections.

In the present case, we can neglect in practice all the relativistic correction terms in (4.38). We can thus neglect the second and third terms in the curly brackets and further use the following approximations:

$$I_k = 1 \;; \qquad K_k = \hbar/mc \;; \qquad \mathcal{E}_k = mc^2 + (\hbar^2 k^2/2m) \,,$$

and

$$f_k = (\exp[\beta(\hbar^2 k^2/2m) - \beta\zeta] + 1)^{-1} \,.$$

Assuming temperatures sufficiently low compared with the degeneracy temperature and neglecting small temperature-dependent terms, we get

$$\Sigma_k K_k I_k \frac{\partial f_k}{\partial \varepsilon_k} = -\frac{V}{2\pi c\hbar}\left(\frac{3n}{\pi}\right)^{1/3}, \qquad (4.40)$$

were n is the number of electrons per volume. Introducing (4.40) into (4.38) and neglecting all the correction terms, we have, for the singular part of the kernel,

$$K_M(q) = -K_0/q^2 , \qquad (4.41)$$

$$K_0 = \frac{1}{4\pi}\left(\frac{3}{\pi}\right)^{2/3} \frac{n^{2/3}e^4}{c\hbar^2} . \qquad (4.42)$$

As discussed in § 2, (iv) the kernel given by (4.41) and (4.42) leads to the London equation of the form (2.33). It is of great interest that the expression for K_0 obtained here has quite a different form from that derived according to the London theory, i.e.

$$K_0 = ne^2/mc , \qquad (4.43)$$

while the order of magnitude is the same in both cases.

In order to examine the order of magnitude of the Meissner-Ochsenfeld effect to be expected in the present theory, it is convenient to derive the penetration depth of the field and to compare it with that obtained in the experiment on actual superconductors. As well known, the penetration depth, λ, is related to the constant K_0 by the equation

$$\lambda = (c/4\pi K_0)^{1/2} . \qquad (4.44)$$

From (4.42) and (4.44) the penetration depth according to the present model becomes

$$\lambda = (\pi/3)^{1/3}(c^2\hbar^2/n^{2/3}e^4)^{1/2} . \qquad (4.45)$$

Inserting (4.43) into (4.44) gives the penetration depth in the London theory:

$$\lambda_L = (1/4\pi)^{1/2}(mc^2/ne^2)^{1/2} . \qquad (4.46)$$

In Table I the theoretical values of λ according to (4.45) and (4.46) assuming one electron per atom are listed for several elements and compared with the experimental values extrapolated to the absolute zero of temperature. We should note that the penetration depth given by (4.45) is to be considered as giving the value at the absolute zero of temperature. The temperature variation will be discussed in Part II. It is rather surprising that (4.45) gets so good agreement with experiment, in view of the fact that the interaction (4.41) on which the whole theory is based has never been introduced in a quantitatively unambiguous way.

Table I. Theoretical values of λ assuming one electron per atom and experimental values at $T=0°$K taken from D. Shoenberg: Superconductivity 2. ed. (1952) 188.

	Element	In	Sn	Hg	Pb
$\lambda \times 10^6$ cm	The present theory: Eq. (4.50)	4.1	4.2	3.9	4.3
	The London theory: Eq. (4.51)	2.7	2.8	2.5	2.9
	Experiment: $T=0°$K	6.4	5.2	4.1	3.9

We have shown that the interaction (4.1) produces the M-O effect, but this is not the only one to bring upon this effect. The interaction of the form

$$U_M' = e^2(\boldsymbol{s}_1\cdot\boldsymbol{r})(\boldsymbol{s}_2\cdot\boldsymbol{r})/r^3 \qquad (\boldsymbol{r}=\boldsymbol{x}_2-\boldsymbol{x}_1) \qquad (4.47)$$

can be shown to have the same effect as (4.1). As simple mathematics shows, the perturbative term in the Hamiltonian due to this interaction is

$$H_M{}'=\frac{\pi e^2}{2V}\sum_q\sum_{kl}\sum_{s's''t't''}\frac{1}{q^2}\Big\{(\boldsymbol{k}'s'|\boldsymbol{\sigma}|\boldsymbol{k}''s'')\cdot(\boldsymbol{l}''t''|\boldsymbol{\sigma}|\boldsymbol{l}'t')$$
$$-\frac{2(\boldsymbol{k}'s'|\boldsymbol{\sigma}\cdot\boldsymbol{q}|\boldsymbol{k}''s'')(\boldsymbol{l}''t''|\boldsymbol{\sigma}\cdot\boldsymbol{q}|\boldsymbol{l}'t')}{q^2}\Big\}a_{k'}{}^{(s')*}a_{k''}{}^{(s'')}a_{l''}{}^{(t'')*}a_{l'}{}^{(t')}\,. \tag{4.48}$$

As we are considering the current linear in $H_M{}'$, the currents arising from separate terms in $H_M{}'$ are additive. The first term in { } on the right-hand side of (4.48) is identical to (4.4) and accordingly leads to the same M–O effect as already described. Only the second term in (4.48) is thus to be discussed here. The mean current density to be expected from this part of interaction is given, apart from a numerical factor, by replacing $R_{\mu\nu}{}^{jj}$ in (4.20) with

$$R_{\mu\nu}{}^{ij}(\boldsymbol{k},\boldsymbol{l},\boldsymbol{q},s',s'',t',t'')=(q_iq_j/q^2)(\boldsymbol{k}'s'|\sigma_i|\boldsymbol{k}''s'')(\boldsymbol{l}''t''|\sigma_j|\boldsymbol{l}'t')(\boldsymbol{k}''s''|\alpha_\mu|\boldsymbol{k}'s')(\boldsymbol{l}'t'|\alpha_\nu|\boldsymbol{l}''t'') \tag{4.49}$$

and summing over i. The quantity corresponding to $\Lambda_{\mu\nu}{}^{\xi}$ in (4.21) is designated by the same symbol with a prime. We are again confined to the calculation for the case $\mu=\nu=x$. We have then

$$\Lambda_{xx}{}^{1'}=q^{-2}\sum_{ij}q_iq_j\Big\{\sum_k\sum^+_{s's''}(\boldsymbol{k}'s'|\sigma_i|\boldsymbol{k}''s'')(\boldsymbol{k}''s''|\alpha_x|\boldsymbol{k}'s')\frac{f_{k'}-f_{k''}}{\varepsilon_{k'}-\varepsilon_{k''}}\Big\}$$
$$\times\Big\{\sum_l\sum^+_{t't''}(\boldsymbol{l}''t''|\sigma_j|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')\frac{f_{l'}-f_{l''}}{\varepsilon_{l'}-\varepsilon_{l''}}\Big\}\,, \tag{4.50}$$

$$\Lambda_{xx}{}^{2'}=\Lambda_{xx}{}^{3'}=\Lambda_{xx}{}^{4'}=\Lambda_{xx}{}^{5'}$$
$$=q^{-2}\sum_{ij}q_iq_j\Big\{\sum_k\sum^+_{s's''}(\boldsymbol{k}'s'|\rho_i|\boldsymbol{k}''s'')(\boldsymbol{k}''s''|\alpha_x|\boldsymbol{k}'s')\frac{f_{k'}-f_{k''}}{\varepsilon_{k'}-\varepsilon_{k''}}\Big\}$$
$$\times\Big\{\sum_l\sum^+_{t''}\sum^-_{t'}(\boldsymbol{l}''t''|\sigma_j|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')\frac{f_{l''}}{\varepsilon_{l'}+\varepsilon_{l''}}\Big\}\,, \tag{4.51}$$

$$\Lambda_{xx}{}^{6'}=\Lambda_{xx}{}^{7'}=\Lambda_{xx}{}^{8'}=\Lambda_{xx}{}^{9'}$$
$$=q^{-2}\sum_{ij}q_iq_j\Big\{\sum_k\sum^+_{s''}\sum^-_{s'}(\boldsymbol{k}'s'|\sigma_i|\boldsymbol{k}''s'')(\boldsymbol{k}''s''|\alpha_x|\boldsymbol{k}'s')\frac{f_{k''}}{\varepsilon_{k'}+\varepsilon_{k''}}\Big\}$$
$$\times\Big\{\sum_l\sum^+_{t''}\sum^-_{t'}(\boldsymbol{l}''t''|\sigma_j|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')\frac{f_{l''}}{\varepsilon_{l'}+\varepsilon_{l''}}\Big\}\,. \tag{4.52}$$

Note that

$$q_iq_j\Big\{\sum_k\sum^+_{s's''}(\boldsymbol{k}'s'|\sigma_i|\boldsymbol{k}''s'')(\boldsymbol{k}''s''|\alpha_r|\boldsymbol{k}'s')\frac{f_{k'}-f_{k''}}{\varepsilon_{k'}-\varepsilon_{k''}}\Big\}$$
$$\times\Big\{\sum_l\sum^+_{t't''}(\boldsymbol{l}''t''|\sigma_j|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')\frac{f_{l'}-f_{l''}}{\varepsilon_{l'}-\varepsilon_{l''}}\Big\}$$
$$=\begin{cases}0\,, & i\text{ or }j=x\,,\\ \left(\sum_kK_kI_k\dfrac{\partial f_k}{\partial\varepsilon_k}\right)^2q_y{}^2q_z{}^2\,, & i=j=y\text{ or }z\,,\\ -\left(\sum_kK_kI_k\dfrac{\partial f_k}{\partial\varepsilon_k}\right)^2q_y{}^2q_z{}^2\,, & i,\ j=y\text{ or }z;\ i\neq j\,,\end{cases} \tag{4.53}$$

$$q_iq_j\Big\{\sum_k\sum^+_{s's''}(\boldsymbol{k}'s'|\sigma_i|\boldsymbol{k}''s'')(\boldsymbol{k}''s''|\alpha_x|\boldsymbol{k}'s')\frac{f_{k'}-f_{k''}}{\varepsilon_{k'}-\varepsilon_{k''}}\Big\}$$
$$\times\Big\{\sum_l\sum^+_{t''}\sum^-_{t'}(\boldsymbol{l}''t''|\sigma_j|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')\frac{f_{l''}}{\varepsilon_{l'}+\varepsilon_{l''}}\Big\}$$
$$=\begin{cases}0\,, & i\text{ or }j=x\,,\\ \dfrac{1}{6}\sum_{kl}K_kI_kK_l{}^3l^2\dfrac{\partial f_k}{\partial\varepsilon_k}\dfrac{\partial f_l}{\partial\varepsilon_l}q_y{}^2q_z{}^2\,, & i=j=y\text{ or }z\,,\\ -\dfrac{1}{6}\sum_{kl}K_kI_kK_l{}^3l^2\dfrac{\partial f_k}{\partial\varepsilon_k}\dfrac{\partial f_l}{\partial\varepsilon_l}q_y{}^2q_z{}^2\,, & i,\ j=y\text{ or }z;\ i\neq j\,,\end{cases} \tag{4.54}$$

and

$$q_iq_j\left\{\sum_k\sum^{+}_{s''}\sum^{-}_{s'}(\boldsymbol{k}'s'|\sigma_i|\boldsymbol{k}''s'')(\boldsymbol{k}''s''|\alpha_x|\boldsymbol{k}'s')\frac{f_{k''}}{\varepsilon_{k'}+\varepsilon_{k''}}\right\}$$
$$\times\left\{\sum_l\sum^{+}_{t''}\sum^{-}_{t'}(\boldsymbol{l}''t''|\sigma_j|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')\frac{f_{l''}}{\varepsilon_{l'}+\varepsilon_{l''}}\right\}$$
$$=\begin{cases} 0\,, & i \text{ or } j=x\,,\\ -\frac{1}{36}\sum_{kl}K_k{}^3K_l{}^3k^2l^2\frac{\partial f_k}{\partial\varepsilon_k}\frac{\partial f_l}{\partial\varepsilon_l}q_y{}^2q_z{}^2\,, & i=j=y \text{ or } z\,,\\ \frac{1}{36}\sum_{kl}K_k{}^3K_l{}^3k^2l^2\frac{\partial f_k}{\partial\varepsilon_k}\frac{\partial f_l}{\partial\varepsilon_l}q_y{}^2q_z{}^2\,, & i,j=y \text{ or } z;\ i\neq j\,. \end{cases} \qquad (4.55$$

The derivations of these results are achieved by applying (4.25) and (4.34).

Substitution of (4.53), (4.54) and (4.55) in (4.50), (4.51) and (4.52) respectively reveals tha all the $A_{\tau x}{}^{\xi''}$s vanish. This means that the kernel $K_{xx}(\boldsymbol{q})$ and, in consequence, $K_{\mu\nu}($ vanish for the second part of $H_M{}'$ in (4.48) in the limit $q\to 0$. The current then arises onl from the first part, which is identical to the interaction (4.4). It is thus concluded that th interactions U_M and $U_M{}'$ give exactly the same Meissner-Ochsenfeld effect and that an linear combination of them, i.e. $aU_M+bU_M{}'$, brings on the M–O effect of the correct ord of magnitude provided that $a+b$ is a positive number of order 1.

§ 5. The Known Type of Interaction

According to Breit, the interaction energy between two moving electrons is given, in th order of $(v/c)^2$, by

$$U_B=\frac{e^2}{r}-\frac{e^2}{r}\boldsymbol{\alpha}_1\cdot\boldsymbol{\alpha}_2+\frac{e^2}{2r}\left\{\boldsymbol{\alpha}_1\cdot\boldsymbol{\alpha}_2-\frac{(\boldsymbol{\alpha}_1\cdot\boldsymbol{r})(\boldsymbol{\alpha}_2\cdot\boldsymbol{r})}{r^2}\right\}=U_{BI}+U_{BII}+U_{BIII}\,, \qquad (5.1)$$

where the first and third terms represent the retarded Coulomb interaction and the secon term the magnetic interaction. The Hamiltonian of the system of electrons interacting each other with this type of interaction is given by

$$H=H_0+H_A+H_B\,,$$

where H_A is the preturbation due to the magnetic field and

$$H_B=H_{BI}+H_{BII}+H_{BIII}\,,$$
$$H_{BI}=\frac{2\pi e^2}{V^2}\sum_{kl}\sum_q\sum_{s's''t't''}\frac{(\boldsymbol{k}'s'|\boldsymbol{k}''s'')(\boldsymbol{l}''t''|\boldsymbol{l}'t')}{q^2}a_{k'}{}^{(s')*}a_{k''}{}^{(s'')}a_{l''}{}^{(t'')*}a_{l'}{}^{(t')}\,, \qquad (5.2$$
$$H_{BII}=-\frac{2\pi e^2}{V^2}\sum_{kl}\sum_q\sum_{s's''t't''}\frac{(\boldsymbol{k}'s'|\boldsymbol{\alpha}|\boldsymbol{k}''s'')\cdot(\boldsymbol{l}''t''|\boldsymbol{\alpha}|\boldsymbol{l}'t')}{q^2}a_{k'}{}^{(s')*}a_{k''}{}^{(s'')}a_{l''}{}^{(t'')*}a_{l'}{}^{(t')}\,, \qquad (5.3)$$
$$H_{BIII}=\frac{2\pi e^2}{V^2}\sum_{kl}\sum_q\sum_{s's''t't''}\frac{(\boldsymbol{k}'s'|\boldsymbol{\alpha}\cdot\boldsymbol{q}|\boldsymbol{k}''s'')(\boldsymbol{l}''t''|\boldsymbol{\alpha}\cdot\boldsymbol{q}|\boldsymbol{l}'t')}{q^4}a_{k'}{}^{(s')*}a_{k''}{}^{(s'')}a_{l''}{}^{(t'')*}a_{l'}{}^{(t')}\,. \qquad (5.4$$

The object of this section is to show that none of the three parts of H_B exhibits the M– effect even if the relativistic theory of an electron is applied.

(i) *The Coulomb interaction, H_{BI}*

In order to obtain the mean current density in this case (apart from a trivial numerica factor) we replace $\sum_j R_{\mu\nu}{}^{jj}$ in (4.20) by

$$R_{\mu\nu}(\boldsymbol{k},\boldsymbol{l},\boldsymbol{q},s',s'',t',t'')=(\boldsymbol{k}'s'|\boldsymbol{k}''s'')(\boldsymbol{l}''t''|\boldsymbol{l}'t')(\boldsymbol{k}''s''|\alpha_\mu|\boldsymbol{k}'s')(\boldsymbol{l}'t'|\alpha_\nu|\boldsymbol{l}''t'')\,. \qquad (5.5$$

The equation obtained will be designated as (4.20′). It is again sufficient to evaluate $K_{\mu\nu}(\boldsymbol{q}$ only for the case $\mu=\nu=x$.

Applying the explicit values of the matrix elements in Table II of the Appendix, we can asily verify the following equations:

$$\left.\begin{aligned}&\Sigma_k\Sigma^+_{s'=s''}(\boldsymbol{k}'s'|\boldsymbol{k}''s'')(\boldsymbol{k}''s''|\alpha_x|\boldsymbol{k}'s')\frac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}}=0\ ,\\&\Sigma_k\Sigma^+_{s'\neq s''}(\boldsymbol{k}'s'|\boldsymbol{k}''s'')(\boldsymbol{k}''s''|\alpha_x|\boldsymbol{k}'s')\frac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}}=0\ .\end{aligned}\right\}\tag{5.6}$$

his implies that the first five terms on the right-hand side of (4.20′) vanish. We have urther

$$\begin{aligned}&\Sigma_l\Sigma^+_{t''}\Sigma^-_{t'}(\boldsymbol{l}''t''|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')\frac{f_{l''}}{\mathcal{E}_{l'}+\mathcal{E}_{l''}}\\&=\frac{1}{2}\Sigma_\pm\Sigma_l\Sigma^+_{t''}\Sigma^-_{t'}(\boldsymbol{l}''t''|\boldsymbol{l}'t')_\pm(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')_\pm\frac{f_{l'}+f_{l''}}{\mathcal{E}_{l'}+\mathcal{E}_{l''}}\ .\end{aligned}\tag{5.7}$$

$$\begin{aligned}&\Sigma_l\Sigma^+_{t'}\Sigma^-_{t''}(\boldsymbol{l}''t''|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')\frac{f_{l'}}{\mathcal{E}_{l'}+\mathcal{E}_{l''}}\\&=\frac{1}{2}\Sigma_\pm\Sigma_l\Sigma^+_{t'}\Sigma^-_{t''}(\boldsymbol{l}''t''|\boldsymbol{l}'t')_\pm(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')_\pm\frac{f_{l'}+f_{l''}}{\mathcal{E}_{l'}+\mathcal{E}_{l''}}\ .\end{aligned}\tag{5.8}$$

t is easy to show that the non-vanishing terms in (5.7) are just equal to the non-vanishing erms in (5.8) with opposite sign. This implies that the sixth and eighth terms in (4.20′) ancel the seventh and nineth terms respectively.

It is thus confirmed that the right-hand side of (4.20′) vanishes and that the M–O effect loes not occur for the Coulomb interaction.

ii) *The magnetic interaction, H_{BII}*

Since the exact calculation is very troublesome for this interaction, only the zeroth order erms of q_μ are evaluated exactly in the relativistic sense and the terms of order $q_\mu q_\nu$ are valuated in the approximation neglecting all the relativistic (in the ordinary sense) correcions. As will be seen, the calculation in the present approximation is sufficient to show hat the magnetic interaction cannot be considered to produce superconductivity.

The kernel $K_{\mu\nu}(\boldsymbol{q})$ for this interaction can be obtained (apart from a trivial numerical actor) when $R_{\mu\nu}{}^{jj}$ in (4.20) is replaced by the quantity

$$R_{\mu\nu}{}^{jj}(\boldsymbol{k},\boldsymbol{l},\boldsymbol{q},s',s'',t',t'')=(\boldsymbol{k}'s'|\alpha_j|\boldsymbol{k}''s'')(\boldsymbol{l}''t''|\alpha_j|\boldsymbol{l}'t')(\boldsymbol{k}''s''|\alpha_\mu|\boldsymbol{k}'s')(\boldsymbol{l}'t'|\alpha_\nu|\boldsymbol{l}''t'')\ .\tag{5.9}$$

he equation thus obtained will be quoted as (4.20″) and, corresponding to $\Lambda_{\mu\nu}{}^{\xi}$ in (4.21), e introduce $\Lambda_{\mu\nu}{}^{\xi''}$. The calculations are restricted to the case $\mu=\nu=x$.

We first consider

$$\Lambda_{xx}{}^{1''}=\Sigma_j\Sigma_{kl}\Sigma^+_{s's''}\Sigma^+_{t't''}R_{xx}{}^{jj}\frac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}}\frac{f_{l'}-f_{l''}}{\mathcal{E}_{l'}-\mathcal{E}_{l''}}\ .\tag{5.10}$$

t is insufficient for the present purpose to evaluate the expression

$$\Sigma_k\Sigma^+_{s's''}(\boldsymbol{k}'s'|\alpha_j|\boldsymbol{k}''s'')(\boldsymbol{k}''s''|\alpha_x|\boldsymbol{k}'s')\frac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}}\tag{5.11}$$

nerely in the first order of q_μ as in the preceding section. It is necessary to take further he second order terms of q_μ into account, because (5.11) has non-vanishing zeroth order erms of q_μ and the current consists of the products of two expressions of this type. Using he values of matrix elements in the Appendix we obtain the following results correct in the rder of $q_\mu q_\nu$:

$$\sum_k\sum^{+}_{s's''}(\boldsymbol{k}'s'|\alpha_k|\boldsymbol{k}''s'')(\boldsymbol{k}''s''|\alpha_x|\boldsymbol{k}'s')\frac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}}$$

$$=\begin{cases}\sum_k\Big\{2K^2(\boldsymbol{k},\boldsymbol{q})k_x^2+2L^2(\boldsymbol{k},\boldsymbol{q})(k_y^2+k_z^2)+\dfrac{1}{2}K^2(\boldsymbol{k},\boldsymbol{q})(q_y^2+q_z^2) \\ \qquad\qquad -2K(\boldsymbol{k},\boldsymbol{q})L(\boldsymbol{k},\boldsymbol{q})\boldsymbol{k}\cdot\boldsymbol{q}\Big\}\dfrac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}}\,, & j=x\,, \\ -\sum_k\Big\{\dfrac{1}{2}K^2(\boldsymbol{k},\boldsymbol{q})(q_xq_y+q_xq_z)+2L^2(\boldsymbol{k},\boldsymbol{q})(k_xk_y+k_xk_z) \\ \qquad\qquad -K(\boldsymbol{k},\boldsymbol{q})L(\boldsymbol{k},\boldsymbol{q})(k_zq_x+k_xq_z)\Big\}\dfrac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}}\,, & j=y\,, \\ -\sum_k K(\boldsymbol{k},\boldsymbol{q})L(\boldsymbol{k},\boldsymbol{q})(k_zq_x+k_xq_z)\dfrac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\pi_{k''}}\,, & j=z\,.\end{cases}\qquad (5.$$

We have to consider here $(f_{k'}-f_{k''})/(\mathcal{E}_{k'}-\mathcal{E}_{k''})$ in the second order with respect to q_μ, becau the brackets preceding this quantity contain a zeroth order term in q_μ for $j=x$. Substitu i

$$(f_{k'}-f_{k''})/(\mathcal{E}_{k'}-\mathcal{E}_{k''})=(\partial f_k/\partial\mathcal{E}_k)+\omega(\boldsymbol{k},\boldsymbol{q})\,,\qquad (5.$$

$$\omega(\boldsymbol{k},\boldsymbol{q})=\frac{c^2\hbar^2q^2}{8\mathcal{E}_k}\frac{\partial^2 f_k}{\partial\mathcal{E}_k^2}+\frac{c^4\hbar^4(\boldsymbol{k}\cdot\boldsymbol{q})^2}{24\mathcal{E}_k^2}\frac{\partial^3 f_k}{\partial\mathcal{E}_k^3}\,,\qquad (5.$$

in (5.12) and using the results, we have

$$\sum_{kl}\sum^{+}_{s's''}\sum^{+}_{t't''}R_{xx}{}^{jj}\frac{f_{k'}-f_{k''}}{\mathcal{E}_{k'}-\mathcal{E}_{k''}}\frac{f_{l'}-f_{l''}}{\mathcal{E}_{l'}-\mathcal{E}_{l''}}$$

$$=\begin{cases}4\sum_{kl}K_k^2K_l^2k_x^2l_x^2\dfrac{\partial f_k}{\partial\mathcal{E}_k}\dfrac{\partial f_l}{\partial\mathcal{E}_l}+\sum_{kl}K_k^2K_l^2(k_x^2+l_x^2)(q_y^2+q_z^2)\dfrac{\partial f_k}{\partial\mathcal{E}_k}\dfrac{\partial f_l}{\partial\mathcal{E}_l} \\ \qquad\qquad +4\sum_{kl}K_k^2K_l^2k_x^2l_x^2\Big\{\omega(\boldsymbol{l},\boldsymbol{q})\dfrac{\partial f_k}{\partial\mathcal{E}_k}+\omega(\boldsymbol{k},\boldsymbol{q})\dfrac{\partial f_l}{\partial\mathcal{E}_l}\Big\}\,, & j=x\,, \\ 0\,, & j=y\,, \\ 0\,, & J=z\,.\end{cases}\qquad (5.1$$

We should note that the second and third terms on the right-hand side are of order $q_\mu q_\nu$ a of the same order with respect to $(v/c)^2$, and further that the $q_\mu q_\nu$-terms of still high orders in $(v/c)^2$ are all neglected. Introducing this result into (5.10) and using

$$\sum_k K_k^2k_\mu^2\frac{\partial f_k}{\partial\mathcal{E}_k}=-\sum_k\left(1-\frac{c^2\hbar^2k_\mu^2}{\mathcal{E}_k^2}\right)\frac{f_k}{\mathcal{E}_k}=-\sum_k I_k\frac{f_k}{\mathcal{E}_k}\,,\qquad (5.1$$

give

$$\Lambda_{xx}{}^{1''}=4\sum_{kl}I_kI_l\frac{f_kf_l}{\mathcal{E}_k\mathcal{E}_l}-4\sum_{kl}K_k^2I_l\Big\{\frac{1}{2}(q_y^2+q_z^2)+2k_x^2\omega(\boldsymbol{k},\boldsymbol{q})\Big\}\frac{f_l}{\mathcal{E}_l}\,.\qquad (5.1$$

We proceed now to the next four terms on the right-hand side of (4.20′′). It is an ea matter to show that these four terms are equal to each other. We thus evaluate only t second term. We should note first

$$\sum_l\sum_{(t'',t')=(1,3),\,(2,4)}(\boldsymbol{l}''t''|\alpha_j|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}''t'')\frac{f_{l''}}{\mathcal{E}_{l'}+\mathcal{E}_{l''}}$$

$$=\begin{cases}\sum_l\Big\{N^2(\boldsymbol{l},\boldsymbol{q})l_z^2l_x^2+\dfrac{1}{4}N^2(\boldsymbol{l},\boldsymbol{q})(l_z^2q_y^2+l_y^2q_z^2)\Big\}\dfrac{f_{l'}+f_{l''}}{\mathcal{E}_{l'}+\mathcal{E}_{l''}}\,, & j=x\,, \\ 0\,, & j=y\,, \\ \dfrac{1}{4}\sum_l N_l\Big\{M_l+N_l\Big(l_x^2-\dfrac{1}{2}l^2\Big)\Big\}q_zq_x\dfrac{f_{l'}+f_{l''}}{\mathcal{E}_{l'}+\mathcal{E}_{l''}}\,, & j=z\,,\end{cases}\qquad (5.1$$

$$\Sigma_l \Sigma_{(t'',t')=(1,4),\,(2,3)} (\boldsymbol{l}'t''|\alpha_j|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}'t'') \frac{f_{l''}}{\varepsilon_{l'}+\varepsilon_{l''}}$$

$$= \begin{cases} \Sigma_l\Big[\Big\{M(\boldsymbol{l},\boldsymbol{q})+N(\boldsymbol{l},\boldsymbol{q})\Big(\frac{1}{2}l^2-l_x^2\Big)\Big\}^2+N^2(\boldsymbol{l},\boldsymbol{q})l_x^2l_y^2 & \\ \quad +\frac{1}{4}N_l\Big\{M_l+N_l\Big(\frac{1}{2}l^2-l_x^2\Big)\Big\}\Big(\frac{1}{2}q_x^2-q^2\Big)\Big]\frac{f_{l'}+f_{l''}}{\varepsilon_{l'}+\varepsilon_{l''}}\,, & j=x\,, \\ 0\,, & j=y\,, \\ \frac{1}{4}\Sigma_l N_l\Big\{M_l+N_l\Big(\frac{1}{2}l^2-l_x^2\Big)\Big\}q_zq_x\frac{f_{l'}+f_{l''}}{\varepsilon_{l'}+\varepsilon_{l''}}\,, & j=z\,. \end{cases} \tag{5.19}$$

t is then easily seen that all the $q_\mu q_\nu$-terms on the right-hand side of (5.18) and (5.19), when multiplied by the right-hand side of (5.12) with the same j, provide at most small quantities f order $(v/c)^2$ compared with the largest $q_\mu q_\nu$-term in (5.15). Accordingly in evaluating the second term of (4.20′′) in the same approximation as in the case of the first, we can neglect ll the $\boldsymbol{q}$-dependent terms in (5.18) and (5.19). From these equations we have then, using A.2) and (A.3),

$$\Sigma_l \Sigma^+_{t''} \Sigma^-_{t'} (\boldsymbol{l}'t''|\alpha_j|\boldsymbol{l}'t')(\boldsymbol{l}'t'|\alpha_x|\boldsymbol{l}'t'') \frac{f_{l''}}{\varepsilon_{l'}+\varepsilon_{l''}}$$

$$= \begin{cases} \Sigma_l I_l f_l/\varepsilon_l\,, & j=x\,, \\ 0\,, & j=y\,, \\ 0\,, & j=z\,, \end{cases} \tag{5.20}$$

where I_l is given by (4.26) with $\boldsymbol{k}$ replaced by l. From (5.12) and (5.19) we get

$$\Lambda_{xx}{}^{2''}=\Lambda_{xx}{}^{3''}=\Lambda_{xx}{}^{4''}=\Lambda_{xx}{}^{5''}=\Sigma_j\Sigma_{\boldsymbol{kl}}\Sigma^+_{s's''t''}\Sigma^-_{t'}R_{xx}{}^{jj}\frac{f_{k'}-f_{k''}}{\varepsilon_{k'}-\varepsilon_{k''}}\frac{f_{l''}}{\varepsilon_{l'}+\varepsilon_{l''}}$$

$$=2\Sigma_{\boldsymbol{kl}}K_k{}^2I_l\Big\{k_x{}^2+\frac{1}{4}(q_y{}^2+q_z{}^2)\Big\}\Big\{\frac{\partial f_k}{\partial\varepsilon_k}+\omega(\boldsymbol{k},\boldsymbol{q})\Big\}\frac{f_l}{\varepsilon_l}$$

$$=-2\Sigma_{\boldsymbol{kl}}I_kI_l\frac{f_kf_l}{\varepsilon_k\varepsilon_l}+\Sigma_{\boldsymbol{kl}}K_k{}^2I_l\Big\{\frac{1}{2}(q_y{}^2+q_z{}^2)\frac{\partial f_k}{\partial\varepsilon_k}+2k_x{}^2\omega(\boldsymbol{k},\boldsymbol{q})\Big\}\frac{f_l}{\varepsilon_l}\,. \tag{5.21}$$

Now we consider the last four terms in 4.20′′). It is also easy to see that these four terms are equal to each other. The $\boldsymbol{q}$-dependent terms in (5.18) and (5.19) can be neglected also in this case on account of the same reason as mentioned in the discussion preceding eq. (5.20). Then applying (5.20) twice gives

$$\Lambda_{xx}{}^{6''}=\Lambda_{xx}{}^{7''}=\Lambda_{xx}{}^{8''}=\Lambda_{xx}{}^{9''}$$

$$=\Sigma_j\Sigma_{\boldsymbol{kl}}\Sigma^+_{s''t''}\Sigma^-_{s't'}R_{xx}{}^{jj}\frac{f_{k''}}{\varepsilon_{k'}+\varepsilon_{k''}}\frac{f_{l''}}{\varepsilon_{l'}+\varepsilon_{l''}}$$

$$=\Sigma_{\boldsymbol{kl}}I_kI_lf_kf_l/\varepsilon_k\varepsilon_l\,. \tag{5.22}$$

From (5.17), (5.21) and (5.22) it follows

$$\Sigma_\xi\Lambda_{xx}{}^{\xi''}=0\,.$$

This result means that $K_{\mu\nu}(\boldsymbol{q})$ vanishes exactly with respect to the zeroth order term in q_μ and approximately with respect to the second order term. The approximation we have used leaves the possibility of the M–O effect with

$$K_{\mu\nu}(\boldsymbol{q})=-(\delta_{\mu\nu}-q_\mu q_\nu/q^2)K_0''\,,$$

$$K_0''\sim\Big(\frac{v}{c}\Big)^2\frac{4\pi ce^4}{V^2}\Sigma_{\boldsymbol{kl}}K_k{}^2K_l{}^2k_x{}^2\frac{\partial f_k}{\partial\varepsilon_k}\frac{\partial f_l}{\partial\varepsilon_l}$$

$$\sim\Big(\frac{v}{c}\Big)^4K_0\,, \tag{5.23}$$

where K_0 is the constant given by (4.42). (Compare the expression in the middle of the second line in (5.23) with the main contribution in (4.38).) Since the order of magnitude of this K_0 gave a very nice correspondence to that required from experiment, we can say that the magnetic interaction never leads to the M–O effect larger than 10^{-8} times that observed in superconductors and, in consequence, that it is never be responsible for superconductivity, at least, of real metals.

(iii) *The interaction term arising from the retardation effect in the Coulomb force,* H_{BIII}

In order to obtain $K_{\mu\nu}(\boldsymbol{q})$ belonging to this interaction, the $R_{\mu\nu}{}^{ij}$ in (4.20) should be replaced by

$$\sum_i R_{\mu\nu}{}^{ij}(\boldsymbol{k}, \boldsymbol{l}, \boldsymbol{q}, s', s'', t', t'') = \sum_i (q_iq_j/q^2)(\boldsymbol{k}'t'|\alpha_i|\boldsymbol{k}''s'')(\boldsymbol{l}''t''|\alpha_j|\boldsymbol{l}'t') \times(\boldsymbol{k}''s''|\alpha_\mu|\boldsymbol{k}'s')(\boldsymbol{l}'t'|\alpha_\nu|\boldsymbol{l}''t'') : \tag{5.24}$$

We need to carry out the actual calculation only for the case $\mu=\nu=x$. The sum of the contributions from $R_{xx}{}^{ij}$ with $i=j$ should give the same kernel as obtained for the magnetic interaction described in (ii) of this section, apart from a factor $q_x{}^2/q^2$, and, in consequence, it vanishes to the same degree of approximation as adopted there. We have now to investigate the contributions from $R_{\mu\nu}{}^{ij}$ with $i\neq j$ in the same approximation. For this purpose, the $\boldsymbol{q}$-dependent terms in (5.18) and (5.19) can be again neglected and the approximate result (5.20) can be applied. From (5.12) and (5.20) it is obvious that the non-vanishing contribution for $i\neq j$ might only arise in the two cases: $i=y$, $j=x$ and $i=x$, $j=y$. The contribution from these cases to the quantity corresponding to $\Lambda_{xx}{}^1$ is obtained from (5.12) as

$$-2(q_xq_y/q^2)\left\{\sum_k \frac{1}{2} K_k{}^2(q_xq_y+q_xq_z)\frac{\partial f_k}{\partial \varepsilon_k}\right\} \times\left\{\sum_l 2K_l{}^2 l_x{}^2 \frac{\partial f_l}{\partial \varepsilon_l}\right\} . \tag{5.25}$$

The contribution to the quantity corresponding to the sum $\sum_{\xi=2}^{5}\Lambda_{xx}{}^{\xi}$ is obtained from (5.12) and (5.20):

$$-4(q_xq_y/q^2)\left\{\sum_k \frac{1}{2} K_k{}^2(q_xq_y+q_xq_z)\frac{\partial f_k}{\partial \varepsilon_k}\right\} \times\left\{\sum_l l_l \frac{f_l}{\varepsilon_l}\right\} . \tag{5.26}$$

Since the quantity corresponding to $\sum_{\xi=6}^{9}\Lambda_{xx}{}^{\xi}$ has no contribution, the total contribution from the cases $i\neq j$ is the sum of those given by (5.25) and (5.26). Application of (5.16) shows that these two contributions cancel each other. Consequently, the whole contribution of H_{BIII} to the M–O effect vanishes to the same degree of approximation as in the preceding case, (ii). It is thus concluded that the retardation effect in the Coulomb interaction cannot also produce the M–O effect, a least, large enough to account for superconductivity.

Summarizing the results of this section, w conclude that the well-known type of electron electron interaction leads to no Meissner Ochsenfeld effect as long as the first orde effect is considered.

§ 6. Discussion

We have introduced in § 4 a special type o electron-electron interaction which brings upo the Meissner-Ochsenfeld effect in quantitativ agreement with experiment. It is, however of an unfamiliar type, and there seems to b two possible interpretations of it: one (i) t assume that the interaction originates from an inherent property of the electron, and the other (ii) to assume that it arises as a resul of modification, in a metal, of the known type of interaction, say (5.1). We do not want t discuss in this paper the physical foundation of this interaction and to decide which is the better of the above alternatives. However it seems worthwhile to discuss some other experimental facts besides the M–O effect in connection with the proposed interaction.

Pippard[10] introduced a concept of coherence length in order to account for his findings that the penetration depth of the field depends on the amount of impurity and begings to increase when the mean free path of an electron becomes as small as the penetration depth. Schafroth and Blatt[11] showed that in order to get agreement with this experiment, the kernel for the London equation should be modified as

$$K(q)=-K_0/q(q+\mu) \tag{6.1}$$

with μ of the same order of magnitude as the reciprocal mean free path. μ^{-1} was called the correlation length. The kernel (6.1) with $\mu=0$ corresponds of course to the London equation.

It is interesting to note that, if we assume a finite effective range of interaction and modify (4.1) in the form

$$U_M=e^2\boldsymbol{s}_1\cdot\boldsymbol{s}_2\exp\left[-r/d\right]/r\,, \quad (d>0) \tag{6.2}$$

we can well explain the experiment of Pippard. Indeed, the perturbative part of the Hamiltonian due to (6.2) becomes

$$H_M=\frac{\pi e^2}{2V}\sum_{kl}\sum_q\sum_{s's''l't''}$$

$$\times\frac{(\boldsymbol{k}'s'|\boldsymbol{\sigma}|\boldsymbol{k}''s'')\cdot(\boldsymbol{l}''t''|\boldsymbol{\sigma}|\boldsymbol{l}'t')}{q^2+\mu^2}$$

$$\times a_{\boldsymbol{k}'}{}^{(s')*}a_{\boldsymbol{k}''}{}^{(s'')}a_{\boldsymbol{l}''}{}^{(t'')*}a_{\boldsymbol{l}}{}^{(t')} \qquad (6.3)$$

with

$$\mu=d^{-1}\,. \qquad (6.4)$$

The corresponding kernel is given by

$$K(q)=-K_0/(q^2+\mu^2) \qquad (6.5)$$

with K_0 given by (4.42). It is clear that both kernels, (6.1) and (6.5), provide practically the same result as concerns the Meissner-Ochsenfeld effect in the case $\mu\lesssim\lambda_\infty^{-1}$ (λ_∞: penetration depth for $\mu^{-1}\to\infty$), because then the Fourier components of current, roughly speaking, contribute or do not contribute to this effect in both kernels according as the wave number q is larger or smaller than μ. As Pippard's experiment belongs to this case, his experimental results are well explained if we assume an effective range of interaction force, d, of the order of the mean free path. According to this consideration, we are led to conclude that the mean free path of an electron in the metal determines the effective range of the interaction causing superconductivity. This conclusion seems to be in favour of the second of the alternative interpretations of the interaction force mentioned at the beginning of this section, though not decisively. Comparing the two forms of kernel, (6.1) and (6.5), we should remark that, as mentioned above, the latter allows a simpler physical interpretation than the former. Since these kernels differ in detailed penetration law of the field, especially for a small mean free path, it is hoped to decide, by suitable experimental arrangements, which is the better form of the two.*

There is another interesting result to be expected from the assumption of (4.1) or (6.2) and to be correlated to experiment. Before discussing this, it is advantageous to give a brief account of the problem of the superconducting transition. (A detailed account of this topic will be given in Part II.) It can be shown that the M-O effect due to electron-electron interaction is suppressed by the disturbing effect of the electron-phonon interaction as the temperature increases. The superconducting-normal transition is considered to occur when the temperature becomes so high that the electron-phonon interaction makes the electron-electron interaction causing superconductivity completely ineffective. According to this consideration the interaction of the form (4.1) or (6.2) is supposed to be effective only in the superconducting state and ineffective in the normal. Since the above-mentioned interaction tempts the Pauli paramagnetism to decrease, we expect the smaller Pauli susceptibility in the superconducting than in the normal state. In order to check this prediction, it is most advantageous to use the data on the conduction-electron spin resonance, if available. Unfortunately, this type of resonance has not yet been found experimentally for any superconducting element. Recent observation of the Knight shift in mercury due to Reif$^{12)}$, however, provides some information of this subject. According to Townes *et al*$^{13)}$. the Knight shift in a simple metal should be proportional to the product of the Pauli spin susceptibility, χ_p, and the average probability density at the nucleus of conduction electrons on the Fermi surface, $\langle|\psi_F(0)|^2\rangle_{AV}$. In the experiment of Reif, a decrease of the shift was observed from 2.4% in the normal state to 1.5% in the superconducting state at 1.45°K. It is felt that one can hardly expect such a large change in $\langle|\psi_F(0)|^2\rangle_{AV}$ between the normal and superconducting states that accounts for the observed decrease in the Knight shift. On the other hand, if one assumes an electron-electron interaction of the form (4.1) or (6.2), it is not unlikely to expect such a large decrease of χ_p. In this connection it is interesting to quote the note of Dresdon$^{14)}$, which states that, if the electronic wave function differs considerably between the normol and superconducting states, the lifetime of positrons should be different between these states. Recent experiments$^{15),16)}$ revealed that, within the limits of experimental error, no such difference is observed. Independent determination by means of experiment either of χ_p or of $\langle|\psi_F(0)|^2\rangle_{AV}$ in superconductors is highly desirable.

---

* Note added on March 8, 1957. Quite recently this problem has fully been discussed by Schafroth and Blatt (Nuovo Cimento **4** (1956) 786). For the details of the penetration laws expected from both kernels readers are referred to this work.

Finally we should note that we have not discussed the convergence problem of our perturbation treatment which is of course open to discussion.

Appendix

In Table II, the explicit values of matrix elements $(\boldsymbol{k}'s'|\boldsymbol{k}''s'')$, $(\boldsymbol{k}'s'|\sigma_\mu|\boldsymbol{k}''s'')$ and $(\boldsymbol{k}'s'|\alpha_\mu|\boldsymbol{k}''s'')$ are listed for $\boldsymbol{k}'=\boldsymbol{k}-\frac{1}{2}\boldsymbol{q}$ and $\boldsymbol{k}''=\boldsymbol{k}+\frac{1}{2}\boldsymbol{q}$. For convenience, they are decomposed into two parts, one being an even function of $\boldsymbol{k}$ and the other its odd function. The former is quoted by a (+) symbol and the latter by a (−) symbol. The matrix elements connecting two negative-energy states are omitted, for they do not appear in the text.

The following abbreviations are used:

$$\left.\begin{aligned}
K(\boldsymbol{k},\boldsymbol{q})&=\frac{c\hbar}{2\mathcal{E}_{k'}^{1/2}\mathcal{E}_{k''}^{1/2}}\left\{\frac{(mc^2+\mathcal{E}_{k''})^{1/2}}{(mc^2+\mathcal{E}_{k'})^{1/2}}+\frac{(mc^2+\mathcal{E}_{k'})^{1/2}}{(mc^2+\mathcal{E}_{k''})^{1/2}}\right\},\\
L(\boldsymbol{k},\boldsymbol{q})&=\frac{c\hbar}{2\mathcal{E}_{k'}^{1/2}\mathcal{E}_{k''}^{1/2}}\left\{\frac{(mc^2+\mathcal{E}_{k''})^{1/2}}{(mc^2+\mathcal{E}_{k'})^{1/2}}-\frac{(mc^2+\mathcal{E}_{k'})^{1/2}}{(mc^2+\mathcal{E}_{k''})^{1/2}}\right\},\\
M(\boldsymbol{k},\boldsymbol{q})&=\frac{(mc^2+\mathcal{E}_{k'})^{1/2}(mc^2+\mathcal{E}_{k''})^{1/2}}{2\mathcal{E}_{k'}^{1/2}\mathcal{E}_{k''}^{1/2}},\\
N(\boldsymbol{k},\boldsymbol{q})&=\frac{c^2\hbar^2}{\mathcal{E}_{k'}^{1/2}\mathcal{E}_{k''}^{1/2}(mc^2+\mathcal{E}_{k'})^{1/2}(mc^2+\mathcal{E}_{k''})^{1/2}}.
\end{aligned}\right\}\quad\text{(A.1)}$$

It should be noted that $K(\boldsymbol{k},\boldsymbol{q})$, $M(\boldsymbol{k},\boldsymbol{q})$ and $N(\boldsymbol{k},\boldsymbol{q})$ are even functions of $\boldsymbol{k}$ and $\boldsymbol{q}$ while $L(\boldsymbol{k},\boldsymbol{q})$ is an odd function of each.

All the matrix elements in the table are correct for small $\boldsymbol{q}$ to the second order of q_μ when the following approximations are used:

$$\left.\begin{aligned}
K(\boldsymbol{k},\boldsymbol{q})&=K_k+\varDelta_K; && K_k=c\hbar/\mathcal{E}_k\,, \quad \varDelta_K=-K_k(\hbar^2q^2/8m^2c^2)\,,\\
L(\boldsymbol{k},\boldsymbol{q})&=L_k\boldsymbol{k}\cdot\boldsymbol{q}; && L_k=c^3\hbar^3/2\mathcal{E}_k^2(mc^2+\mathcal{E}_k)\,,\\
M(\boldsymbol{k},\boldsymbol{q})&=M_k+\varDelta_M; && M_k=(mc^2+\mathcal{E}_k)/2\mathcal{E}_k\,, \varDelta_M=-M_k(\hbar^2q^2/16m^2c^2)\,,\\
N(\boldsymbol{k},\boldsymbol{q})&=N_k+\varDelta_N; && N_k=c^2\hbar^2/\mathcal{E}_k(mc^2+\mathcal{E}_k)\,, \quad \varDelta_N=-N_k(3\hbar^2q^2/3m^2c^2)\,.
\end{aligned}\right\}\quad\text{(A.2)}$$

In the text, use is frequently made of the relations

$$L_k=\frac{1}{2}K_kN_k;\qquad M_k=1-\frac{1}{2}N_kk^2\,. \tag{A.3}$$

Note that K_k, L_k, M_k and N_k are all even functions of $\boldsymbol{k}$ and independent of $\boldsymbol{q}$. The correction terms Δ_K, Δ_M and Δ_N in (A.2) can be omitted when we want to calculate the matrix elements to the first order of q_μ.

When double signs (± or ∓) are used, the upper (or lower) sign always belongs to the upper (or lower) pair of s', s'' in the left column of the table.

Diffuse Scattering of X-rays by a Point-Imperfection in Diamond Lattice

By Sigeo YOMOSA and Takeo NAGAMIYA

Department of Physics, Osaka University

(Received February 12, 1957)

The temperature independent diffuse scattering of X-ray by a diamond lattice, in which a few carbon atoms are missing or have been replaced by foreign atoms of valency four is investigated. By the method given by Matsubara the intensity of diffuse scattering is calculated in terms of the force constants which are related to changes in bond length and of bond angle. The diffuse patterns observed by Lonsdale and Smith in natural diamonds are of streak or spike type but ours are of lemniscate type. Our patterns may be observed in radiation damaged diamond crystals.

§ 1. Introduction

The object of this paper is to investigate theoretically the diffuse scattering of X-rays by a diamond lattice in which a few carbon atoms are missing or have been replaced by foreign atoms of valency four (Si, for example). Natural diamonds may or may not contain defects of such a kind, but a recent radiation damage experiment1) and its interpretation2) show an evidence of the creation of vacancies (as well as other kinks of defects) in the lattice. The original aim of the present paper was to explain the well-known temperature-independent diffuse scattering of X-rays observed by Lonsdale and Smith3) and recently by Hoerni and Wooster4) in natural diamonds of type I. This type is distinguished from type II by the existence of this diffuse scattering, as well as of certain infrared and ultra-violet absorption, and the absence of mosaic structure. The results of our calculation were, however, unfavourable, and this deterred the present authors from publishing the calculation, though the work was announced in 1952 in a paper by Matsubara5). Recently Frank6) successfully explained the diffuse scattering in diamonds of type I assuming segregated Si atoms on (100) planes. Formerly Olmer7) was also able to explain it assuming a suitable Fourier decomposition of the distortion which might exist in diamonds of type I. We have, however, some hope in testing our theory with the use of radiation damaged crystals, though we have so far no such data*.

We confine ourselves to point type defect and assume that the atomic displacements around the foreign atom or the vacancy have cubic symmetry. The method used in the present paper is based on that expounded by Matsubara[6] He sets up the equation of equilibrium determining the atomic displacements around the defect and, by constructing their Fourier transforms, finds a set of equations to be satisfied by the scattering amplitudes. This method enables one to find the intensity of diffuse scattering in terms of the force constants between the forign and normal atoms and those among normal atoms.

§ 2. Deformation around a Foreign Atom or Vacancy

When a carbon atom in a diamond crystal is replaced by a foreign atom of valency four, the nearest neighbouring four carbon atoms will be acted upon by radial forces and will be radially displaced. We shall denote these forces by $\gamma \boldsymbol{r}_1$, $\gamma \boldsymbol{r}_2$, $\gamma \boldsymbol{r}_3$ and $\gamma \boldsymbol{r}_4$, where $\boldsymbol{r}_i$'s are the vectors joining each atom to its neighbours in the normal lattice and γ a constant. We assume that the elastic force constant related with changes in bond angles, including the angle in (foreign atom)-(carbon)-(carbon) bonds, to be the same as that in the normal lattice. These simplifications will not seriously affect the result for the diffuse scattering, since the latter may arise mainly from a certain spread region of deformation around the foreign atom. In the case of a vacancy, the four unpaired electrons left in it will probably form the state of the highest multiplicity[2] and the same situation will be realized with a different value of γ.

We shall denote by d the atomic distance in the normal lattice and by a the lattice constant $(a=4d/\sqrt{3})$. Dividing the normal lattice into two interpenetrating face-centred cubic lattice, A and B, of lattice constant a, the lattice points are given by

$$A: \quad \boldsymbol{R}_l=l_1\boldsymbol{a}_1+l_2\boldsymbol{a}_2+l_3\boldsymbol{a}_3 \qquad (l_1+l_2+l_3=\text{even})$$

$$B: \quad \boldsymbol{R}_m'=m_1\boldsymbol{a}_1+m_2\boldsymbol{a}_2+m_3\boldsymbol{a}_3+\boldsymbol{r}_1 \qquad (m_1+m_2+m_3=\text{even})$$

where

$$\boldsymbol{a}_1=(a/2, 0, 0), \quad \boldsymbol{a}_2=(0, a/2, 0), \quad \boldsymbol{a}_3=(0, 0, a/2),$$

and $r_1=(a/4, a/4, a/4)$.

Let the displacement of the atom at $\boldsymbol{R}_l$ be denoted by $\boldsymbol{u}_l$ and that at $\boldsymbol{R}_m'$ by $\boldsymbol{u}_m'$. The change of length of the bond between, say, $\boldsymbol{R}_l'$ and $\boldsymbol{R}_l$ is $\boldsymbol{r}_1\cdot(\boldsymbol{u}_l'-\boldsymbol{u}_l)/d$, and the corresponding increase in potential energy will be written as

$$\frac{1}{2}k_1[\boldsymbol{r}_1\cdot(\boldsymbol{u}_l'-\boldsymbol{u}_l)/d]^2 . \tag{1}$$

The change of the bond angle between, say, $\boldsymbol{R}_l'-\boldsymbol{R}_l$ and $\boldsymbol{R}_m'-\boldsymbol{R}_l$ with $\boldsymbol{R}_m'=\boldsymbol{R}_l+\boldsymbol{r}_2$ is

$$\begin{aligned}\varDelta\vartheta=-\frac{1}{d^2\sin\vartheta_0}&[(\boldsymbol{r}_2-\boldsymbol{r}_1\cos\vartheta_0)\cdot(\boldsymbol{u}_l'-\boldsymbol{u}_l)\\ &+(\boldsymbol{r}_1-\boldsymbol{r}_2\cos\vartheta_0)\cdot(\boldsymbol{u}_m'-\boldsymbol{u}_l)] ,\end{aligned} \tag{2}$$

where $\cos\vartheta_0=-1/3$ and $\sin\vartheta_0=2\sqrt{2}/3$. The corresponding increase in potential energy will be written as

$$\frac{1}{2}k_2(d\varDelta\vartheta)^2 . \tag{3}$$

The total potential energy will be assumed to be the sum of the potential energies of type (1) and type (3). For a moment we drop those terms which represent the interactions between next-nearest neighbours, but later (in § 4) we shall take them into account. Then the potential energy can be written[8]

$$\begin{aligned}W=&\frac{1}{2}\sum_l\boldsymbol{u}_l\cdot\varPhi_0\cdot\boldsymbol{u}_l+\frac{1}{2}\sum_m\boldsymbol{u}_m'\cdot\varPhi_0\cdot\boldsymbol{u}_m'\\ &+\frac{1}{2}\sum_l\sum_{i=1}^{4}\boldsymbol{u}_l\cdot\varPhi_i\cdot\boldsymbol{u}_{li}'+\frac{1}{2}\sum_m\sum_{i=1}^{4}\boldsymbol{u}'\cdot\varPhi_i\cdot\boldsymbol{u}_{mi} ,\end{aligned} \tag{4}$$

where $\varPhi_0$, $\varPhi_1$, $\varPhi_2$, $\varPhi_3$, $\varPhi_4$ are symmetric diadics defined by

$$\begin{aligned}\varPhi_0=&\frac{k_1}{d^2}\sum_{i=1}^{4}\boldsymbol{r}_i\boldsymbol{r}_i+\frac{k_2}{d^2}\frac{(1-\cos\theta_0)^2}{\sin^2\theta_0}\sum_{i=1}^{i}\sum_{k(\neq i)}\\ &\times(\boldsymbol{r}_i+\boldsymbol{r}_k)(\boldsymbol{r}_i+\boldsymbol{r}_k) ,\end{aligned} \tag{5}$$

$$\begin{aligned}\varPhi_i=&-\frac{k_1}{d^2}\boldsymbol{r}_i\boldsymbol{r}_i-\frac{k_2}{d^2}\frac{2(1-\cos\theta_0)}{\sin^2\theta_0}\sum_{k(\neq i)}\\ &\times(\boldsymbol{r}_k+\boldsymbol{r}_i)(\boldsymbol{r}_k-\boldsymbol{r}_i\cos\theta_0) ,\\ &(i=1, 2, 3, 4;\ k=1, 2, 3, 4)\end{aligned} \tag{6}$$

$$\varPhi_0+\sum_{i=1}^{4}\varPhi_i=0 . \tag{7}$$

In (4), $\boldsymbol{u}_{li}'$ is the displacement of the atom at $\boldsymbol{R}_m'=\boldsymbol{R}_l+\boldsymbol{r}_i$, and $\boldsymbol{u}_{mi}$ that of the atom at $\boldsymbol{R}_l=\boldsymbol{R}_m'-\boldsymbol{r}_i$. If the atoms at $\boldsymbol{R}_l$ and $\boldsymbol{R}_m'$ are acted upon by external forces $\boldsymbol{F}_l$ and $\boldsymbol{F}_m'$, respectively, the equilibrium conditions are

---

* H. Kanzaki recently made calculations similar to ours (private communication).

$$\left.\begin{aligned}\boldsymbol{\Phi}_0\cdot\boldsymbol{u}_l+\sum_i\boldsymbol{\Phi}\cdot\boldsymbol{u}_{li}{}'&=\boldsymbol{F}_l\ ,\\ \boldsymbol{\Phi}_0\cdot\boldsymbol{u}_m{}'+\sum_i\boldsymbol{\Phi}_i\cdot\boldsymbol{u}_{mi}&=\boldsymbol{F}_m{}'.\end{aligned}\right\}\qquad(8)$$

We now suppose that a foreign atom or a vacancy is at the origin. Then, external forces act only upon those atoms which directly surround the origin, i. e.,

$$\begin{aligned}&\boldsymbol{F}_{000}{}'=\gamma\boldsymbol{r}_1\ , &&\boldsymbol{F}_{-1-10}{}'=\gamma\boldsymbol{r}_2\ ,\\ &\boldsymbol{F}_{-10-1}{}'=\gamma\boldsymbol{r}_3\ , &&\boldsymbol{F}_{0-1-1}{}'=\gamma\boldsymbol{r}_4\ ,\\ &\text{other}\quad \boldsymbol{F}_m{}'=0\ , &&\text{all}\quad \boldsymbol{F}_l=0\ .\end{aligned}\qquad(9)$$

(8) and (9) determine the deformation around the defect.

We define the Fourier transforms of the displacements by

$$\left.\begin{aligned}\boldsymbol{S}(\boldsymbol{b})&=\sum_l\boldsymbol{u}_l\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{R}_l\right]\ ,\\ \boldsymbol{S}'(\boldsymbol{b})&=\sum_m\boldsymbol{u}_m{}'\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{R}_m{}'\right]\ ,\end{aligned}\right\}\qquad(10)$$

where $\boldsymbol{b}$ is an arbitrary vector. From (8) we find

$$\begin{aligned}&\boldsymbol{\Phi}_0\cdot\boldsymbol{S}(\boldsymbol{b})+\Big(\sum_i\boldsymbol{\Phi}_i\exp\left[-2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_i\right]\Big)\cdot\boldsymbol{S}'(\boldsymbol{b})\\ &\qquad=\sum_l\boldsymbol{F}_l\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{R}_l\right]\ ,\\ &\boldsymbol{\Phi}_0\cdot\boldsymbol{S}'(\boldsymbol{b})+\Big(\sum_i\boldsymbol{\Phi}_i\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_i\right]\Big)\cdot\boldsymbol{S}(\boldsymbol{b})\\ &\qquad=\sum_m\boldsymbol{F}_m{}'\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{R}_m{}'\right]\ .\end{aligned}\qquad(11)$$

The right hand side of the first equation is zero and that of the second equation is

$$\gamma\sum_i\boldsymbol{r}_i\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_i\right]\ .\qquad(12)$$

To solve (11), we write, after Begbie[9], Born[8] and Smith[10], the matrices of $\boldsymbol{\Phi}_0$ and $\boldsymbol{\Phi}_i(i=1, 2, 3, 4)$ explicitly as follows:

$$\boldsymbol{\Phi}_0=4\alpha\begin{pmatrix}1&0&0\\0&1&0\\0&0&1\end{pmatrix},\qquad \boldsymbol{\Phi}_1=-\begin{pmatrix}\alpha&\beta&\beta\\\beta&\alpha&\beta\\\beta&\beta&\alpha\end{pmatrix},$$

$$\boldsymbol{\Phi}_3=-\begin{pmatrix}\alpha&\beta&-\beta\\\beta&\alpha&-\beta\\-\beta&-\beta&\alpha\end{pmatrix},\qquad \boldsymbol{\Phi}_3=-\begin{pmatrix}\alpha&-\beta&\beta\\-\beta&\alpha&-\beta\\\beta&-\beta&\alpha\end{pmatrix},$$

$$\boldsymbol{\Phi}_4=-\begin{pmatrix}\alpha&-\beta&-\beta\\-\beta&\alpha&\beta\\-\beta&\beta&\alpha\end{pmatrix},\qquad(13)$$

where

$$\alpha=\frac{1}{3}(k_1+8\,k_2)\ ,\quad \beta=\frac{1}{3}(k_1-4k_2)\ .\qquad(14)$$

(13) and (14) can be derived easily by observing that

$$\begin{aligned}&\boldsymbol{r}_1=\frac{1}{4}(a, a, a), &&\boldsymbol{r}_2=\frac{1}{4}(\bar{a}, \bar{a}, a)\ ,\\ &\boldsymbol{r}_3=\frac{1}{4}(\bar{a}, a, \bar{a},\ ), &&\boldsymbol{r}_4=\frac{1}{4}(a, \bar{a}, \bar{a});\\ &\boldsymbol{r}_1+\boldsymbol{r}_2+\boldsymbol{r}_3+\boldsymbol{r}_4=0\ ,\end{aligned}$$

and that therefore $\boldsymbol{\Phi}$'s are simplified to

$$\begin{aligned}\boldsymbol{\Phi}_0&=\frac{k_1+8k_2}{d^2}\sum_{i=1}^{4}\boldsymbol{r}_i\boldsymbol{r}_i\ ,\\ \boldsymbol{\Phi}_i&=-\frac{(k_1-4k_2)}{d^2}\boldsymbol{r}_i\boldsymbol{r}_i-\frac{3k^2}{d^2}\sum_{k=1}^{4}\boldsymbol{r}_k\boldsymbol{r}_k\ .\end{aligned}$$

Then (11), with (12), can be written

$$\begin{pmatrix}S_x\\S_y\\S_z\end{pmatrix}-\begin{pmatrix}\vartheta_0{}^*&\vartheta_3{}^*&\vartheta_2{}^*\\\vartheta_3{}^*&\vartheta_0{}^*&\vartheta_1{}^*\\\vartheta_2{}^*&\vartheta_1{}^*&\vartheta_0{}^*\end{pmatrix}\begin{pmatrix}S_x{}'\\S_y{}'\\S_z{}'\end{pmatrix}=0\ ,$$

$$\begin{pmatrix}S_x{}'\\S_y{}'\\S_z{}'\end{pmatrix}-\begin{pmatrix}\vartheta_0&\vartheta_3&\vartheta_2\\\vartheta_3&\vartheta_0&\vartheta_1\\\vartheta_2&\vartheta_1&\vartheta_0\end{pmatrix}\begin{pmatrix}S_x\\S_y\\S_z\end{pmatrix}+\gamma'\begin{pmatrix}\vartheta_1\\\vartheta_2\\\vartheta_3\end{pmatrix}=0\ ,\qquad(15)$$

where

$$\begin{aligned}\vartheta_0&=\frac{1}{4}\sum_{i=1}^{4}\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_i\right]\ ,\\ \vartheta_1&=\frac{\beta}{4\alpha}\big(\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_1\right]-\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_2\right]\\ &\qquad-\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_3\right]+\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_4\right]\big)\ ,\\ \vartheta_2&=\frac{\beta}{4\alpha}\big(\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_1\right]-\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_2\right]\\ &\qquad+\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_3\right]-\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_4\right]\big)\ ,\\ \vartheta_3&=\frac{\beta}{4\alpha}\big(\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_1\right]+\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_2\right]\\ &\qquad-\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_3\right]-\exp\left[2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_4\right]\big)\ ,\end{aligned}\qquad(16)$$

and

$$\gamma'=-\gamma a/4\beta\ .\qquad(17)$$

ϑ^*'s are the conjugate complexes of ϑ's.

Eliminating S from (15), we have

$$\begin{pmatrix}A-1&D&E\\D^*&B-1&F\\E^*&F^*&C-1\end{pmatrix}\begin{pmatrix}S_x{}'\\S_y{}'\\S_z{}'\end{pmatrix}=\gamma'\begin{pmatrix}\vartheta_1\\\vartheta_2\\\vartheta_3\end{pmatrix},\qquad(18)$$

where

$$\begin{aligned}A&=|\vartheta_0|^2+|\vartheta_2|^2+|\vartheta_3|^2\ ,\\ B&=|\vartheta_0|^2+|\vartheta_1|^2+|\vartheta_3|^2\ ,\\ C&=|\vartheta_0|^2+|\vartheta_1|^2+|\vartheta_2|^2\ ,\\ D&=\vartheta_0\vartheta_3{}^*+\vartheta_3\vartheta_0{}^*+\vartheta_2\vartheta_1{}^*;\\ E&=\vartheta_0\vartheta_2{}^*+\vartheta_3\vartheta_1{}^*+\vartheta_2\vartheta_0{}^*\ ,\\ F&=\vartheta_3\vartheta_2{}^*+\vartheta_0\vartheta_1{}^*+\vartheta_1\vartheta_0{}^*\ .\end{aligned}\qquad(19)$$

Solving (18) we get $\boldsymbol{S}'$, and putting it into the first equation of (15) we find $\boldsymbol{S}$. Further calculations will be given in the next section.

§ 3. Intensity of Diffuse Scattering

The intensity of the scattered X-ray with wave vector $\boldsymbol{k}$ when incident X-ray with wave vector $\boldsymbol{k}_0$ is passing through the diamond crystal is given by

$$I=I_e|f(\boldsymbol{b})\sum_l{}' \exp[2\pi i\boldsymbol{b}(\boldsymbol{R}_l+\boldsymbol{u}_l)]$$
$$+f(\boldsymbol{b})\sum_m \exp[2\pi i\boldsymbol{b}(\boldsymbol{R}_m'+\boldsymbol{u}_m')+f_0(\boldsymbol{b})|^2, \tag{20}$$

where $\boldsymbol{b}=\boldsymbol{k}-\boldsymbol{k}_0$, $f(\boldsymbol{b})$ the atom form factor of carbon (of a tetrahedral form when speaking rigorously), $f_0(\boldsymbol{b})$ that of the foreign atom at the origin of the coordinates, $\sum_l{}'$ indicating the sum with the exception of $\boldsymbol{R}_l=0$, and I_e the Thomson factor, i. e. the intensity of scattering by one electron.

Assuming $\boldsymbol{b}\cdot\boldsymbol{u}_l$ and $\boldsymbol{b}\cdot\boldsymbol{u}_m'$ to be very small compared with 1, (20) can be written, after expanding the exponential functions in power series and retaining the first order terms, as

$$I=I_e|G_0(\boldsymbol{b})+G_1(\boldsymbol{b})|^2\,, \tag{21}$$

where

$$G_0(\boldsymbol{b})=f(\boldsymbol{b})(\sum_l \exp[2\pi i\boldsymbol{b}\cdot\boldsymbol{R}_l]$$
$$+\sum_m \exp[2\pi i\boldsymbol{b}\cdot\boldsymbol{R}_m'])\,,$$
$$G_1(\boldsymbol{b})=2\pi i f(\boldsymbol{b})[(\boldsymbol{b}\cdot\boldsymbol{S})+(\boldsymbol{b}\cdot\boldsymbol{S}')]$$
$$+[f_0(\boldsymbol{b})-f(\boldsymbol{b})]\,. \tag{22}$$

$G_0(\boldsymbol{b})$ gives the Laue scattering and vanishes everywhere except at those $\boldsymbol{b}$ which coincide with reciprocal lattice vectors. Apart from the latter, I is given by

$$I=I_e|G_1(\boldsymbol{b})|^2\,. \tag{23}$$

We may further neglect $f_0(\boldsymbol{b})-f(\boldsymbol{b})$ in (22), since the diffuse scattering would arise from a certain spread deformed region around the defect. The intensity of diffuse scattering is given by

$$I_{\text{diffuse}}(\boldsymbol{b})=I_e|f(\boldsymbol{b})|^2|2\pi\boldsymbol{b}\cdot(\boldsymbol{S}+\boldsymbol{S}')|^2\,. \tag{24}$$

The quantity $2\pi\boldsymbol{b}\cdot(\boldsymbol{S}+\boldsymbol{S}')$ can be calculated from the formulas given in § 2.

In the following we shall confine ourselves to a simple case of $b_x=b_y$, and moreover only to those $\boldsymbol{b}$ which are in the neighbourhood of reciprocal lattice vectors with $b_x=b_y$; it can be shown generally that the diffuse scattering is intense in the neighbourhood of the Laue scattering vectors. We put

$$\xi=\pi ab_x\,,\quad \zeta=\pi ab_z\,, \tag{25}$$

and have

$$\vartheta_0=\frac{1}{2}(e^{i\zeta/2}\cos\xi+e^{-i\zeta/2})\,,$$
$$\vartheta_1=\frac{i\beta}{2\alpha}e^{i\zeta/2}\sin\xi\,,$$
$$\vartheta_2=\vartheta_1\,,$$
$$\vartheta_3=\frac{\beta}{2\alpha}(e^{i\zeta/2}\cos\xi-e^{-i\zeta/2}); \tag{26}$$

$$A=B=\frac{1}{4}(1+2\cos\zeta\cos\xi+\cos^2\xi)$$
$$+\frac{\beta^2}{2\alpha^2}(1-\cos\zeta\cos\xi)\,,$$
$$C=\frac{1}{4}(1+2\cos\zeta\cos\xi+\cos^2\xi)$$
$$+\frac{\beta^2}{2\alpha^2}\sin^2\xi\,,$$
$$D=-\frac{\beta}{2\alpha}\left(1-\frac{\beta}{2\alpha}\right)\sin^2\xi\,,$$
$$E=F=-\frac{\beta}{2\alpha}\left(1-\frac{\beta}{2\alpha}\right)\sin\xi\sin\zeta$$
$$-\frac{i\beta^2}{4\alpha^2}\sin\xi(\cos\xi-\cos\zeta)\,. \tag{27}$$

Solving (18) and (15) for $\boldsymbol{S}$ and $\boldsymbol{S}'$, we have

$$2\pi\boldsymbol{b}\cdot(\boldsymbol{S}+\boldsymbol{S}')=\frac{2\gamma'}{a}\frac{1}{(C-1)(A+D-1)-2|E^2|}$$
$$[2\xi\{[(C-1)\vartheta_1-E\vartheta_3](\vartheta_0{}^*+\vartheta_3{}^*+1)$$
$$+[(A+D-1)\vartheta_3-2E^*\vartheta_1]\vartheta_1{}^*\}$$
$$+\zeta\{[(C-1)\vartheta-{}_1E\vartheta_3]2\vartheta_1{}^*$$
$$+[(A+D-1)\vartheta_3-2E^*\vartheta_1](\vartheta_0{}^*+1)\}] \tag{28}$$

We expand this expression in the neighbourhood of reciprocal lattice vectors in powers of $(\xi-\xi_0)$ and $(\zeta-\zeta_0)$, where $(\xi_0/\pi, \xi_0/\pi, \zeta_0/\pi)$ represent a reciprocal lattice vector, or indices of the corresponding reflection. Further, we put

$$\xi-\xi_0=\frac{1}{\sqrt{2}}\rho\sin\varphi,\ \ \zeta-\zeta_0=\rho\cos\varphi\,. \tag{29}$$

If the expansion of (28) in ascending powers of ρ around a given reciprocal lattice point begins with a constant term or a term proportional to ρ, then we have practically no observable diffuse pattern around the corresponding Laue spot. If, on the other hand, the expansion begins with a term proportional to ρ^{-1}, we have an intense diffuse pattern around the corresponding Laue spot which fades away with increasing distance from the Laue spot. In the latter case, the structure of the diffuse pattern is mainly determined by the φ-dependence of that term. The infinite rise of the intensity for $\rho\to 0$ in this case results from our mathematical simplification of replacing $\exp(2\pi i\boldsymbol{b}\cdot\boldsymbol{u}_l)$ and $\exp(2\pi i\boldsymbol{b}\cdot\boldsymbol{u}_m')$ of (20) by $1+2\pi i\boldsymbol{b}\cdot\boldsymbol{u}_l$ and $1+2\pi i\boldsymbol{u}_m'$, respectively, and thus it should not be taken seriously.

The general expansion formula of (28) in powers ρ may not need be reproduced here. We summarize below our results obtained for several indices of reflection of lower degrees.

For reciprocal lattice points 000,001,002,112, where there are no normal Laue spots by extiction law, the expansion begins with a constant term (a function of φ). Therefore, there is no observable diffuse spot.

For 110, where we have also no normal Laue spot, the expansion begins with a term proportional to ρ. Therefore, we have also no observable diffuse spot.

For 111. 113, 220, where we have normal Laue spots and where anomalous patterns were observed in natural diamond of type I by Lonsdale and Smith[3)], and Hoerni and Wooster[4)], the expansion of (28) begins with a term proportional to ρ^{-1}. This term is as follows:

$$111:\quad -(1+i)\frac{4\pi\gamma'\beta'}{a}\times\frac{\sqrt{2}(1-\mu+2\mu\sin^2\varphi)\sin\varphi+(1+\mu\cos^2\varphi)\cos\varphi}{\Phi(\mu,\varphi)}\times\frac{1}{\rho},$$

$$113:\quad (1-i)\frac{4\pi\gamma'\beta'}{a}\times\frac{\sqrt{2}(1-\mu+2\mu\sin^2\varphi)\sin\varphi+3(1+\mu\cos^2\varphi)\cos\varphi}{\Phi(\mu,\varphi)}\times\frac{1}{\rho},$$

$$220:\quad -i\,\frac{16\sqrt{2}\,\pi\gamma'\beta'}{a}\,\frac{(1-\mu+2\mu\sin^2\varphi)\sin\varphi}{\Phi(\mu,\varphi)}\,\frac{1}{\rho}, \tag{30}$$

where

$$\Phi(\mu,\varphi)=1+\mu+\mu(1-4\mu)\sin^2\varphi+\mu^2(4-\mu)\sin^4\varphi,$$
$$\beta'=\beta/\alpha\,. \tag{31}$$

§ 4. Improved Treatment

We have so far neglected the forces between next-nearest neighbours. Considering them, we have to add to (4) the following terms:

$$\frac{1}{2}\sum_l\sum_{i,j=1}^{4}{}'\,\boldsymbol{u}_l\cdot\Phi_{ij}\cdot\boldsymbol{u}_{lij}+\frac{1}{2}\sum_m\sum_{i,j=1}^{4}{}'\,\boldsymbol{u}_m'\cdot\Phi_{ij}\cdot\boldsymbol{u}_{mij}'\,. \tag{4)'$$

Here $\sum'$ indicates summation with $i\neq j$; Φ_{ij} are symmetric diadics defined by

$$\Phi_{ij}=\frac{k_2}{d^2}\frac{1}{\sin^2\vartheta_0}(\boldsymbol{r}_j-\boldsymbol{r}_i\cos\vartheta_0)(\boldsymbol{r}_i-\boldsymbol{r}_j\cos\vartheta_0)\,. \tag{6)'$$

In (4)', $\boldsymbol{u}_{lij}$ is the displacement of the atom at $\boldsymbol{R}_{l'}=\boldsymbol{R}_l+\boldsymbol{r}_i-\boldsymbol{r}_j$, and $\boldsymbol{u}_{mij}$ that of the atom at $\boldsymbol{R}_{m'}'=\boldsymbol{R}_m'+\boldsymbol{r}_i-\boldsymbol{r}_j$. Then (7), (8) and (11) are replaced by

$$\Phi_0+\sum_{i=1}^{4}\Phi_i+\sum_{i,j=1}^{4}{}'\,\Phi_{ij}=0\,, \tag{7)'$$

$$\left.\begin{aligned}\Phi_0\cdot\boldsymbol{u}_l+\sum_i\Phi_i\cdot\boldsymbol{u}_{li}'+\sum_{i,j}{}'\Phi_{ij}\cdot\boldsymbol{u}_{lij}&=\boldsymbol{F}_l\,,\\ \Phi_0\cdot\boldsymbol{u}_m'+\sum_i\Phi_i\cdot\boldsymbol{u}_{mi}+\sum_{i,j}{}'\Phi_{ij}\boldsymbol{u}_{mij}'&=\boldsymbol{F}_m'\end{aligned}\right\} \tag{8)'$$

$$\begin{aligned}&(\Phi_0+\sum_{i,j}{}'\,\Phi_{ij}\exp[-2\pi i\boldsymbol{b}(\boldsymbol{r}_i-\boldsymbol{r}_j)])\cdot\boldsymbol{S}(\boldsymbol{b})\\&\quad+(\sum_i\Phi_i\exp[-2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_i])\cdot\boldsymbol{S}'(\boldsymbol{b})\\&\quad=\sum_l\boldsymbol{F}_l\exp[2\pi i\boldsymbol{b}\cdot\boldsymbol{R}_l]\,,\\&(\Phi_0+\sum_{i,j}{}'\,\Phi_{ij}\exp[-2\pi i\boldsymbol{b}(\boldsymbol{r}_i-\boldsymbol{r}_j)])\cdot\boldsymbol{S}'(\boldsymbol{b})\\&\quad+(\sum_i\Phi_i\exp[2\pi i\boldsymbol{b}\cdot\boldsymbol{r}_i])\cdot\boldsymbol{S}(\boldsymbol{b})\\&\quad=\sum_m\boldsymbol{F}_m'\exp[2\pi i\boldsymbol{b}\cdot\boldsymbol{R}_m']\,.\end{aligned} \tag{11)'$$

To solve (11)' we write after (Begbie, Born and) Smith[10)] the matrices Φ_{ij} explicitly as follows:

$$\Phi_{12}=\Phi_{21}=-\begin{pmatrix}\mu&\nu&0\\\nu&\mu&0\\0&0&\lambda\end{pmatrix},\quad\Phi_{13}=\Phi_{31}=-\begin{pmatrix}\mu&0&\nu\\0&\lambda&0\\\nu&0&\mu\end{pmatrix},$$
$$\Phi_{14}=\Phi_{41}=-\begin{pmatrix}\lambda&0&0\\0&\mu&\nu\\0&\nu&\mu\end{pmatrix},\quad\Phi_{23}=\Phi_{32}=-\begin{pmatrix}\lambda&0&0\\0&\mu&-\nu\\0&-\nu&\mu\end{pmatrix},$$
$$\Phi_{24}=\Phi_{42}=-\begin{pmatrix}\mu&0&-\nu\\0&\lambda&0\\-\nu&0&\mu\end{pmatrix},\quad\Phi_{34}=\Phi_{43}=-\begin{pmatrix}\mu&-\nu&0\\-\nu&\mu&0\\0&0&\lambda\end{pmatrix}, \tag{13)'$$

where

$$\lambda=-2/3\,k_2\,,\quad\mu=\nu=1/6\,k_2\,. \tag{14)'$$

(14)' can be easily derived from (6)'. From

(7)′, Φ_0 is

$$\Phi_0=4(\alpha+\lambda+2\mu)\begin{pmatrix}1&0&0\\0&1&0\\0&0&1\end{pmatrix}.$$

Then we have

$$\begin{pmatrix}a&f&e\\f&b&d\\e&d&c\end{pmatrix}\begin{pmatrix}S_x\\S_y\\S_z\end{pmatrix}-\begin{pmatrix}\vartheta_0{}^*&\vartheta_3{}^*&\vartheta_2{}^*\\\vartheta_3{}^*&\vartheta_0{}^*&\vartheta_1{}^*\\\vartheta_2{}^*&\vartheta_1{}^*&\vartheta_0{}^*\end{pmatrix}\begin{pmatrix}S_x'\\S_y'\\S_z'\end{pmatrix}=0\,,$$

$$\begin{pmatrix}a&f&e\\f&b&d\\e&d&c\end{pmatrix}\begin{pmatrix}S_x'\\S_y'\\S_y'\end{pmatrix}-\begin{pmatrix}\vartheta_0&\vartheta_3&\vartheta_2\\\vartheta_3&\vartheta_0&\vartheta_1\\\vartheta_2&\vartheta_1&\vartheta_0\end{pmatrix}\begin{pmatrix}S_x\\S_y\\S_z\end{pmatrix}$$

$$+\gamma'\begin{pmatrix}\vartheta_1\\\vartheta_2\\\vartheta_3\end{pmatrix}=0\,, \tag{15$'$}$$

where

$$a=\left(1+\frac{\lambda}{\alpha}+\frac{2\mu}{\alpha}\right)-\frac{\lambda}{a}\cos\pi ab_y\cos\pi ab_z$$
$$-\frac{\mu}{\alpha}\cos\pi ab_x(\cos\pi ab_y+\cos\pi ab_z)\,,$$
$$b=\left(1+\frac{\lambda}{\alpha}+\frac{2\mu}{\alpha}\right)-\frac{\lambda}{\alpha}\cos\pi ab_z\cos\pi ab_x$$
$$-\frac{\mu}{\alpha}\cos\pi ab_y(\cos\pi ab_z+\cos\pi ab_x)\,,$$
$$c=\left(1+\frac{\lambda}{\alpha}+\frac{2\mu}{\alpha}\right)-\frac{\lambda}{\alpha}\cos\pi ab_x\cos\pi ab_y\,,$$
$$-\frac{\mu}{\alpha}\cos\pi ab_z(\cos\pi ab_x+\cos\pi ab_y)\,,$$
$$d=-(\nu/\alpha)\sin\pi ab_y\sin\pi ab_z\,,$$
$$e=-(\nu/\alpha)\sin\pi ab_z\sin\pi ab_x\,,$$
$$f=-(\nu/\alpha)\sin\pi ab_x\sin\pi ab_y\,. \tag{16$'$}$$

Solving (15)′, we get S and S'. Calculations similar to those before show that the expressions corresponding to (30) are as follows and that other things are qualitatively the same:

$$111:\quad -(1+i)\frac{4\pi\gamma'\beta'}{a}\frac{g(\varphi)}{f(\varphi)}\frac{1}{\rho}\,,$$
$$113:\quad (1-i)\frac{4\pi\gamma'\beta'}{a}\frac{h(\varphi)}{f(\varphi)}\frac{1}{\rho}\,,$$
$$220:\quad i\,\frac{16\sqrt{2}\,\pi\gamma'\beta'}{a}\frac{l(\varphi)}{f(\varphi)}\frac{1}{\rho}\,,$$

where

$$\begin{aligned}f(\varphi)=&(1-\beta'^2-4\mu')(1-4\lambda'-2\mu')\\&+\{(\beta'-2\lambda'+2\mu')(1-4\lambda'-2\mu')\\&-\beta'^2(5-4\beta'-4\mu')\}\sin^2\varphi\\&+\beta'^2(4-5\beta'+\beta'^2+2\lambda'-2\mu')\sin^4\varphi\,,\end{aligned}$$

$$\begin{aligned}g(\varphi)=&\sqrt{2}\{(1+\beta'^2-2\beta'-4\lambda')\\&-2(\beta'^2-\beta'-2\lambda'+2\mu')\sin^2\varphi\}\sin\varphi\\&+\{(1-\beta'-2\lambda'-2\mu')\\&-(\beta'^2-\beta'-2\lambda'+2\mu')\cos^2\varphi\}\cos\varphi\,,\end{aligned}$$

$$\begin{aligned}h(\varphi)=&\sqrt{2}\{(1+\beta'^2-2\beta'-4\lambda')\\&-2(\beta'^2-\beta'-\lambda'+2\mu')\sin^2\varphi\}\sin\varphi\\&+3\{(1-\beta'-2\lambda'-2\mu')\\&-(\beta'^2-\beta'-2\lambda'+2\mu')\cos^2\varphi\}\,,\end{aligned}$$

$$\begin{aligned}l(\varphi)=&\{(1+\beta'^2-2\beta'-4\lambda')\\&-2(\beta'^2-\beta'-2\lambda'+2\mu')\sin^2\varphi\}\sin\varphi\,,\end{aligned}$$

$$\lambda'=\lambda/\alpha\,,\quad \mu'=\mu/\alpha\,.$$

§ 5. Numerical Computation and Comparison with Experiment

(A) In the approximation of taking account of only the nearest neighbour interactions, the elastic constants are given in terms of α and β as

$$c_{11}=c_{22}=c_{33}=\alpha/a\,,$$
$$c_{12}=c_{13}=c_{23}=(2\beta-\alpha)/a\,,$$
$$c_{44}=c_{55}=c_{66}=\left(\alpha-\frac{\beta^2}{\alpha}\right)\Big/a. \tag{32}$$

Therefore, from (14), the approximate relations between the elastic constants and the force constants k_1 and k_2 are given by

$$c_{11}=\frac{1}{3a}(k_1+8k_2)\,,$$
$$c_{12}=\frac{1}{3a}(k_1-16k_2)\,,$$
$$c_{44}=\frac{8k}{a}\frac{k_1+2k_2}{k_1+8k_2}\,. \tag{33}$$

Determining the values of k_1 and k_2 from the experimental values[11] of c_{11} and c_{12},

$$c_{11}=9.5\times10^{12}\ \text{dyne/cm}^2\,,$$
$$c_{12}=3.9\times10^{12}\ \text{dyne/cm}^2\,, \tag{34}$$

we have

$$k_1=8.13\times10^5\ \text{dyne/cm}\,,$$
$$k_2=0.246\times10^5\ \text{dyne/cm}\,. \tag{35}$$

Using these values and calculating c_{44} from (33), we get

$$(c_{44})_{\text{cal}}=4.72\times10^{12}\ \text{dyne/cm}^2\,. \tag{36}$$

This nearly agrees with the experimental value[11] of $c_{44}=4.4\times10^{12}$ dyne/cm^2.

(B) When the next-neighbour interactions are taken into account, the elastic constants are, in terms of $\alpha, \beta, \lambda, \mu, \nu$,

$$c_{11}=(\alpha+8\mu)/a\,,$$

$$c_{12}=(2\beta-\alpha-4\lambda-4\mu+8\nu)/a\ ,$$

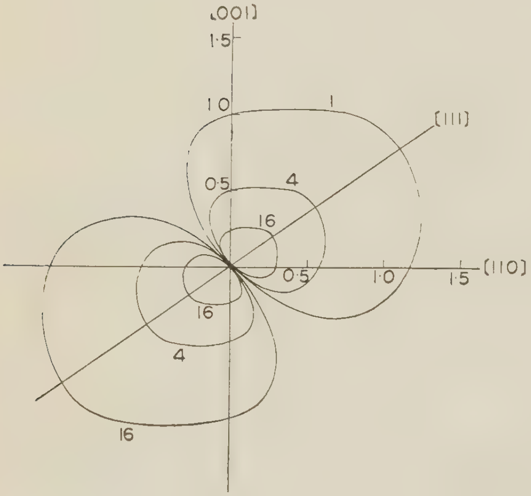
$$c_{44}=\left(\alpha-\frac{\beta^2}{\alpha}+4\lambda+4\mu\right)\Big/a\ .$$

The relations between these elastic constants and k_1 and k_2 are given by

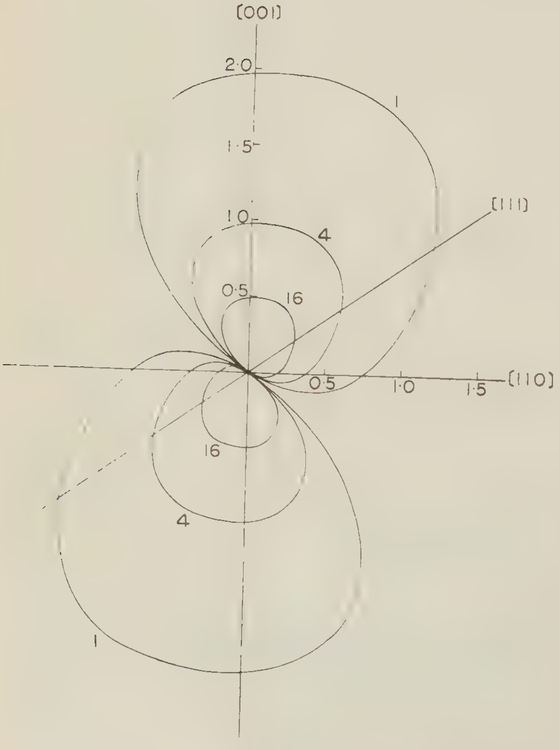
$$c_{11}=(k_1+12\,k_2)/3a\ ,$$

$$c_{12}=(k_1-6\,k_2)/3a\ ,$$

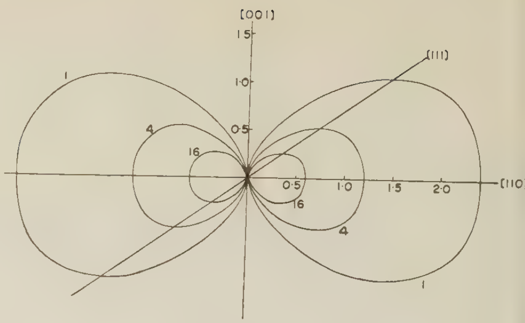
$$c_{44}=\frac{1}{3a}\frac{18\,k_1k_2}{k_1+8\,k_1}\ . \tag{38}$$



(a)



(b)



(c)

Fig. 1. The iso-diffusion curves calculated from the formula (30); (a) for 111, (b) for 113 and (c) for 220.

These coincide with the results given by Bhagavantam and Bhimasenachar. Determining the values of k_1 and k_2 from the experimental values of c_{11} and c_{12}, we get

$$k_1=6.16\times10^5\ \text{dyne/cm},$$

$$k_2=0.332\times10^5\ \text{dyne/cm}\ . \tag{39}$$

The value of c_{44} determined from (38) using these values is $(c_{44})_{\text{cal}}=3.92\times10^{12}\ \text{dyne/cm}^2$, which also nearly agrees with the experimental value of c_{44}. The value of parameter β' in (30) and (31) in the approximation (A) is, according to (35) and (14),

$$\beta'=\beta/\alpha=\frac{k_1-4k_2}{k_1+8k_2}=0.705\ ,$$

and the values of parameters $\beta',\lambda',\mu',\nu'$ in (30) and (31)′ of the approximation (B) are, according to (39), (14) and (14)′,

$$\beta'=\beta/\alpha=\frac{k_1-4k_2}{k_1+8k_2}=0.548\ ,$$

$$\lambda'=\lambda/\alpha=-\frac{2k_2}{k_1+8k_2}=-0.075\ ,$$

$$\mu'=\nu'=\mu/\alpha=\frac{k_2}{2(k_1+8\,k_2)}=0.019\ .$$

In making numerical computation of the scattering intensity, we take $2\pi|\gamma'|/a=1$. This corresponds to an elongation or a contraction of a $C-C$ bond ($C-C=1.54$Å) of the order of 10 % when one of the C atoms is replaced by a Si atom or a vacancy. In drawing the iso-diffusion curves, we take as the unit of intensity the following:

$$J=2I_ef_1^2\left(\frac{2\pi\gamma'\beta'}{a}\right)^2=\begin{cases}6.73\,I_e & \text{for (A)}\ ,\\ 4.07\,I_e & \text{for (B)}\ .\end{cases}$$

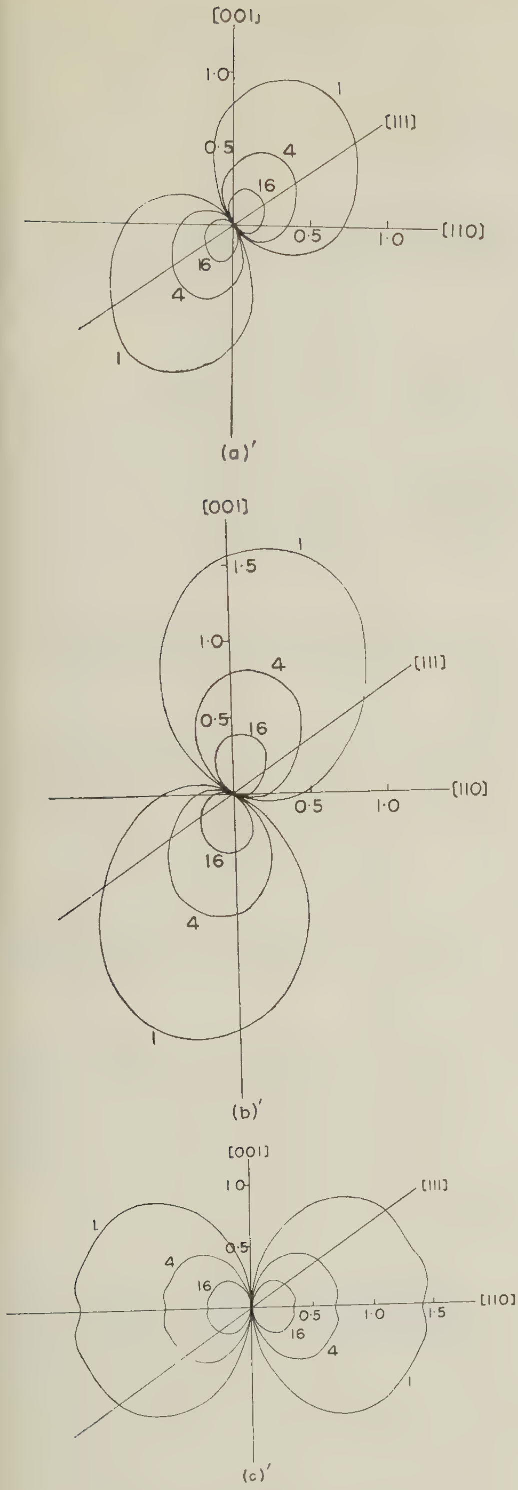


Fig. 2. The iso-diffusion curves calculated from the formula (30)′; (a)′ for 111, (b)′ for 113 and (c)′ for 220.

Accordingly, in (B) for example, the diffusion curves of intensity 1 around the reciprocal lattice points 111, 113 and 220 are given respectively as follows:

$$\rho_1=\left|\frac{g(\varphi)}{f(\varphi)}\right|, \quad \rho_3=\frac{f_3}{f_1}\left|\frac{h(\varphi)}{f(\varphi)}\right|=0.654\left|\frac{h(\varphi)}{f(\varphi)}\right|,$$

$$\rho_2=\frac{4f_2}{f_1}\left|\frac{l(\varphi)}{f(\varphi)}\right|=2.92\left|\frac{l(\varphi)}{f(\varphi)}\right|,$$

where f_1, f_2, and f_3 are the atomic structure factor at the reciprocal lattice points 111, 113, 220, respectively, and $f_1=2.60$, $f_3=1.70$ and $f_2=1.90$[12]. In Fig. 1 and Fig. 2 we show the iso-diffusion curves in the plane $\xi=\eta$ around these reciprocal lattice points. We see that the both approximations give qualitatively the same results.

The diffuse patterns observed by Lonsdale and Smith are as follows: at 111 six horns extend to the directions of the reciprocal axes, at 113 and 220 four horns extend to the directions [100] and [010] but [001] horns are missing, and the diffuse patterns are of streak or spike type (ours are of lemniscate type).

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 6, JUNE, 1957

Effect of Inelastic Waves on Electron Diffraction

By Hide YOSHIOKA

Physical Institute, Nagoya University, Nagoya, Japan

(Received January 25, 1957)

The effect of inelastic scattering on electron diffraction by crystals is theoretically studied. It is proved that the effect of inelastic scattering gives rise to an additional complex term to Fourier coefficient of the inner potential. The imaginary part of the additional term explains qualitatively the observation that two components of a doubly refracted electron beam are subjected to different degrees of absorption (Honjo and Mihama, J. Phys. Soc. Japan **9** (1954) 184). The real part of the additional term gives a correction of about 6~7 % to the calculated value of mean inner potential at accelerating voltages of 30~40 kv. This explains the systematic difference between the mean inner potential experimentally obtained by electron diffraction and that calculated by the use of diamagnetic susceptibility (Miyake, Proc. Physico-Math. Soc. Japan **22** (1940) 666).

§ 1. Introduction

The high resolution method of electron diffraction revealed fine structures in Debye-Scherrer rings given by smoke particles of MgO and CdO, which particles show clear cut cubic shape in electron-microscope.[1),2),3)] The spot group due to a single crystallite appearing on a spotty diffraction ring is composed of a set of doublets. The doublet is caused by the double refraction effect which can be explained by the dynamical theory of electron diffraction.[4),5)] Honjo and Mihama[3)] observed that for a doublet the spot with larger deviation from the unrefracted position is always weaker than the other. This difference in intensity cannot be explained by the dynamical theory which assumes that the crystal is non-absorptive.

Honjo and Mihama[3)] explained this anomaly by the use of a complex periodic potential which was introduced by K. Molière[6)] as a phenomenological concept. In X-ray diffraction, the complex structure factor similar to the complex potential in electron diffraction could explain the anomalous intensity of the transmitted X-rays through the crystal at the setting of Bragg reflexion.[7),8),9),10)] This complex structure factor was established on the quantum-mechanical basis by G. Molière[11)], and can be calculated theoretically. On the other hand, the complex potential in electron diffraction has not yet been established theoretically.

In this paper, we derive the so-called complex potential from a quantum mechanical basis and estimate its numerical value. Our method is to take account of the effect of inelastic scattering on elastic scattering. It will be shown that this effect gives rise to an additional complex term to Fourier coefficients of the inner potential. The imaginary part of the additional term is due to the damping of incident and diffracted waves by inelastic scattering. The real part is due to virtual inelastic scattering process and may be interpreted as representing the dynamic polarization of the crystal induced by the incident electron.

§ 2. Effect of Inelastically Scattered Waves on Elastic Scattering

We consider the interaction of an incident electron with a crystal. The Schrödinger equation of our system is

$$\left(-\frac{\hbar^2}{2m}\nabla^2+H_c+H'\right)\Phi=E\Phi \tag{1}$$

where $-(\hbar^2/2m)\nabla^2$ is the kinetic energy of the electron, H_c the energy of the crystal and H' the interaction energy between the electron and the crystal. The interaction energy is given by

$$H'=\sum_j\frac{e^2}{|\boldsymbol{r}-\boldsymbol{r}_j|}-\sum_k\frac{Z_ke^2}{|\boldsymbol{r}-\boldsymbol{R}_k|}, \tag{2}$$

where $\boldsymbol{r}$ is the coordinate of the incident electron, $\boldsymbol{r}_j$ that of the jth electron of the crystal, $\boldsymbol{R}_k$ that of the kth nucleus with charge Z_ke in the crystal. The effect of thermal motion is neglected.

The wave function of our system Φ depends upon the coordinates $\boldsymbol{r}$ and $\boldsymbol{r}_j$. It can be expanded in the form

$$\Phi(\boldsymbol{r}, \boldsymbol{r}_1, \cdots, \boldsymbol{r}_N)=\varphi_n(\boldsymbol{r})a_n(\boldsymbol{r}_1, \cdots, \boldsymbol{r}_N)\ , \quad (3)$$

where a_n is the wave function representing the nth excited state of the crystal, satisfying the equation

$$H_c a_n = E_n a_n\ . \quad (4)$$

where E_n is energy of the nth state of the crystal. Function $\varphi_0(\boldsymbol{r})$ in (3) describes the elastic scattering, and $\varphi_n(\boldsymbol{r})$ the inelastic scattering which excites the crystal from the normal state to the nth state. Substituting (3) into (1), multiplying by a_n, integrating over $\boldsymbol{r}_j$'s, and then by the help of (4) we obtain

$$\nabla^2\varphi_0+\left(k_0^2+\frac{2m}{\hbar^2}H'_{00}\right)\varphi_0=\frac{2m}{\hbar^2}\sum_{m\neq0}H'_{0m}\varphi_m\ , \quad (5)$$

$$\nabla^2\varphi_n+\left(k_n^2-\frac{2m}{\hbar^2}H'_{nn}\right)\varphi_n=\frac{2m}{\hbar^2}\sum_{m\neq n}H'_{nm}\varphi_m\ , \quad (6)$$

where

$$k_n^2=(2m/\hbar^2)(E-E_n) \quad (7)$$

and

$$H'_{nm}=\int a_n^* H' a_m d\tau\ , \quad d\tau=d\boldsymbol{r}_1\cdots d\boldsymbol{r}_N\ . \quad (8)$$

The term on the right-hand side of (5) represents the effect of inelastic waves. In Bethe's theory of electron diffraction[4] this effect is neglected. On the contrary, in this paper Bethe's theory is modified by taking account of this term.

Terms $H'_{nm}\varphi_m$ $(m\neq0)$ in (6) give only the second order correction to Bethe's theory, because φ_n is small compared with φ_0 and $|2mH'_{nm}/\hbar^2|\ll k_n^2$. In our theory, these terms are neglected, thus (6) is reduced to

$$\nabla^2\varphi_n+k_n^2\varphi_n=(2m/\hbar^2)H'_{n0}\varphi_0\ . \quad (n\geq1)\ . \quad (9)$$

The equation has a solution representing an out-going wave

$$\varphi_n(\boldsymbol{r})=-\frac{m}{2\pi\hbar^2}\int\frac{\exp(ik_n|\boldsymbol{r}-\boldsymbol{r}'|)}{|\boldsymbol{r}-\boldsymbol{r}'|}H'_{n0}(\boldsymbol{r}')\varphi_0(\boldsymbol{r}')d\boldsymbol{r}'\ . \quad (10)$$

Substituting (10) into (5), we have

$$\nabla^2\varphi_0+\left(k_0^2-\frac{2m}{\hbar^2}H'_{00}(\boldsymbol{r})\right)\varphi_0+\frac{2m}{\hbar^2}\int A(\boldsymbol{r}, \boldsymbol{r}')\varphi_0(\boldsymbol{r}')d\boldsymbol{r}'=0 \quad (11)$$

where $A(\boldsymbol{r}, \boldsymbol{r}')$ is given by

$$A(\boldsymbol{r}, \boldsymbol{r}')=-\frac{m}{2\pi\hbar^2}\sum_{n\neq0}H'_{0n}(\boldsymbol{r})H'_{n0}(\boldsymbol{r}')\frac{\exp(ik_n|\boldsymbol{r}-\boldsymbol{r}'|)}{|\boldsymbol{r}-\boldsymbol{r}'|}\ . \quad (12)$$

The integral kernel $A(\boldsymbol{r}, \boldsymbol{r}')$ is considered to vanish for the values of $|\boldsymbol{r}-\boldsymbol{r}'|$ larger than a few interatomic distances*, and satisfies the periodic condition

$$A(\boldsymbol{r}, \boldsymbol{r}')=A(\boldsymbol{r}+\boldsymbol{a}, \boldsymbol{r}'+\boldsymbol{a})\ , \quad (13)$$

where $\boldsymbol{a}$ is the unit-cell vector of the lattice.

§ 3. Derivation of the Generalized Fundamental Equations

Inside the crystal, $H'_{00}(\boldsymbol{r})$ represents the periodic crystal potential and the integral over infinite domain in (11) can be restricted to over the crystal volume owing to the short range of $A(\boldsymbol{r}, \boldsymbol{r}')$. Then, it can be shown, using (13) and the periodicity of $H'_{00}(\boldsymbol{r})$, that $\varphi_0(\boldsymbol{r}+\boldsymbol{a})$ becomes a solution of (11) as well as $\varphi_0(\boldsymbol{r})$. This fact shows that the solution of (11) is given by a Bloch type function. Therefore, we can express the solution of (11) in the form

$$\varphi_0(\boldsymbol{r})=\sum_h\chi_h\exp(i\boldsymbol{K}_h\cdot\boldsymbol{r})\ , \quad (14)$$

where

$$\boldsymbol{K}_h=\boldsymbol{K}+2\pi\boldsymbol{h}\ ,$$

$\boldsymbol{h}$ being a reciprocal lattice vector. Expression

---

* When the crystal has a filled band electronic structure, $A(\boldsymbol{r}, \boldsymbol{r}')$ is easily transformed to

$$A(\boldsymbol{r}, \boldsymbol{r}')=-\frac{me^4}{2\pi\hbar^2}\frac{\exp(i\bar{k}|\boldsymbol{r}-\boldsymbol{r}'|)}{|\boldsymbol{r}-\boldsymbol{r}'|}\times\int_V\int_V|\sum\rho_l(\boldsymbol{r}_1, \boldsymbol{r}_2)|^2\left(\frac{1}{|\boldsymbol{r}-\boldsymbol{r}_1|}-\frac{1}{|\boldsymbol{r}-\boldsymbol{r}_2|}\right)\left(\frac{1}{|\boldsymbol{r}'-\boldsymbol{r}_1|}-\frac{1}{|\boldsymbol{r}'-\boldsymbol{r}_2|}\right)d\boldsymbol{r}_1d\boldsymbol{r}_2\ ,$$

where $\bar{k}$ is given by (38) and $\rho_l(\boldsymbol{r}, \boldsymbol{r}')$ is defined by (40) and the summation with respect to l is over all atoms in the crystal. Since $\rho_l(\boldsymbol{r}, \boldsymbol{r}')$ vanishes if $|\boldsymbol{r}-\boldsymbol{r}'|$ becomes larger than about an interatomic distance, $A(\boldsymbol{r}, \boldsymbol{r}')$ tends rapidly to vanish if $|\boldsymbol{r}-\boldsymbol{r}'|$ goes beyond about an interatomic distance. We exclude the case of metals where collective motion of valence electrons seems to nessecitate a special treatment.

(14) for φ_0 has the same form as that used by Bethe for describing the electron wave in the crystal. We expand the crystal potential $H'_{00}(\boldsymbol{r})$ in a Fourier series

$$H'_{00}(\boldsymbol{r})=\sum_h V_h \exp(i2\pi\boldsymbol{h}\cdot\boldsymbol{r}) . \tag{15}$$

Substituting (14) and (15) into (11), multiplying $\exp(-i\boldsymbol{K}_h\cdot\boldsymbol{r})$ and integrating over the whole volume, V, of the crystal, we obtain

$$\frac{\hbar^2}{2m}(\boldsymbol{K}_h{}^2-k_0{}^2)\chi_h+\sum_g V_{h-g}\chi_g+\sum_g C_{hg}\chi_g=0 , \tag{16}$$

where

$$C_{hg}=\frac{1}{V}\int_V\int_V A(\boldsymbol{r},\boldsymbol{r}')\exp(-i\boldsymbol{K}_h\cdot\boldsymbol{r}+i\boldsymbol{K}_g\cdot\boldsymbol{r}')d\boldsymbol{r}d\boldsymbol{r}' . \tag{17}$$

Equation (16) is the fundamental equation of the dynamical theory generalized by taking account of inelastic waves.

Green function in (10) is expressed in the integral form

$$\frac{1}{4\pi}\frac{\exp(ik_n|\boldsymbol{r}-\boldsymbol{r}'|)}{|\boldsymbol{r}-\boldsymbol{r}'|}=\frac{1}{(2\pi)^3}\int\frac{\exp[i\boldsymbol{K}'\cdot(\boldsymbol{r}-\boldsymbol{r}')]}{\boldsymbol{K}'^2-k_n{}^2}d\boldsymbol{K}' , \tag{18}$$

where the integration is over the whole $\boldsymbol{K}'$ space[18]. By the use of this form, the expression of C_{hg} turns out (Appendix I)

$$C_{hg}=C^r_{hg}+iC^i_{hg} . \tag{19}$$

Here, C^r_{hg} is the volume integral in K'-space

$$C^r_{hg}=-\frac{1}{V}\frac{m}{4\pi^3\hbar^2}\times\sum_{n\neq0}\iiint\frac{E_{0n}(\boldsymbol{K}_h-\boldsymbol{K}')E_{n0}(\boldsymbol{K}'-\boldsymbol{K}_g)}{\boldsymbol{K}'^2-k_n{}^2}d\tau(\boldsymbol{K}') , \tag{20}$$

taking the principal value with respect to the singularity at $|\boldsymbol{K}'|=k_n$. E_{0n} is defined by

$$E_{0n}(\boldsymbol{K}_h-\boldsymbol{K}')\equiv\int_V H'_{0n}(\boldsymbol{r})\exp[-i(\boldsymbol{K}_h-\boldsymbol{K}')\cdot\boldsymbol{r}]d\boldsymbol{r} , \tag{21}$$

and can be interpreted as the matrix element for inelastic scattering from the state $(\boldsymbol{K}_h, a_0)$ to the state $(\boldsymbol{K}', a_n)$. There holds the relation

$$E_{n0}(\boldsymbol{K}'-\boldsymbol{K}_h)=[E_{0n}(\boldsymbol{K}_h-\boldsymbol{K}')]^* . \tag{22}$$

Term C^i_{hg} is the surface integral

$$C^i_{hg}=-\frac{m}{4\pi^2\hbar^2V}\times\sum_{n\neq0}\iint\frac{E_{0n}(\boldsymbol{K}_h-\boldsymbol{K}')E_{n0}(\boldsymbol{K}'-\boldsymbol{K}_g)}{2k_n}d\sigma(\boldsymbol{K}') \tag{23}$$

where the integration is over the surface $|\boldsymbol{K}'|=k_n$.

We mention, here, that $|\boldsymbol{K}'|=k_n$ means the energy conservation in the transition $(\boldsymbol{K}_h, a_0)\to(\boldsymbol{K}', a_n)$ since, then, $E=E_n+\hbar^2\boldsymbol{K}'^2/(2m)$. Thus, we can interprete C^r_{hg} is due to virtual process of inelastic scattering, whereas C^i_{hg} is due to real process.

From (20), (22) and (23), it is evident that

$$\left.\begin{aligned}C^r_{hg}&=(C^r_{gh})^*\\ C^i_{hg}&=(C^i_{gh})^* .\end{aligned}\right\} \tag{24}$$

If the crystal has a center of symmetry, the wave function of the crystal $a_n(\boldsymbol{r}_1, \cdots, \boldsymbol{r}_N)$ can be chosen as a real function with a definite parity

$$a_n(\boldsymbol{r}_1, \cdots, \boldsymbol{r}_N)=\pm a_n(-\boldsymbol{r}_1, \cdots, -\boldsymbol{r}_N) .$$

Therefore, C^r_{hg} and C^i_{hg} are real, thus

$$\left.\begin{aligned}C^r_{hg}&=C^r_{gh}\\ C^i_{hg}&=C^i_{gh} .\end{aligned}\right\} \tag{25}$$

§ 4. Solution of the Generalized Fundamental Equation

(1) *No Bragg reflexion*

When no Bragg reflexion is excited in the crystal the generalized fundamental equation becomes simply

$$\frac{\hbar^2}{2m}(\boldsymbol{K}^2-k_0{}^2)\chi_0+V_0\chi_0+C_{00}\chi_0=0 .$$

Since

$$|\boldsymbol{K}|\sim k_0$$

we have

$$|\boldsymbol{K}|=k_0-(m/\hbar^2k_0)(V_0+C^r_{00}+iC^i_{00}) . \tag{26}$$

Vector $\boldsymbol{K}$ is determined by (26) and the tangential continuity of wave vector on the incident surface. For centrosymmetric crystals (26) indicates that inelastic waves result in the apparent increase of mean inner potential by C^r_{00} and the absorption of elastic wave with the absorption coefficient given by

$$\kappa=-\frac{2m}{\hbar^2k_0}C^i_{00} , \tag{27}$$

where the factor 2 is multiplied since the absorption coefficient is referred to intensity.

(2) *One Bragg reflexion*

When one Bragg reflexion of index $\boldsymbol{h}$ is excited, the generalized fundamental equations are reduced to

$$\left.\begin{aligned}&\left\{\frac{\hbar^2}{2m}(\boldsymbol{K}^2-k_0^2)+V_0+C_{00}\right\}\chi_0\\&\qquad\qquad+(V_{-h}+C_{0h})\chi_h=0\\&(V_h+C_{h0})\chi_0\\&\qquad+\left\{\frac{\hbar^2}{2m}(\boldsymbol{K}_h^2-k_0^2)+V_0+C_{hh}\right\}\chi_h=0\,.\end{aligned}\right\}\tag{28}$$

If we define resonance errors by

$$\left.\begin{aligned}\xi&=|\boldsymbol{K}|-k_0+\frac{m}{\hbar^2k_0}V_0\\\eta&=|\boldsymbol{K}_h|-k_0+\frac{m}{\hbar^2k_0}V_0\end{aligned}\right\}\tag{29}$$

and if we take into account

$$(\boldsymbol{K}^2-k_0^2)\sim 2k_0\{|\boldsymbol{K}|-k_0\}\,,$$

the equation of the dispersion surface is written as

$$\left(\xi+\frac{m}{\hbar^2k_0}C_{00}\right)\left(\eta+\frac{m}{\hbar^2k_0}C_{hh}\right)=\left(\frac{m}{\hbar^2k_0}\right)^2(V_h+C_{h0})(V_{-h}+C_{0h})\,.\tag{30}$$

If we neglect C_{00}, C_{hh} and C_{h0}, (30) is reduced to the dispersion surface in Bethe's approximation,

$$\xi^0\eta^0=\left(\frac{m}{\hbar^2k_0}\right)^2|V_h|^2\,.\tag{31}$$

It is convenient to determine the wave vector at first by Bethe's approximation, and then calculate the correction caused by C_{hg}. We consider the Laue case. The wave vectors in Bethe's approximation are determined by wave points Q_1 and Q_2 which are intersections of the dispersion surface and the normal $\boldsymbol{n}$ to the incident surface determinined by the tangential continuity of wave vectors (Fig. 1). We denote the wave vectors corresponding to Q_1 and Q_2 by $\boldsymbol{K}_1^0$ and $\boldsymbol{K}_2^0$ respectively, and their resonance errors by

$$\left.\begin{aligned}\xi_i^0&=|\boldsymbol{K}_i^0|-k_0+\frac{m}{\hbar^2k_0}V_0\\\eta_i^0&=|\boldsymbol{K}_{hi}^0|-k_0+\frac{m}{\hbar^2k_0}V_0\,.\quad(i=1,2)\end{aligned}\right\}\tag{32}$$

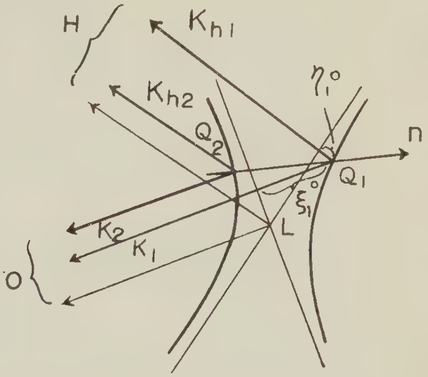

Fig. 1. Dispersion surface in Bethe's approximation.

Next, we consider the correction, $\Delta\boldsymbol{K}_i=\boldsymbol{K}_i-\boldsymbol{K}_i^0$, caused by C_{hg}. By the tangential continuity of the wave vector, correction $\Delta\boldsymbol{K}_i$ is in the direction of the normal $\boldsymbol{n}$, i.e. $\Delta\boldsymbol{K}_i=\varepsilon_i\boldsymbol{n}$. If we denote the angles between $\boldsymbol{n}$ and $\boldsymbol{K}_i^0$ by α_i, and $\boldsymbol{n}$ and $\boldsymbol{K}_{hi}^0$ by β_i, then

$$\left.\begin{aligned}\xi_i-\xi_i^0&=\varepsilon_i\cos\alpha_i\\\eta_i-\eta_i^0&=\varepsilon_i\cos\beta_i\,.\end{aligned}\right\}\tag{33}$$

Substituting (33) into (30), and neglecting higher orders of small quantities, we have

$$\varepsilon_i=\frac{-(m/\hbar^2k_0)(C_{00}\xi_i^0+C_{hh}\eta_i^0)+(m/\hbar^2k_0)^2(V_hC_{0h}+V_{-h}C_{h0})}{\xi_i^0\cos\beta_i+\eta_i^0\cos\alpha_i}\,.\tag{34}$$

The absorption coefficient κ_i is given by twice the imaginary part of ε_i. For centrosymmetric crystals the imaginary part comes from C_{00}^i, C_{hh}^i and C_{h0}^i.

We prove in the next section that, (1) C_{00}^i, C_{hh}^i and C_{h0}^i can be treated practically as constants in the range where the resonance error (ξ_i^0, η_i^0) is the order of $(m/\hbar^2k_0)V_0$, and that (2) C_{hh} are equal to C_{00}, and that (3) C_{h0}^i has the same sign as V_h.

Using

$$\cos\alpha_1\simeq\cos\alpha_2\simeq\cos\beta_1\simeq\cos\beta_2\,,$$

we obtain

$$\kappa_i=\frac{2m}{\hbar^2k_0}\left\{-\frac{C_{00}^i}{\cos\alpha}+\frac{2m}{\hbar^2k_0}\frac{V_hC_{0h}^i}{(\xi_i^0+\eta_i^0)\cos\alpha}\right\}.\tag{35}$$

Thus the absorption coefficient is smaller for ξ_i^0, $\eta_i^0<0$ than for ξ_i^0, $\eta_i^0>0$. In the former case the wave point lies on the branch nearer the origin. This fact agrees with the observed intensity difference in a refraction doublet.

§ 5. Evaluation of C_{hg}

In this section we assume that the crystal have a filled band electronic structure, and calculate the wave functions of each band by the approximation of tight binding. Then, neglecting the overlap integrals, we can transform the expressions (20) and (23) to (Appendix II)

$$C^{r}_{hg}=-\frac{8E_H}{\pi v_0}\iiint\frac{\sum_l s_l(2\pi(\boldsymbol{h}-\boldsymbol{g}),\ \boldsymbol{K}-\boldsymbol{K}'+\pi(\boldsymbol{h}+\boldsymbol{g}))\exp[2\pi i\boldsymbol{R}_l\cdot(\boldsymbol{h}-\boldsymbol{g})]}{(\boldsymbol{K}'^2-\bar{k}^2)(\boldsymbol{K}_h-\boldsymbol{K}')^2(\boldsymbol{K}_g-\boldsymbol{K}')^2}d\tau(\boldsymbol{K}') \tag{36}$$

$$C^{i}_{hg}=-\frac{4E_H}{\bar{k}v_0}\iint\frac{\sum_l s_l(2\pi(\boldsymbol{h}-\boldsymbol{g}),\ \boldsymbol{K}-\boldsymbol{K}'+\pi(\boldsymbol{h}+\boldsymbol{g}))\exp[2\pi i\boldsymbol{R}_l\cdot(\boldsymbol{h}-\boldsymbol{g})]}{(\boldsymbol{K}_h-\boldsymbol{K}')^2(\boldsymbol{K}_g-\boldsymbol{K}')^2}d\sigma(\boldsymbol{K}')\,. \tag{37}$$

Here, the summation is over the atoms in a unit-cell, and v_0 is the volume of the unit cell, E_H the atomic unit of energy $me^4/(2\hbar^2)$ and

$$\bar{k}=k_0-(m/\hbar^2k_0)\overline{\Delta E}\,, \tag{38}$$

where $\overline{\Delta E}$ is an appropriately weighted mean of excitation energy E_n-E_0 and is of the order of a half the ionization energy. Function s_l is given by

$$s_l(2\pi(\boldsymbol{h}-\boldsymbol{g}),\ \boldsymbol{K}-\boldsymbol{K}'+\pi(\boldsymbol{h}+\boldsymbol{g}))=2\Big[\int\rho_l(\boldsymbol{r},\ \boldsymbol{r})\exp[i2\pi(\boldsymbol{h}-\boldsymbol{g})\cdot\boldsymbol{r}]d\boldsymbol{r}$$
$$-\iint|\rho_l(\boldsymbol{r},\ \boldsymbol{r}')|^2\exp[i(\boldsymbol{K}_h-\boldsymbol{K}')\boldsymbol{r}-i(\boldsymbol{K}_g-\boldsymbol{K}')\boldsymbol{r}']d\boldsymbol{r}d\boldsymbol{r}'\Big]\,. \tag{39}$$

$\rho_l(\boldsymbol{r},\ \boldsymbol{r}')$ is Dirac's density matrix

$$\rho_l(\boldsymbol{r},\ \boldsymbol{r}')=\sum_n\phi_n{}^*(\boldsymbol{r})\phi_n(\boldsymbol{r}')\,, \tag{40}$$

where the summation is over all the orbitals occupied in the lth atom.

(1) C^{i}_{00} and C^{r}_{00}

From (36) and (37) coefficients C^{i}_{00} and C^{r}_{00} are written as

$$C^{i}_{00}=-\frac{4E_H}{v_0k_0}\iint\frac{\sum_l s_l(0,\ \boldsymbol{K}-\boldsymbol{K}')}{(\boldsymbol{K}-\boldsymbol{K}')^4}d\sigma(\boldsymbol{K}') \tag{41}$$

$$C^{r}_{00}=-\frac{8E_H}{\pi v_0}\iiint\frac{\sum_l s_l(0,\ \boldsymbol{K}-\boldsymbol{K}')}{(\boldsymbol{K}'^2-\bar{k}^2)(\boldsymbol{K}-\boldsymbol{K}')^4}d\tau(\boldsymbol{K}')\,. \tag{42}$$

Function $s_l(0,\ \boldsymbol{K}-\boldsymbol{K}')$ was calculated as a function of v_l by Bewilogua[12] using Thomas-Fermi model (Fig. 2), where

$$v_l=b_l|\boldsymbol{K}-\boldsymbol{K}'|$$
$$=\frac{0.176}{Z_l{}^{2/3}}\times10^{-8}\times|\boldsymbol{K}-\boldsymbol{K}'|\ cm^{-1}\,. \tag{43}$$

However, this approximation becomes bad for small values of $|\boldsymbol{K}-\boldsymbol{K}'|$. For small values we evaluate s_l by expanding exponentials in the integrand of (39) into power series of $\boldsymbol{K}-\boldsymbol{K}'$. The result is

$$s_l(0,\ \boldsymbol{K}-\boldsymbol{K}')=B_l|\boldsymbol{K}-\boldsymbol{K}'|^2+\cdots\,, \tag{44}$$

where B_l is given by

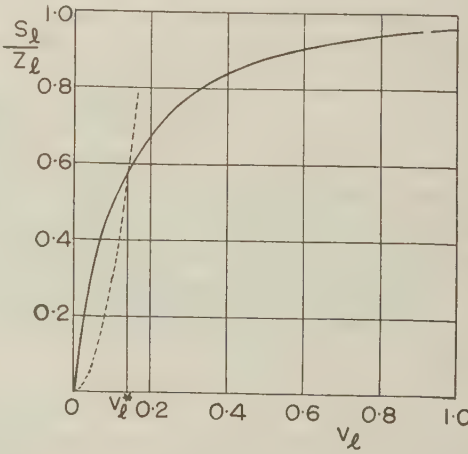

Fig. 2. $s_l(0,\ \boldsymbol{K}-\boldsymbol{K}')/Z_l$ as a function of $v_l=b_l|\boldsymbol{K}-\boldsymbol{K}'|$.

solid curve: utilizing Thomas-Fermi model.

dotted curve: utilizing power series expansion for Mg ion.

$$B_l=\frac{1}{3}\int\rho_l(\boldsymbol{r},\boldsymbol{r})\boldsymbol{r}^2d\boldsymbol{r}\,. \tag{45}$$

In Fig. 2 the value of s_l given by (44) is shown by a dotted curve. According to Koppe[13)], the above expansion is a good approximation for $|\boldsymbol{K}-\boldsymbol{K}'|<q_l^*$, while for $|\boldsymbol{K}-\boldsymbol{K}'|>q_l^*$ the Thomas-Fermi model gives a good approximation, where $q_l^*=b_l v_l^*$, v_l^* is the abscissa of intersection of the two curves in Fig. 2. The contribution to the integral of C^i_{00} and C^r_{00} from the domain $|\boldsymbol{K}-\boldsymbol{K}'|>q_l^*$ is very small and can be neglected. Thus we can calculated the integral by using (44) and obtain (Appendix IV)

$$C^i_{00}=-\frac{8\pi E_H}{v_0k_0}\sum_l B_l\log\frac{q_l^*}{|\boldsymbol{K}|-\bar{k}} \tag{46}$$

$$C^r_{00}=-\frac{4\pi^2E_H}{v_0k_0}\sum_l B_l\,. \tag{47}$$

Since C^r_{00} does not depend on $\boldsymbol{K}$, C^r_{00} can be treated as a constant. The expression of C^i_{00} depends on $\boldsymbol{K}$. This is given by

$$|\boldsymbol{K}|=k_0-(m/\hbar^2k_0)V_0$$

provided there is no Bragg reflexion. When one Bragg reflexion is excited, $|\boldsymbol{K}|$ is given by (29)

$$|\boldsymbol{K}|=k_0-\frac{m}{\hbar^2k_0}V_0+\xi\,,$$

or using (38),

$$|\boldsymbol{K}|-\bar{k}=(m/\hbar^2k_0)(\overline{\varDelta E}-V_0)+\xi\,,$$

where the resonance error ξ has the order of $(m/\hbar^2k_0)V_h$. Since, however, we have $\overline{\varDelta E}-V_0\gg|V_h|$, the change of C^i_{00} with $|\boldsymbol{K}|$ is so small that C^i_{00} is practically a constant within a deviation of a few percents.

Since the mean inner potential V_0 is expressed in the form

$$V_0=-\frac{2\pi e^2}{v_0}\sum_l B_l\,, \tag{48}$$

C^r_{00} is proportional to V_0,

$$\frac{C^r_{00}}{V_0}=\frac{2\pi E_H}{k_0e^2}=\frac{\lambda}{2a_0} \tag{49}$$

where λ is the wave length of the incident electron and a_0 is Bohr radius.

(2) C^i_{hh} and C^r_{hh}

Coefficients C^i_{hh} has the same form as C^i_{00} and C^r_{hh} the same as C^r_{00}, $\boldsymbol{K}$ in C^i_{00} and C^r_{00} being replaced by $\boldsymbol{K}_h$ in C^i_{hh} and C^r_{hh}. If $\boldsymbol{h}$-reflexion is excited, the difference between $|\boldsymbol{K}|$ and $|\boldsymbol{K}_h|$ is the order of resonance error. Thus, C^i_{hh} and C^r_{hh} can be treated as constants equal to C^i_{00} and C^r_{00}, respectively.

(3) C^i_{h0}

From (37), this coefficient is written as

$$C^i_{h0}=-\frac{4E_H}{k_0v_0}\times\iint\frac{\sum_l s_l(2\pi\boldsymbol{h},\boldsymbol{K}-\boldsymbol{K}'+\pi\boldsymbol{h})\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{R}_l)}{(\boldsymbol{K}-\boldsymbol{K}')^2(\boldsymbol{K}_h-\boldsymbol{K}')^2}d\sigma(\boldsymbol{K}'). \tag{50}$$

We evaluate (50) near $\boldsymbol{h}$-reflexion, i.e. assuming the resonance error (32) is small. Function $s_l(2\pi\boldsymbol{h},\boldsymbol{K}-\boldsymbol{K}'+\pi\boldsymbol{h})$ was calculated using Thomas-Fermi model (Appendix III) in the same way as $s_l(0,\boldsymbol{K}-\boldsymbol{K}')$[14)]. The result is shown in Fig. 3 as a function of $v_l=b_l|\boldsymbol{K}-\boldsymbol{K}'+\pi\boldsymbol{h}|$. Although Thomas-Fermi model gives inaccurate result for small value of $|\boldsymbol{K}-\boldsymbol{K}'+\pi\boldsymbol{h}|$*, the contribution from this range to the integral of C^i_{h0} may be less dominant than in the calculation of C^i_{00} on account of a finite value of the denominator of the integrand at $\boldsymbol{K}-\boldsymbol{K}'+\pi\boldsymbol{h}=0$. Therefore, the calculation using Thomas-Fermi model is not meaningless for a rough estimation of C^i_{h0}, though it is never exact.

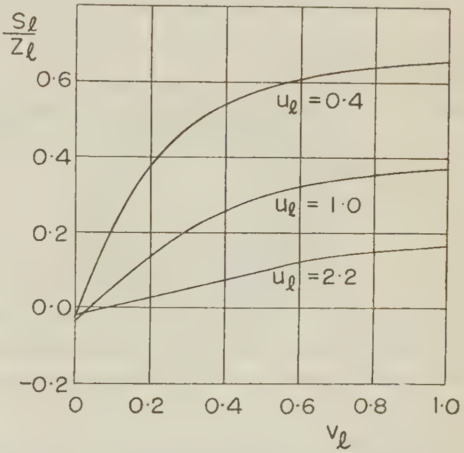

Fig. 3. $s_l(2\pi\boldsymbol{h},\boldsymbol{K}-\boldsymbol{K}'+\pi\boldsymbol{h})$ as a function of $v_l=b_l|\boldsymbol{K}-\boldsymbol{K}'+\pi\boldsymbol{h}|$ with the parameter $u_l=a_l|2\pi\boldsymbol{h}|$. ($Z_l=12$.).

The curve in Fig. 3 is almost linear in the range from the origin of v_l to about ten times of $b_l|\pi\boldsymbol{h}|$, and the contribution to the integral of (50) from the larger values of v_l is negligibly small owing to the large values of the denominator in the integrand. Hence, we can evaluate (50) approximately by replacing s_l by $T_l(\boldsymbol{h})(|\boldsymbol{K}-\boldsymbol{K}'+\pi\boldsymbol{h}|-|\pi\boldsymbol{h}|)$, where $T_l(\boldsymbol{h})$ is the tangent of $s_l(2\pi\boldsymbol{h}, q)$ at $q=0$, and given by

---

* Though Pauling and Sherman's method may be better for the calculation of this range, their method requires a very complicated calculation.

$$T_l(\boldsymbol{h})=\frac{3}{2}b_lZ_l\int_0^\infty \frac{\varphi(x)}{x}\frac{\sin u_lx}{u_lx}x^2dx \qquad (51)$$

where u_l is the parameter

$$u_l=a_l|2\pi\boldsymbol{h}|=\frac{0.468}{Z_l^{1/3}}\times10^{-8}\times|2\pi\boldsymbol{h}|\ cm^{-1}\ , \qquad (52)$$

and φ is the function given by Fermi (Appendix V). Thus, the integral turns out (Appendix V)

$$C^i_{h0}=-\frac{8\pi E_H}{v_0k_0}\frac{\log 2}{|2\pi\boldsymbol{h}|}\sum_l T_l(\boldsymbol{h})\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{R}_l)\ . \qquad (53)$$

This coefficient can also be treated as a constant.

Coefficient $T_l(\boldsymbol{h})$ has a similar behavior to the atomic scattering factor for X-rays $f_l(\boldsymbol{h})$ which is given by

$$f_l(\boldsymbol{h})=Z_l\int_0^\infty\left(\frac{\varphi(x)}{x}\right)^{3/2}\frac{\sin u_lx}{u_lx}x^2dx\ . \qquad (54)$$

Therefore, C^i_{h0} has a similar character to the crystal structure factor for X-rays and thus to V_h. C^i_{h0} is large, when V_h is large, and C^i_{h0} has the same sign as that of V_h when the crystal is centrosymmetric.

Numerical values for MgO

We calculate the coefficients C^i_{00}, C^r_{00} and C^i_{h0} for MgO crystal using (45), (46) and (53).

Table I. Values of C_{hg} and V_h for MgO. Values of V_0 and V_h are those obtained by Honjo and Mihama[3].

C^r_{00}		-0.59 (ev)			
C^i_{00}		-1.47 (ev)	V_0		-15.6 (ev)
C^i_{h0}	(111)	-0.016	V_h	(111)	~ -1.7
	(200)	-0.068		(200)	~ -7
	(220)	-0.027		(220)	-5.5
	(420)	-0.009		(420)	-4.2

The value of B_l can be calculated from the experimental value of diamagnetic susceptibility $\chi_{\text{mol},l}$ by the use of the relation

$$\chi_{\text{mol},l}=-\frac{Le^2}{6mc^2}B_l=-2.832\times10^{-10}B_l \qquad (55)$$

where L is Loschmidt number. Using the value of χ_{mol} in Van Vleck's book[15] we have $B_{Mg}=37.7\times10^{-18}\ cm^2$, $B_O=148\times10^{-18}\ cm^2$. The value of $\overline{\Delta E}$ is taken to be $25\ ev$ from the strongest peak in the energy loss curve reported by Watanabe[16]. The energy of the incident electron is taken to be $40\ kv$ corresponding to $\lambda=0.061A$. The results are shown in Table I.

§ 6. Comparison with Experiments

We have concluded above that inelastic waves result in the increase of V_0 by C^r_{00} and of V_h by C^r_{h0}, as well as the absorption due to C^i_{00} and C^i_{h0}. We compare these results with experiments.

(1) C^r_{00}

Previously, Miyake[17] calculated V_0 using the formula (48) with the value of B_l determined from the experimental value of diamagnetic susceptibility χ_{mol}. He found that for simple ionic crystals the calculated value is systematically smaller than the experimental value measured by electron diffraction. He inferred that the deviation is caused by the underestimate of B_l either through the neglect of temperature independent paramagnetic terms in χ_{mol} or through the effect of ferromagnetic impurity in the sample. However, our result indicates that the deviation may be explained by the correction term C^r_{00}, which amounts to 6∼7% of V_0 at accelerating voltages 30∼40 kv. Table II gives the values reported by Miyake together with our corrected values $V_0+C^r_{00}$. The agreement between the calculated values and the experimental values is fairly improved by the introduction of C^r_{00}. The origin of the large deviation for MgO even after the correction is not clear. It is to be mentioned, however, that the experimental value of V_0 of MgO is obtained by transmission method, while all the other values are obtained by the rotating crystal method.

(2) C^i_{00} and C^i_{h0}

When there is no Bragg reflexion, the absorption coefficient is given by (27). This result is the same as that obtained by Koppe[13], provided we neglect overlapping of neighbor atoms.

When $\boldsymbol{h}$-Bragg reflexion is excited, there exist two wave fields corresponding to the two wave points on the dispersion surface. The bsorption coefficients for these two wave ields are different and are given by (35). quation (35) implies that the difference is arge for large C^i_{h0}. Since C^i_{h0} is large for arge V_h, the intensity difference must be onspicuous for strong Bragg reflexions. This s in accordance with the observations of Ionjo and Mihama[3]. Their photograph for louble refraction implies that the order of C^i_{h0} is 1/3∼1/10 of the value of C^i_{00} for strong eflexions by MgO. The calculated value of C^i_{h0} in Table I is small compared with this rder. The discrepancy between the calculated alue and the experimental value is probably lue to the inaccuracy of the evaluation of C^i_{h0} described in § 5. We may expect that a etter agreement will be obtained by using auling and Sherman's method in the calcuation of C^i_{h0}.

The coefficient C^r_{h0} gives a correction for V_h. Although we cannot estimate its order wing to the difficulty of the integration in he formula (37), it is worth noting that Ionjo and Mihama report a deviation between he theoretical value of V_h and the value neasured by electron diffraction.

Table II. Calculated mean inner potential V_0, corrected value $V_0+C^r_{00}$, and mean inner potential obtained by electron diffraction V_{0e}.

	$-V_0$	$-C^r_{00}$	$-(V_0+C^r_{00})$	$-V_{0e}$
NaCl	7.1	0.4	7.5	7.3
NaF	7.4	0.5	7.9	8.3
NaBr	8.2	0.5	8.7	7.5
KCl	6.7	0.4	7.1	8.5
ZnS	10.6	0.6	11.2	12.5
PbS	11.2	0.6	11.8	13.2
PbO	11.9	0.7	12.6	12.3
ZnO	12.0	0.7	12.7	12.3
MgO	12.8	0.8	13.6	15.6

Values of V_0 for crystals except MgO are those calculated by Miyake[17]. Value of V_0 for MgO is from the paper of Honjo and Mihama[3]. Value of C^r_{00} for MgO is calculated from (49) using the above value of V_0 and, therefore, different from that given in Table I.

The author would like to thank Prof. R. Jyeda for his guidance and Dr. Y. Kainuma or his helpful discussions.

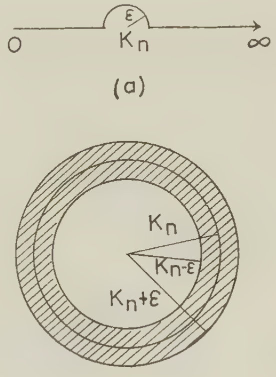
Appendix

(I) *Derivation of (19)*

Substituting (18) into (17) we find

$$C_{hg}=-\frac{m}{4\pi^3\hbar^2V}$$
$$\times\sum_{n\neq0}\iint\exp(-i\boldsymbol{K}_h\cdot\boldsymbol{r}+i\boldsymbol{K}_g\cdot\boldsymbol{r}')H'_{0n}(\boldsymbol{r})H'_{n0}(\boldsymbol{r}')$$
$$\times\int\frac{\exp[i\boldsymbol{K}'\cdot(\boldsymbol{r}-\boldsymbol{r}')]}{K'^2-k_n^2}d\boldsymbol{K}'d\boldsymbol{r}d\boldsymbol{r}'$$
$$=-\frac{m}{4\pi^3\hbar^2V}$$
$$\times\sum_{n\neq0}\int\frac{E_{0n}(\boldsymbol{K}_h-\boldsymbol{K}')E_{n0}(\boldsymbol{K}'-\boldsymbol{K}_h)}{K'^2-k_n^2}d\boldsymbol{K}'\ . \tag{A.1}$$

The last step is obtained by changing the order of integration and with definition (21).



(a)

(b)

Fig. 4.

The volume element is $d\boldsymbol{K}'=\rho^2d\rho d\Omega$, and integration for ρ is carried out along the contour shown in Fig. 4a, which is devided into two parts, one is the part on the real axis and the other the semicircle around k_n[18]. The integration over the real axis results in a volume integral over the whole $\boldsymbol{K}'$-space except a shell shaded in Fig. 4b. In the limit of $\varepsilon\to0$ this integral becomes C^r_{hg} as defined by (20).

The integration along the semicircle becomes half the residue at $\rho=k_n$ in the limit of $\varepsilon\to0$. Thus the result is

$$\int\frac{[E_{0n}(\boldsymbol{K}_h-\boldsymbol{K}')E_{n0}(\boldsymbol{K}'-\boldsymbol{K}_g)]_{\rho=k_n}}{2k_n}k_n^2d\Omega$$
$$=\int_{|K'|=k_n}\frac{E_{0n}(\boldsymbol{K}_h-\boldsymbol{K}')E_{n0}(\boldsymbol{K}'-\boldsymbol{K}_g)}{2k_n}d\sigma(\boldsymbol{K}')\ .$$

This gives C^i_{hg} defined in (23).

(II) *Derivation of (36) (37).*

Using the formula[19]

$$\int \frac{\exp(i\boldsymbol{K}\cdot\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{r}'|}\,d\boldsymbol{r}' = \frac{4\pi}{\boldsymbol{K}^2}\exp(i\boldsymbol{K}\cdot\boldsymbol{r})\ , \qquad (A.2)$$

(21) can be transformed into

$$\begin{aligned} &E_{0n}(\boldsymbol{K}_h-\boldsymbol{K}') \\ &= \frac{4\pi e^2}{|\boldsymbol{K}_h-\boldsymbol{K}'|^2}\int a_n^*\Big(\sum_j \exp\left[-i(\boldsymbol{K}_h-\boldsymbol{K}')\cdot\boldsymbol{r}_j\right]\Big)a_0 d\tau \\ &\equiv \frac{4\pi e^2}{|\boldsymbol{K}_h-\boldsymbol{K}'|}\,F_{0n}(\boldsymbol{K}_h-\boldsymbol{K}')\ . \qquad (A.3) \end{aligned}$$

Thus

$$\begin{aligned} &C^r_{hg} = -\frac{8E_H}{\pi V} \\ &\times \sum_{n\neq 0}\iiint \frac{F_{0n}(\boldsymbol{K}_h-\boldsymbol{K}')F_{n0}(\boldsymbol{K}'-\boldsymbol{K}_g)}{(\boldsymbol{K}'^2-k_n^2)(\boldsymbol{K}_h-\boldsymbol{K}')^2(\boldsymbol{K}_g-\boldsymbol{K}')^2}\,d\tau(\boldsymbol{K}') \\ &\qquad (A.4) \end{aligned}$$

$$\begin{aligned} &C^i_{hg} = -\frac{4E_H}{V} \\ &\times \sum_{n\neq 0}\iint \frac{F_{0n}(\boldsymbol{K}_h-\boldsymbol{K}')\,F_{n0}(\boldsymbol{K}'-\boldsymbol{K}_g)}{k_n(\boldsymbol{K}_h-\boldsymbol{K}')^2(\boldsymbol{K}_g-\boldsymbol{K}')^2}\,d\sigma(\boldsymbol{K}') \qquad (A.5) \end{aligned}$$

where $E_H = me^4/(2\hbar^2)$ is the atomic unit of energy. Since E_n-E_0 is small compared with the kinetic energy of the incident electron $\hbar^2k_0^2/(2m)$, we have from (7)

$$k_n = k_0 - m(E_n-E_0)/(\hbar^2 k_0)\ . \qquad (A.6)$$

We can obtain a simplified expression for C_{hg}, if we replace E_n-E_0 by an appropriately weighted mean of E_n-E_0, say $\overline{\varDelta E}$. According to Koppe[13)] the order of this mean excitation energy $\overline{\varDelta E}$ is roughly a half the ionization energy. Then using $\bar{k}$ which is given by

$$\bar{k} = k_0 - (m/\hbar^2 k_0)\overline{\varDelta E}\ , \qquad (A.7)$$

we have

$$\begin{aligned} &C^r_{hg} = -\frac{8E_H}{\pi V} \\ &\times \iiint \frac{S(\boldsymbol{K}_h-\boldsymbol{K}'\ \boldsymbol{K}_g-\boldsymbol{K}')}{(\boldsymbol{K}'^2-\bar{k}^2)(\boldsymbol{K}_h-\boldsymbol{K}')^2(\boldsymbol{K}_g-\boldsymbol{K}')^2}\,d\tau(\boldsymbol{K}') \\ &\qquad (A.8) \end{aligned}$$

$$\begin{aligned} &C^i_{hg} = -\frac{4E_H}{V} \\ &\times \iint_{|\boldsymbol{K}'|=\bar{k}} \frac{S(\boldsymbol{K}_h-\boldsymbol{K}',\ \boldsymbol{K}_g-\boldsymbol{K}')}{\bar{k}(\boldsymbol{K}_h-\boldsymbol{K}')^2(\boldsymbol{K}_g-\boldsymbol{K}')^2}\,d\sigma(\boldsymbol{K}') \qquad (A.9) \end{aligned}$$

where $S(\boldsymbol{K}_h-\boldsymbol{K}',\ \boldsymbol{K}_g-\boldsymbol{K}')$ is given by

$$\begin{aligned} &S(\boldsymbol{K}_h-\boldsymbol{K}',\ \boldsymbol{K}_g-\boldsymbol{K}') \\ &\quad = \sum_{n\neq 0} F_{0n}(\boldsymbol{K}_h-\boldsymbol{K}')F_{n0}(\boldsymbol{K}'-\boldsymbol{K}_g)\ . \qquad (A.10) \end{aligned}$$

The functions S was calculated by Kainuma[14)] in his study on Kikuchi patterns. According to him,

$$\begin{aligned} &S(\boldsymbol{K}_h-\boldsymbol{K}',\ \boldsymbol{K}_g-\boldsymbol{K}') \\ &\quad = N\sum_l s_l(2\pi(\boldsymbol{h}-\boldsymbol{g}),\ \boldsymbol{K}-\boldsymbol{K}'+\pi(\boldsymbol{h}+\boldsymbol{g})) \\ &\qquad \times \exp(-2\pi i(\boldsymbol{h}-\boldsymbol{g})\cdot\boldsymbol{R}_l)\ , \qquad (A.1 \end{aligned}$$

where $\boldsymbol{R}_l$ is the position of the lth atom i an unit cell relative to the lattice point, ar the sum is over the whole atoms in the un cell. The function s_l is that is called b Kainuma the atomic scattering factor fo Kikuchi lines. In the case of all spins couple it is given by (39), if we neglect overlappi of atomic orbitals between neighbor atoms[14,

(III) *Calculation of* $s_l(2\pi\boldsymbol{h},\ \boldsymbol{K}-\boldsymbol{K}'+\pi\boldsymbol{h})$ *usin Thomas-Fermi model.*

Equation (39) can be written as

$$\begin{aligned} s_l(\boldsymbol{Q},\boldsymbol{q}) = 2\iint |\rho_l(\boldsymbol{r},\boldsymbol{r}')|^2 \Big\{&\exp\Big(-i\frac{\boldsymbol{Q}}{2}\cdot(\boldsymbol{r}-\boldsymbol{r}' \\ &- \exp(-i\boldsymbol{q}\cdot(\boldsymbol{r}-\boldsymbol{r}'))\Big\} \\ &\times \exp\Big(i\frac{\boldsymbol{Q}}{2}\cdot(\boldsymbol{r}+\boldsymbol{r}')\Big)d\boldsymbol{r}d\boldsymbol{r}'\ , \qquad (A.1 \end{aligned}$$

where we put

$$\left.\begin{aligned} &\boldsymbol{Q} = 2\pi(\boldsymbol{h}-\boldsymbol{g}) \\ &\boldsymbol{g} = \boldsymbol{K}-\boldsymbol{K}'+\pi(\boldsymbol{h}+\boldsymbol{g})\ . \end{aligned}\right\} \qquad (A.1$$

In the Thomas-Fermi model, we put

$$\rho(\boldsymbol{r},\boldsymbol{r}') = \frac{1}{h^3}\int d\boldsymbol{p}f(\boldsymbol{p})\exp\left\{\frac{i}{\hbar}\boldsymbol{p}\cdot(\boldsymbol{r}-\boldsymbol{r}')\right\} \qquad (A.1$$

where

$$\left.\begin{aligned} &f(\boldsymbol{P}) = 1 \quad \text{for} \quad |\boldsymbol{P}| < P_m\Big(\frac{\boldsymbol{r}+\boldsymbol{r}'}{2}\Big) \\ &f(\boldsymbol{P}) = 0 \quad \text{for} \quad |\boldsymbol{P}| > P_m\Big(\frac{\boldsymbol{r}+\boldsymbol{r}'}{2}\Big) \end{aligned}\right\} \qquad (A.1$$

and $P_m((\boldsymbol{r}+\boldsymbol{r}')/2)$ is maximun of the momentu allowed at the point $(\boldsymbol{r}+\boldsymbol{r}')/2$. Then $s_l(\boldsymbol{Q},$ becomes

$$s_l(\boldsymbol{Q},\boldsymbol{q}) = Z_l(G(u_l, v_{0l}) - G(u_l, v_l))\ . \qquad (A.1$$

Here,

$$\begin{aligned} &G(u, v) \\ &= \int_0^{x_0}\Big(v-\sqrt{\frac{\varphi(x)}{x}}\Big)^2\Big(\frac{1}{2}v+\sqrt{\frac{\varphi(x)}{x}}\Big)\frac{\sin ux}{ux}x^2dx \\ &\qquad (A.1 \end{aligned}$$

where $\varphi(x)$ is the function given by Fermi an

$$u_l = a_l|\boldsymbol{Q}|\ , \qquad v_l = b_l|\boldsymbol{q}|\ , \qquad v_{0l} = b_l\left|\frac{\boldsymbol{Q}}{2}\right|\ ,$$

with a_l, b_l defined by (53) and (43). Th upper limit of integration x_0 is determined b $v = [\varphi(x_0)/x_0]^{1/2}$.

For $\boldsymbol{Q}=0$, we have

$$s_l(0, \boldsymbol{q}) = Z_l - Z_l G(v) \,, \tag{A.18}$$

vhich is the same function obtained by ewilogua[12]. Our expression for s_l, (A.16), s a little different from that given by Kai-uma since we applied the approximation A.14) to both the term in (39). Our procedure s needed to guarantee that s_l vanishes when $\boldsymbol{K}' = \boldsymbol{K}_h$ or $\boldsymbol{K}' = \boldsymbol{K}_g$.

IV) *Derivation of (46), (47).*

Coefficient C^i_{00} is given by (41),

$$C^i_{00} = -\frac{4E_H}{v_0 k_0} \sum_l \iint \frac{s_l(0, \boldsymbol{q})}{|\boldsymbol{K}-\boldsymbol{K}'|^4} d\sigma(\boldsymbol{K}') \,. \tag{A.19}$$

ince the contribution to the integral is al-nost from the neighborhood of $\boldsymbol{K}$, we can eplace the sphere $|\boldsymbol{K}'| = k$ by its tangential lane. Then, we obtain immediately (46),

$$C^i_{00} = -\frac{8\pi E_H}{v_0 k_0} \sum_l B_l \log \frac{q_l^*}{q_0} \,,$$

vhere

$$q_0 = |\boldsymbol{K}| - \bar{k} \,. \tag{A.20}$$

For coefficient C^r_{00} given by (42)

$$C^r_{00} = -\frac{8E_H}{\pi v_0} \sum_l \iiint \frac{s_l(0, \boldsymbol{q})}{(\boldsymbol{K}'^2 - \bar{k}^2)(\boldsymbol{K}-\boldsymbol{K}')^4} d\tau(\boldsymbol{K}') \,, \tag{A.21}$$

we can replace the $|\boldsymbol{K}'| = \bar{k}$ by its tangential lane, and put

$$\boldsymbol{K}'^2 - \bar{k}^2 \doteqdot 2k_0(|\boldsymbol{K}'| - \bar{k})$$

since

$$q_l^* \ll \bar{k} \,.$$

Then, using the cylindrical coordinates, we have

$$C^r_{00} = -\frac{4E_H}{\pi v_0 k_0} \left(\sum_l B_l \iint \frac{2\pi r dr dz}{(z + k_0 - \bar{k})(r^2 + z^2)} \right) .$$

The integral becomes after integration of r

$$2\pi \int_{-q_l^*}^{q_l^*} \frac{\log (q_l^*/|z|)}{z + k_0 - \bar{k}} dz \,.$$

This integral can be shown by means of con-tour integration to be equal to

$$2\pi[\pi^2/2 - 2\sinh\{(K_0 - \bar{k})/q_l^*\}] \,.$$

Thus we have, neglecting the small quantity f order $(K_0 - \bar{k})/q_l^*$,

$$C^r_{00} = -\frac{4\pi^2 E_H (\sum B_l)}{v_0 k_0} \,. \tag{A.22}$$

V) *Deviation of (52), (54).*

The tangent $T_l(\boldsymbol{h})$ of $s_l(Q, \boldsymbol{q})$ at $\boldsymbol{q} = 0$, is btained from (A.17)

$$\begin{aligned} T_l(\boldsymbol{h}) &= -Z_l \left(\frac{\partial G(u, v)}{\partial v} \right)_{v=0} b_l \\ &= \frac{3}{2} b_l Z_l \int_0^\infty \frac{\varphi(x)}{x} \frac{\sin u_l x}{u_l x} x^2 dx \end{aligned} \tag{A.23}$$

which is (51).

Expression (50) for C^i_{h0} becomes, by the use of the approximation (51),

$$\begin{aligned} C^i_{h0} = &-\frac{4E_H}{v_0 k_0} \sum_l \exp(i2\pi \boldsymbol{h} \cdot \boldsymbol{R}_l) T_l(\boldsymbol{h}) \\ &\times \iint \frac{|\boldsymbol{K}-\boldsymbol{K}'+\pi\boldsymbol{h}| - |\pi\boldsymbol{h}|}{(\boldsymbol{K}-\boldsymbol{K}')^2(\boldsymbol{K}_h-\boldsymbol{K}')^2} d\sigma(\boldsymbol{K}') \,. \end{aligned}$$

Since the Bragg angle is usually small, we can consider the surface of the integration to be a plane as in the above case. In the case of $|\boldsymbol{K}_h| = |\boldsymbol{K}|$, the above integral becomes

$$\begin{aligned} &\int_0^\infty \int_0^{2\pi} \frac{\{(r^2+q_0^2)^{1/2} - h\} r dr d\theta}{(r^2+q_0^2+h^2) - 4r^2h^2 \cos\theta} \\ &= 2\pi \int_{q_0}^\infty \frac{(q-h) q dq}{(q^2+h^2)\{(q^2-h^2)^2 + 4q_0^2 h^2\}^{1/2}} \end{aligned}$$

where $q_0 = |\boldsymbol{K}| - \bar{k}$ and $h = |\pi\boldsymbol{h}|$. We can neglect q_0 in the above integral, since the error caused by the neglect is very small as long as $q_0 \ll h$. Then, the integration is easily carried out with the result

$$C^i_{h0} = -\frac{8\pi E_H}{v_0 k_0} \frac{\log 2}{|2\pi\boldsymbol{h}|} \sum_l T_l(\boldsymbol{h}) \exp(2\pi i \boldsymbol{h} \cdot \boldsymbol{R}_l) \,. \tag{A.24}$$

Though we have assumed $|\boldsymbol{K}_h| = |\boldsymbol{K}|$, this assumption is not necessary because the final result is obtained with the neglect of q_0. We can consider the formula (A.24) holds as long as $||\boldsymbol{K}| - \bar{k}|$ and $||\boldsymbol{K}_h| - \bar{k}|$ are both $\ll |\pi\boldsymbol{h}|$.

Fine Structures of X-ray Absorption Spectra of Cobalt in the Face Centered Cubic Lattice and Close-packed Hexagonal Lattice

By Masao SAWADA, Kenjiro TSUTSUMI and Akira HAYASE

Department of Physics, Faculty of Science, University of Osaka

(Received February 18, 1957)

Samples of cobalt of the α-modification (hexagonal close-packed lattice) and the β-modification (face centered cubic lattice) and their mixtures were prepared, and their crystal structures were examined by means of the X-ray diffraction method. Fine structures of the X-ray K absorption spectra of these cobalt samples were photographed by a bent crystal spectrograph and the mass absorption coefficients in the X-ray K absorption spectral region were measured by using the North American Philips Diffraction Unit and Wide Range Spectrometer modified to a tube spectrometer with a Geiger-Müller counter. By comparing these photometer curves of these spectrograms or the recorded curves, the fine structures of the absorption spectra of these cobalt samples were found to be very similar. The wavelength values and the mass absorption coefficient of the fine structures of the absorption spectra also nearly coincided within experimental errors, and thus the position and the form of the maximum and minimum of these structures were found to be the same. We conclude that this is due to the fact that atoms in the α-cobalt have the same immediate surroundings as those in the β-cobalt

§ 1. Introduction

According to Kronig's theory[1] of the fine structure of X-ray K absorption edge in solid crystalline substances, the phenomenon of the fluctuation of the absorption coefficient in the short wave-length side of the absorption edge (so-called "fine structure") is as follows. The X-rays are absorbed by the electrons, which make transitions from the X-ray K levels to empty levels lying above the Fermi distribution. These empty levels are grouped into zones and exist as forbidden and allowed bands caused by the periodic field in the crystal. As the absorption coefficient is proportional to the product of the transition probability and the state density, a fine structure occurs. From Kronig's theory it must concluded that the fine structure should highly dependent upon the type of the cryst lattice in which the absorption element is im bedded. This can experimentally be teste in several ways[2] and many peculiarities the fine structure of X-ray absorption edge can fully be understood on the basis Kronig's theory. However in some specia cases, there seemed to be at first sight som discrepancy between theory and experimen and it has been demonstrated that the im mediate surroundings in the crystal lattice the atoms in question are also of great im portance.[3] Rigorously speaking, we may sa that the fine structures are identical (apa from the usual reduction) only for elements which have identical positions in the same crystal or in the same type of the crystal lattice. However, the surroundings of atoms which crystallize in a cubic close-packed crystal lattice are very similar to those of atoms which crystallize in a hexagonal close-packed crystal lattice, and it is therefore of some importance to compare the fine structures of these two kinds of crysral lattices. Thus, Coster[4] compared the absorption edge of Ti (hexagonal) to that of Ca (f.c.c.) and also the edge of α-brass (f. c. c.) to that of ε-brass (hexagonal) and concluded that the positions of the maximum and minimum relative to the main edges are the same. But there remained still some typical differences in the forms of the maximum and minimum of the photometer curves for these two cases, which had to be ascribed to the difference between the cubic and hexagonal close-packed lattices. However, Ti and ε-brass are not exactly hexagonal closed-packed ($c/a=1.59$ for Ti and 1.56 for ε-brass respectively instead of 1.63 for the ideal close-packed hexagonal), and the distance of the neighboring atoms are not the same in these cases of the hexagonal close-packed and face centered cubic lattices, though some reduction can be done at the comparison. Besides, the atomic numbers of the two elements are different in the case of Ti (22) and Ca (20), and in the case of α-brass and ε-brass, the surrounding atoms in the crystal lattices of the atoms in question consist of two kinds of element, Zn (30) and Cu (29).

The fact that the cobalt metal has two allotropic modifications, α (hexagonal close-packed lattice) and β (face contered cubic lattice), was found by A. W. Hull,[5] and it was ascertained later by H. Masumoto[6] and others that each modification has its own stable temperature region. Though these facts have already been well-known, it has been experienced actuality by many investigators that the β-modification (stable at high temperatures) is often observed at room temperature in a mixed state with the α-modification. For instance, a sample of cobalt prepared by electrolysis, reducing the oxide in hydrogen at 600°C, crystallized almost in the face centered cubic lattice.[5] Similar phenomena have been reported by several investigators also in the case of electrodeposited cobalt, which suggests itself that the electrodeposited cobalt is a mixture of the hexagonal close-packed and face centered cubic crystals, their contents differing in accordance with the electrolytic condition. Okuno[7] investigated the crystal structure of the cobalt electrodeposited from cobalt-sulfate solution at various electrolytic current densities and with various P_H of the solution. He concluded that, at low current densities and high P_H, the deposits are always of the hexagonal close-packed lattice, while in all other cases the deposits are always of mixtures of the hexagonal close-packed lattice and the face centered cubic lattice, in general the former modification tending to deposit more easily at high P_H than at law P_H and *vice versa* for the latter modification. In the face centered cubic cobalt, the lattice constant is 3.554Å and the distance to the nearest neighboring atom is 2.514Å, while in the hexagonal close-packed cobalt the lattice constants are $a=2.514$Å, $c=4.105$Å, corresponding to the axial ratio $a:c=1:1.633$ (which corresponds to that of the ideal hexagonal close-packed lattice), and the distance to the nearest neighbor is 2.514 Å, exactly being equal to that of the face centered cubic cobalt. For this reason we compared directly, without reduction, the fine structures of the X-ray K absorption edges of these two modifications of cobalt.

§ 2. Experiments

Preparation of the specimen. Following Okuno's method, we made electrolyte of the following composition: $CoSO_4 \cdot 7H_2O$ ··· 150 g, NaCl···6 g, H_3BO_3···13 g and water···1000 cc. The P_H of the electrolyte was regulated with sulfuric acid or ammonia-water. The electrodeposition was carried out in a 500 cc beaker kept in the water bath held at 30°C. We used a stainless steel cathode 4.5 cm wide immersed to a depth of 7 cm placed 4 cm apart from a cobalt anode. The contents of the α-cobalt and β-cobalt depended on the current density and P_H of the electrolyte. These conditions are shown in Table I. The time of electrolysis was 0.2–1 hour to obtain a suitable thickness for the X-ray absorption spectrum. Some of them were annealed in a vaccum furnace at 600°C for 3–5 hours in order to increase the content of β-cobalt.

sheets were pasted one over the other.

The radius of the powder camera was 57.3 mm. The X-ray tube with a cobalt-target was loaded with 30 kV, 10 mA. The time of exposure ranged from about 2 to 3 hours. The specimens were rotated in order to avoid the influence of preferred orientations. Photo. 1 shows these diffraction patterns. The contents of α-cobalt and β-cobalt were compared by the intensities of the diffraction lines (101) K_α from α-cobalt and (200) K_α from β-cobalt following Okuno's method,⁷⁾ that is, (1) for almost all β, α (101) K_α is weak as compared even with β (200) K_β; (2) for $\beta > \alpha$, α (101) K_α is fainter than β (200) K_α but more intense than β (200) K_β; (3) for $\beta \sim \alpha$, α (101) K_α has about the same intensity as β (200) K_α. For opposite inequalities to the above apply similar criteria. The intensities of diffraction lines were also measured by the Geiger-counter method using the North American Philips Diffraction Unit and Wide Range Goniometer.

Absorption spectrum. The fine structures of X-ray *K* absorption spectra of cobalt were taken with a bent crystal focusing spectrograph of the Cauchois type. The diameter of the focal circule was 20 cm, and the second order reflection by (100) plane of a quartz crystal was used. Generally a current 10 mA at 10 kV was passed through an ion-type X-ray tube. The time of exposure was varied from 15 to 20 hours. The spectrograms and the microphotometer curves of the *K* absorption spectral region of cobalt are reproduced in Photo. 2 and Photo. 3. Photo. 3a shows the microphotometer curves taken by the photometer with a rather large slit width (0.1 mm) which was used in order to avoid the influence of the grain size of the photographic plate, and Photo. 3b shows the microphotometer curves taken by a photometer with a slit 0.025 mm wide in order to measure exactly the fine structure near the absorption edge. The measurements of wavelengths were carried out referring to the Co K_{α_1} and Cu K_{α_2} lines photographed on the same plate.

* This value is not the mass absorption coeffi- ent at the principal *K* edge of cobalt but is that the wavelength of 1610 x. u.

The unit is mechanically so arranged as to maintain a 1:2 ratio of rotational speed between the crystal holder of the center of the spectrometer and Geiger-Müller counter as required for Bragg reflections. We used this unit as the tube spectrometer described by Coster and De Lang.[9] The details of our modified method will be published in another paper.[10] The divergency of the slit system of this instrument is about 0.0004 radians. LiF is used as a reflecting crystal. As we can directly measure the primary X-ray intensity I_0 and the transmitted X-ray intensity I, it is easier to get the mass absorption coefficient μ/ρ from the equation

$$\frac{\mu}{\rho}=\frac{1}{\rho x}(\log I_0-\log I)\,,$$

where x and ρ are the thickness and density of the material, respectively, and I_0 is the intensity of the spectrum without the absorber in the same condition in which the absorption spectrum is recorded. Now ρx is about 7.7 mg/cm² in the case of $\beta>\alpha$-cobalt and 8.7 mg/cm² in the case of α-cobalt. Fig. 1 shows the μ/ρ curves near the absorption edges of $\beta>\alpha$-cobalt and α-cobalt thus measured and photo. 4 shows the recorded curves of the fine structures in the X-ray *K* absorption spectral region of these cobalts. Table IV shows the wavelength values and values of the mass absorption coefficients obtained by this method.

§ 3. Results and Discussions

By comparing photometer curves in Photo. 3 or recorded curves in Photo. 4, it will be seen that the fine structures of the absorption spectra of these sorts of cobalt are very similar. The wavelength values and the mass absorption coefficients of these fine structures also nearly coincide within the limit of experimental errors as seen from Table II, III and IV. In our case, the form of the maximum and minimum of the fine structures of the absorption edges are also the same contrary to Coster's case. This seems to be due to the fact mentioned in introduction. α-cobalt is of an ideal close-packed hexagonal lattice, the neighboring atoms being of the same kind and the distance to the nearest neighbor being equal to that in β-cobalt (f.c.c.). This is clearly seen in Table V which gives the successive shells of atoms in the case of α- and β-cobalt. The number of surrounding atoms and their distances from the central atom are identical in the first two shells. In our previous paper[11] on the fine structures of X-ray absorption spectra of amorphous substances, we found that the fine structures of the absorption spectra in amorphous state have similar forms and positions to those in substances which have undergone crystallization. We considered such results to be due to the fact that an amorphous substance is not an irregular assembly of atoms but has a certain definite structure, i.e., it has the same surroundings of atoms as in its crystalline state. Kiestra[12] remarks that the fine structure is determined by the immediate surroundings of the atom in question in t region about 40 eV to 150 eV from the absor tion edge. This is well supported by o experimental results.

Table V. Different successive shells of atom surrounding a definite cobalt atom in a close-packed hexagonal and face centered cubic lattice.

Variation of Electron Diffraction Intensity with Crystal Size

By Shigeya KUWABARA

Department of Physics, Faculty of Science, Hiroshima University, Hiroshima, Japan

(Received September 12, 1956)

Intensity of electron diffraction Debye-Scherrer rings was studied for evaporated films of Al, Ag, Au, NaCl, KCl and MgO of various thicknesses and crystal sizes. The observed intensity deviates from the value calculated by the kinematical theory of diffraction at crystal sizes less than 100 Å for all the materials examined. This result agrees with the conclusion of Blackman's dynamical theory (Proc. Roy. Soc. **173** (1939) 68).

Yamzin & Pinsker's conclusion (Dokl. Akad. Nauk **65** (1949) 645) that the kinematical theory can hold for films of thickness up to 500 Å, apparently contradicts the present result. It was pointed out that Yamzin & Pinsker's conclusion resulted from the fact that they neglected the effect of the temperature factor.

§1. Introduction

Intensity of electron diffraction Debye-Scherrer rings was first studied by G. P. Thomson[1] and later by several investigators[2-7]. Thomson, Mark and Wierl[2] and Shirai[3] found that the observed intensity is proportional to the square of structure factor in accordance with the kinematical theory, but Ornstein *et al.*[4,5] and Friesen and Lennander[6,7] found that the observed intensity deviates from the kinematical value. Blackman[8] treated these results theoretically and concluded that the deviation found by Ornstein *et al.* is caused by the dynamical effect of the diffraction.

In the diffraction of electrons, which interact with matter very strongly, the kinematical theory fails and the dynamical theory must be refered to even for comparatively small crystals. According to Blackman, the crystal size of Thomson's specimens was small enough for the holding of the kinematical theory. However, in the specimen of Mark and Wierl and Ornstein *et al.* the crystal size was not so small, as was indicated by the sharpness of their Debye-Scherrer rings. Blackman pointed out that the deviation found by Ornstein *et al.* could be explained by the dynamical theory but the agreement with the kinematical theory found by Mark & Wierl could not be explained.

Recently, crystal analysis by electron diffraction was developed mainly by Soviet investigators[9]. They assumed the holding of the kinematical theory, and in order to examine the assumption, Yamzin[10] and Yamzin and Pinsker[11] carried out an experiment similar to that of G. P. Thomson. Specimen studied by Yamzin were Al, Cu, Ag, Au, Zn and Sn, and the accelerating voltage was from 38 to 56 kV. Although he measured crystal size, he stated his conclusion not in terms of crystal size but in terms of film thickness. He concluded that the kinematical theory holds for thickness less than 500Å, except for the material so heavy as Au. According to him, the apparent failure of the kinematical theory as observed by Ornstein *et al.*[4,5] and Friesen and Lennander[6] might be attributed to textures in the specimen films. Based upon the experimental result of Yamzin, Pinsker[12] concluded that Blackman's treatment is not sound. On the other hand, the dynamical theory was proved by many experiments[13] and we could not understand why Blackman's treatment is not sound.

The aim of the present investigation is to elucidate this contradiction. Specimens studied were Al, Ag, Au, NaCl, KCl and the accelerating voltage was from 32 to 60kV. First, the relation between intensity and thickness was studied to check the result of Yamzin and Pinsker. Against their conclusion it was found that the dynamical effect appears for films thinner than 100Å for all the materials examined. Next, the relation between intensity and crystal size was studied and it was found that the intensity varies with crystal size in accordance with Blackman's theory.

In analysing the intensity data the temperature effect, which was neglected by Yamzin and Blackman, was taken into account. The contradicting conclusions of Yamzin and Pinsker seems to have been resulted from the neglecting of the temperature effect.

§ 2. Experimentals

Specimens. Specimen films of Al, Ag, Au, NaCl and KCl were prepared by evaporation in high vacua of the order of 10^{-5} mmHg. Substrate for sepcimen was collodion film put on the standard specimen grid for electron microscope. The range of thickness was 100–1000 Å for Al, 10–150 Å for Ag and Au, and 100–150 Å for NaCl and KCl. Specimen film films of MgO were prepared by evaporating Mg in low vacua of the order of 10^{-3} mmHg. Thus the evaporated Mg, which would produce Mg-film of thickness from 50 to 300 Å, was oxidized into MgO as confirmed by electron diffraction. If the condition of evaporation was kept the same, the crystal size increased with film thickness. To control the crystal size at a given film thickness, the rate of evaporation and the temperature were changed. The time of evaporation was varied from 1 seconds to 10 minutes. The temperature the substrate was changed from room tempera ture to 230°C. The crystal size was large for high substrate temperature and high evap ration rate. To prevent the crystal growt after the evaporation, film was quickly coole in vacuum by taking it away from the furna after the evaporation.

Prefered orientation was examined carefull by tilting the specimen film up to about 40° Diffraction patterns were photometered alon two directions, one is parallel and the othe perpendicular to the tilting axis. For Al, A Au and MgO no prefered orientation was foun while for NaCl and KCl there was a tren that (001) plane becomes parallel to the sub strate film plane.

Diffraction equipment. The electron diffrac tion equipment used in the present experimen was constructed in our laboratory. The specimen-plate distance was 338 mm. The ac celerating voltage was from 32 to 60 kV.

Method of intensity measurement. Intensity of Debye-Scherrer rings was measured by the photographic method which was almost the same as that of Karle and Karle[14].

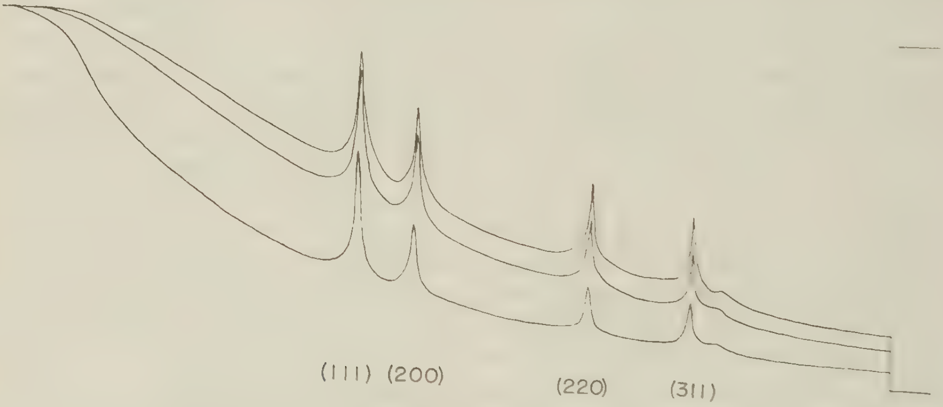

Fig. 1. Microphotometer curves of Debye-Scherrer rings of Al (Accelerating voltage 48 kV).

Fig. 1 shows an example of microphotometer curves. In this example three records with different exposure times are shown.

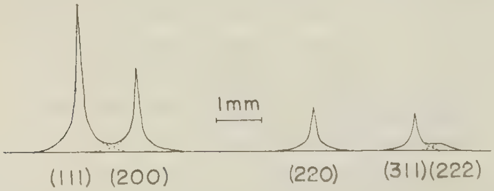

Fig. 2. Intensity curves of Debye-Scherrer rings obtained from Fig. 1.

Intensity curves of Debye-Scherrer rings were obtained by substracting the background from the total intensity.

For very thin specimen, the effect of halos due to collodion film was substracted by the method described by Kimoto[15]. For thicker specimen the effect of hales was negligible. Fig. 2 shows an example of intensity curves obtained from Fig. 1.

Determination of crystal size. Integral breadth B of a Debye-Scherrer ring is defined by

$$B=\int P(r)\,dr/P_m-B_0\;, \tag{1}$$

where r is the radius, $P(r)$ the intensity, P_m the maximum value of $P(r)$ and B_0 the diameter of the incident spot (0.13 mm).

Crystal size $\bar{A}$ is calculated by

$$\bar{A}=\lambda L/B\cos\theta\;,^{*} \tag{2}$$

where L is the specimen-plate distance (338 mm) and θ is Bragg angle which is so small that $\cos\theta$ can be taken as equal to unity. An example of crystal size and integrated intensity determination is shown in Table I, which was obtained from the microphotometer curve Fig. 1.

Table I. Example of integrated intensity, integral breadth and crystal size of Al (Accelerating voltage 48kV).

	hkl	(111)	(200)	(220)	(311)	mean
Integrated intensity		48_7	20_1	100	9_1	
		43_8	22_1	100	9_0	46_5 20_8 100 9_0
		47_2	20_2	100	8^8	
Integral breadth B (mm)		0.11_9	0.11_4	0.12_0	0.10_7	
		0.10_3	0.12_6	0.09_8	0.10_2	0.11_5
		0.11_7	0.14_5	0.10_6	0.12_5	
Crystal size (Å)		15_4	16_0	15_3	17_1	
		17_8	14_5	18_7	17_9	16_0
		15_6	12_6	17_3	14_6	

Determination of integrated intensity. Integrated intensity I was obtained by measuring the area of the intensity curve. For all specimens (220)-intensity was normalized to 100.

§ 3. Theoretical Formulas

In the kinematical theory the integrated intensity of a Debye-Scherrer ring is given by

$$I_h{}^K \backsim |S_h|^2\cdot p\cdot e^{-2M}/\theta^2\;, \tag{3}$$

while in the dynamical theory it is given by

$$I_h{}^D \backsim |S_h|\cdot p\cdot e^{-M}/\theta^2\;, \tag{4}$$

where the superfixes K and D indicate kinematical and dynamical, respectively; h is the index of a ring, S_h the structure factor for electrons and p the lattice plane multiplicity. Factors e^{-2M} and e^{-M} are the temperature factors for the kinematical and dynamical cases, respectively. Yamzin mentioned that the temperature effect is so small that it can be neglected for low order reflections. Actually, however, it is not small as is shown in Table II[17]. Thus in the following section the temperature effect is taken into account.

Table II. Calculated values of temperature factor

Specimen		(111)	(200)	(220)	(311)	(400)	(420)
Al	e^{-2M}	0.92_1	0.89_6	0.80_3	0.74_0	0.64_4	0.58_9
	e^{-M}	0.96_0	0.94_6	0.89_6	0.86_0	0.80_3	0.76_7
Ag	e^{-2M}	0.93_5	0.91_4	0.83_3	0.78_0	0.69_5	0.63_4
	e^{-M}	0.96_6	0.95_6	0.91_3	0.88_3	0.83_2	0.79_7
Au	e^{-2M}	0.94_8	0.93_1	0.86_7	0.82_3	0.75_2	0.69_8
	e^{-M}	0.97_4	0.96_5	9.93_2	0.90_7	0.86_8	0.83_5
NaCl	e^{-2M}	0.93_0	0.90_9	0.82_1	0.77_0	0.68_3	0.62_0
	e^{-M}	0.96_5	0.95_3	0.90_8	0.87_8	0.82_6	0.78_7
KCl	e^{-2M}	0.93_7	0.91_5	0.83_7	0.78_3	0.70_2	0.64_0
	e^{-M}	0.96_8	0.95_6	0.91_5	0.88_5	0.83_8	0.80_0

According to Blackman[8], the integrated intensity for parallel sided single crystal is given by

$$I \backsim I_0|S_h|\lambda^2/(v_0\theta)\int_0^A J_0(2x)\,dx\;, \tag{5}$$

where v_0 is the volume of the unit cell, J_0 the zeroth order Bessel function and

$$A=|S_h|D\lambda/v_0\;, \tag{6}$$

where D means the thickness of the single crystal. For small values of A, Eq. (5) becomes

$$I \backsim I_0|S_h|^2 D\lambda^3/(v_0{}^2\theta)\;, \tag{5$'$}$$

which is characteristic of the kinematical theory. For large value of A Eq. (5) becomes

$$I \backsim I_0|S_h|\lambda^2/(2v_0\theta)\;. \tag{5$''$}$$

Adopting Eq. (5), the intensity of Debye-Scherrer rings becomes

$$I_h \backsim I_0\frac{|S_h|}{\theta^2}\cdot e^{-M}\cdot p\int_0^{Ae^{-M}} J_0(2x)\,dx\;. \tag{7}$$

The numerical integration of this equation gives the relation between intensity and crystal size. In Fig. 4 the values calculated by Eq. (7) are shown by fully lines.

---

* In the previous paper[16] the crystal size was estimated too small, since the evaluation of B_0 was incorrect.

§ 4. Experimental Results

(a) *Intensity variaton with film thickness.* The variation of intensity with film thickness was studied at first, the evaporation being carried out under the same evaporation speed and the same temperature of the substrate.

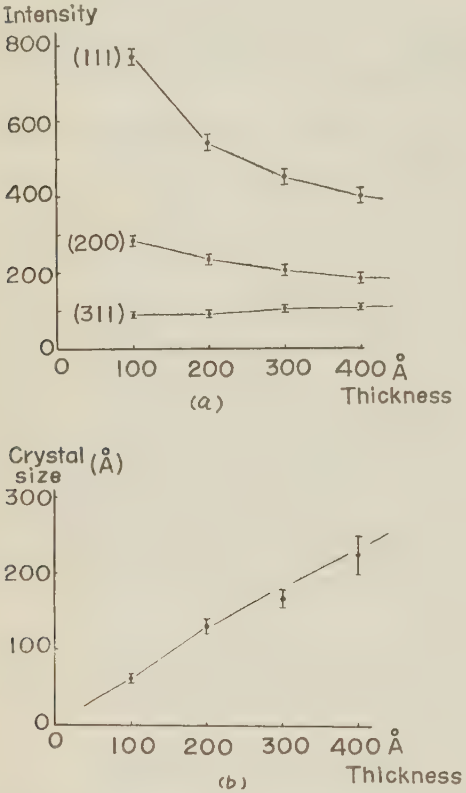

Fig. 3. (a) Intensity variation with film thickness of Al (Accelerating voltage 40 kV).
(b) Relation between crystrl size and film thickness of this specimen.

The result obtained from Al is shown in Figs. 3 a and b. The intensity ratios are plotted against the thickness of the film in (a), and the relation between crystal size and thickness is plotted in (b). The experimental errors are shown by the vertical line segments in each figure. As the thickness of film is increased the crystal size becomes larger, and at the same time, the intensity ratios vary appreciably.

b) *Intensity variation with crystal size.* Next, the intensities were measured for many specimens of the same thickness but of various crystal sizes. For all the specimens except NaCl and KCl, intensity of (111)-, (200)-, (220)-, and (311)- or (222)-reflections were studied. For NaCl and KCl only (hk0)-reflections wer studied to avoid the effect of the texture.

The result is shown in Figs. 4 a–f. In eac figure the experimental errors of intensity an crystal size are shown by vertical and horizontal line segments, respectively. The curve obtained from Fq. (7) are shown for accelerating voltage of 48 kV. Except for MgO, th temperature effect was taken into account i the calculation of Eq. (7). $(hkl)^K$ shows th kinematical intensities from Eq. (3), an $(hkl)_0{}^K$ shows the kinematical intensities without the temperature effect (*cf.* Tables II an III).

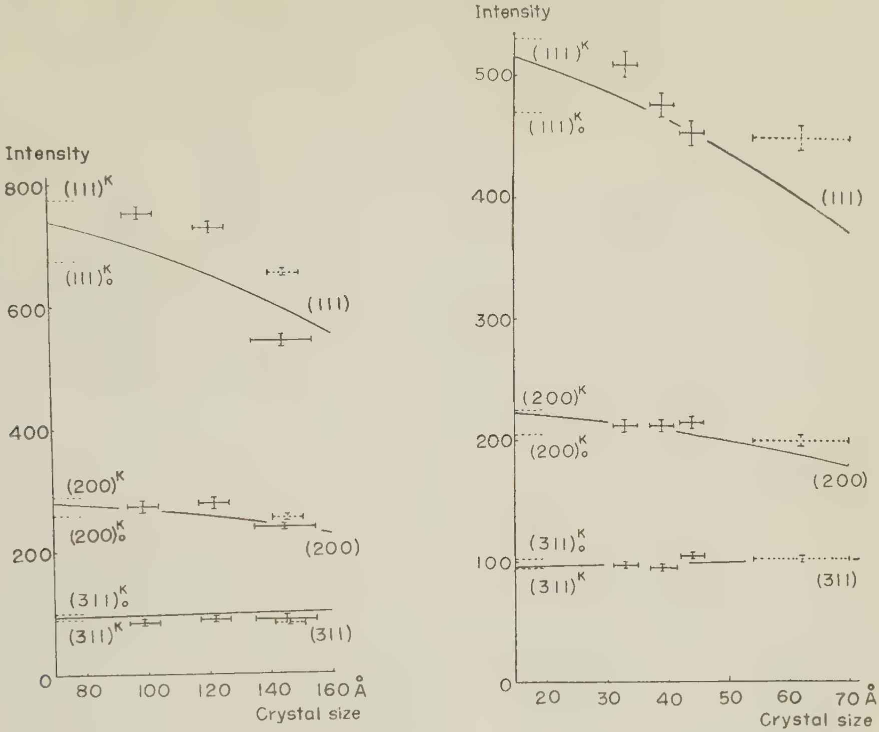
Table III. Kinematical intensity ratios with and without the temperature factor.

Specimen		(111)	(200)	(220)	(311)	(400)	(420)
Al	with	77_2	28_9	100	89	—	—
	without	67_5	26_0	100	97	—	—
Ag	with	52_7	22_6	100	95	—	—
	without	46_9	20_8	100	10_1	—	—
Au	with	48_5	21_0	100	98	—	—
	without	44_2	19_4	100	10_3	—	—
NaCl	with	—	22_3	100	—	9	19
	without	—	20_2	100	—	11	26
KCl	with	—	20_5	100	—	9	20
	without	—	18_8	100	—	11	26

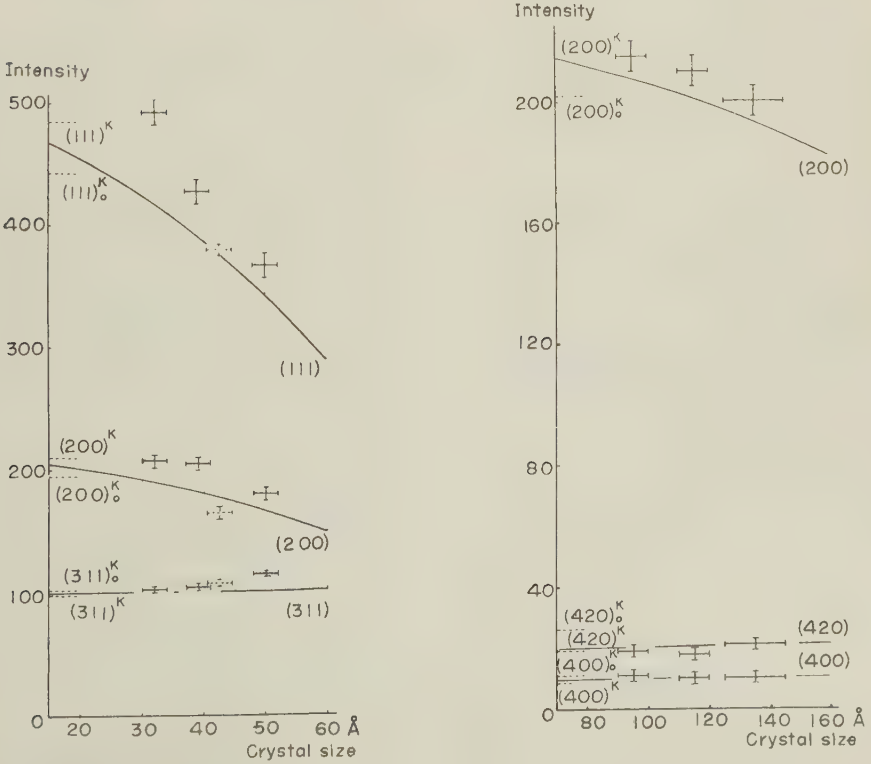
The observed values do not exactly coincide with the theoretical values. However, it is obviously recognized that the observed intensities vary appreciably with crystal size and the reflections, the structure factors of which are larger than that of the standard reflection, have an inclination to decrease in their intensities as the crystal size becomes larger, and the ones, the structure factors of which are smaller than that of the standard one, tc increase in their intensities for the larger crystal size. This fact coincides at least qualitatively with the theoretical result and can be considered to be due to the dynamical effect.

§ 5. Discussions

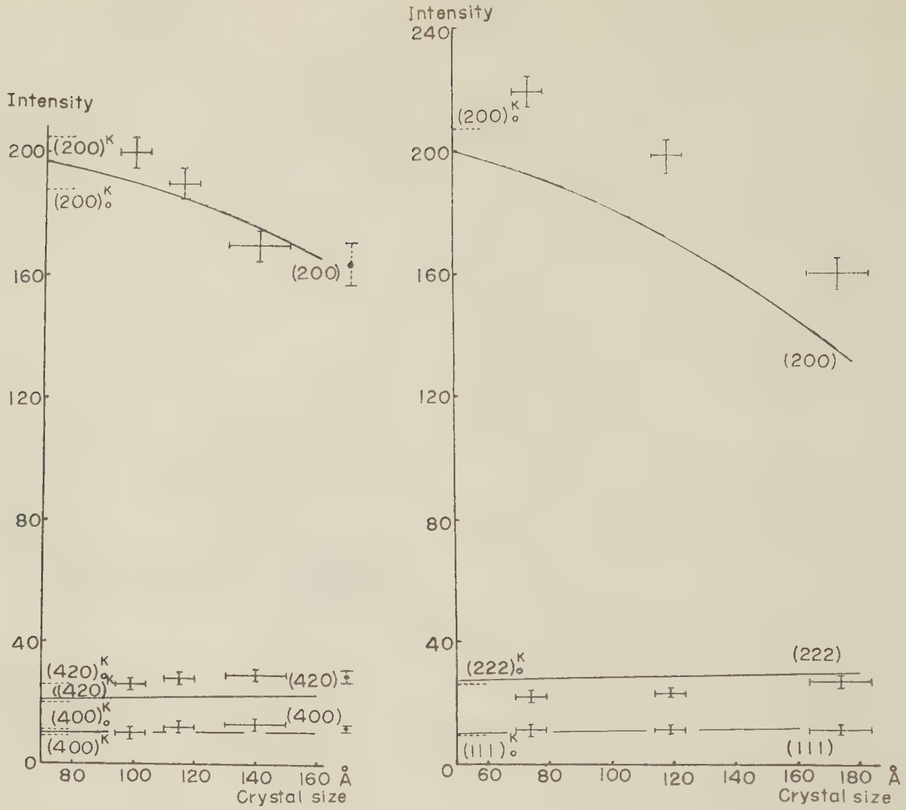
Comparison with Yamzin's result. Materials studied both by Yamzin and the present author are Al, Ag and Au. Yamzin performed the experiment with various film thicknesses



(a) Al (150Å in thickness).　　(b) Ag (20Å in thickness).



(c) Au (15Å in thickness).　　(d) NaCl (400Å in thickness).



(e) KCl (300Å in thickness). (f) MgO (Mg, 100Å in thickness).

Fig. 4. Intensity variation with crystal size. (Accelerating voltage, 48 kV). Dotted plots show the results obtained from Yamzin and Shirai's experiments. Shirai did not show his result in terms of crystal size. Then only the intensity ratios should be compared with our result in the case of KCl.

and he did not observe any remarkable intensity change with the film thickness. His experimental values are plotted in Figs. 4 a–c.*

As is seen in these figures, his values do not deviate from those of the present investigation. They coincide with the kinematical values except the case of Au, if the temperature factor is not taken into account. This agreement, however, does not mean the holding of the kinematical theory.

Comparison with the results of the other investigators. G. P. Thomson[1)], Mark and Wierl[2)] and Shirai[3)] reported that the observed intensity agreed with the values expected by the kinematical theory, but all of them neglected the temperature factor. The results obtained by them are tabulated in Table IV. Comparing these results with Table III and Fig. 4, it can be said that their results contain the dynamical effect for low order reflections as (111) and (200) except the case of Al.

Ornstein *et al.*[4,5)] and Lennander *et al.*[6,7)] reported that the kinematical theory could not be applied for their specimen films. The results obtained by them are also shown in Table IV. Their values show much more deviation from the kinematical values than those of G. P. Thomson and others.

In conclusion, the kinematical theory can be applied when the crystal size of the specimen is very small, and the intensity varies gradually when the crystal size becomes larger. In analysing the data it is necessary to take into account the temperature effect which is too large to be neglected.

Acknowledgements

The present experiment was suggested by

---

* Yamzin calculated the crystal size by using half-width. The accelerating voltage in his experiment was 45, 53 and 42 kv for Al, Ag and Au, respectively.

Effect of the Basic Strength of Attached Groups on Light Absorption Spectra I.

Light Absorption of Triphenylmethane Dyes

By Reikiti ITOH*

Kobayasi Institute of Physical Research Kokubunzi, Tokyo

(Received August 28, 1956)

The electronic energy levels of typical triphenylmethane dyes, Döbner's Violet and Rosaniline, are calculated through the simple LCAO MO method. The electron densities and the bond orders in the ground states are also computed. Then, with these values of electron densities and the bond orders, the differences of the coulomb and of the resonance integrals, $\Delta\alpha_i$ and $\Delta\beta_{ij}$, respectively, as well as those between the carbon and the nitrogen atoms are taken into account and the electronic energy levels calculated above are modified by perturbation method. The differences of the coulomb integrals between the carbon and the nitrogen atoms cause profound effects to the absorption energy which amount to 23~27 Kcal (40~50 %), whereas those of different carbon atoms affect to the absorption only 4 Kcal (10 %). The energy levels of the various derivatives of Döbner's Violet and Rosaniline, e.g. dimethyl and diethyl derivatives of Döbner's Violet, Malachite Green, Brilliant Green, Hoffmann's Violet, Crystal Violet, Ethyl Violet etc. are also calculated by the method of perturbation. The values of the coulomb integrals of attached end groups are estimated through the basicity of the groups. The calculated absorption energies for these derivatives are compared with the observed light absorptions and it is shown that the course of the calculations is reasonable.

§ 1. Introduction

It is well known that the absorption spectra of triphenylmethane dyes e.g. Döbner's Violet and Rosaniline vary in wave length[1] and intensities with the terminal groups attached to phenyl groups. Although there are evidences that three phenyl groups are not in the same plane, Brickstock and Pople[2] calculated the resonance energies and charge distributions of triphenylmethyl group by means of semi-empirical molecular orbital method in S. C. F. scheme, asuming as if they were planer, and their treatment seems to be allowable in the first order approximation. In this paper, the absorption spectra and charge distributions of triphenylmethyl group with two or three substituents are calculated by the perturbation method in the simple semi-empirical MO theory. In the latter part of this paper (§ 5, 6), the correlations between the basicities of terminal groups and the absorption spectra of the triphenylmethane dyes are investigated. The data of absorption spectra and pK_b of these dyes are collected in Table I and IX.

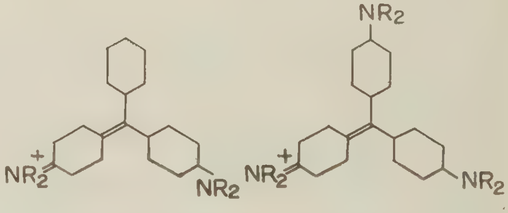

Fig. 1. Cations of Triphenylmethane dyes.

In these dyes, altering basicity of the terminal groups influences the light absorption as it does in the dyes of cyanine type; increasing basicity shifts the absorption band towards longer wave lengths. Thus, Döbner's Violet (I) and its dimethyl (II) and diethyl (III) derivatives absorb the light of higher frequencies than Malachite Green (IV), while the tetraethyl derivative, Brilliant Green (V), absorbs at lower frequencies. In the same manner, Rosaniline (I′) derivatives, i.e. Hoffmann's Violet (III′), Crystal Violet (IV′) and Ethyl Violet (V′), also absorb the light of

---

* Previous name R. Miyasaka was altered by R. Itoh.

Table I. The light absorption of Triphenylmethane dyes[1].

NR_2 group	No. of Days	absorption wave length	No. of Days	absorption wave length
NH_2	I	5616 A	I′	5430 A
$NH(CH_3)$	II	5870	II′	——
$NH(C_2H_5)$	III	5898	III′	5850
$N(CH_3)_2$	IV	6160	IV′	5905
$N(C_2H_5)_2$	V	6230	V′	5961

longer wave lengths than Rosaniline in this order.

In the first place, the light absorptions of the dyes (I) and (I′) will be computed by semi-empirical LCAO MO method with first order perturbation. In the second place, the light absorptions of other dyes (11), (111), ···(IV′) and (V′) etc. will be computed by the use of pK_b data of their terminal groups.

§ 2. Theoretical Preparations

It is assumed that electronic absorption bands of these dyes arise from transitions involving only the π electrons, not the σ electrons, and our attention will be restricted to the former. It is convenient to express the molecular orbitals (MO) of the electrons as linear combinations of suitable atomic orbitals (LCAO approximation). Each MO is then written in the form

$$\psi=\sum_{r} c_r\phi_r\,, \qquad (1)$$

where ϕ_r is the $2p\pi$ orbital of the r-th atom. The predictions will all be made by the following prescription;

(1) Compute the roots, x, of the secular equation determining the LCAO MO's, neglecting overlap integrals, and setting all coulomb integrals α_i and all resonance integrals β equal.

(2) Compute the one electron energies corrected for $\Delta\alpha_1$, which is the difference in coulomb integral between carbon atoms and nitrogen atoms and is assumed to be

$$\Delta\alpha_1=1.6\beta^{6)}.$$

(3) These energies are expressed in terms of β. Then put $\beta=-3\,\text{eV}$.

With these assumptions, the equations determining the MO's take the form

$$(\alpha-\mathcal{E})c_r+\sum_{\substack{s\text{ bonded}\\ \text{to } r}}\beta_{rs}c_s=0\,, \qquad (2)$$

or, more briefly,

$$-xc_r+\sum_{\substack{s\text{ bonded}\\ \text{to } r}}c_s=0\,, \qquad (3)$$

where $x=(\mathcal{E}-\alpha)/\beta$ and c_r is the MO coefficient of the r-th atom.

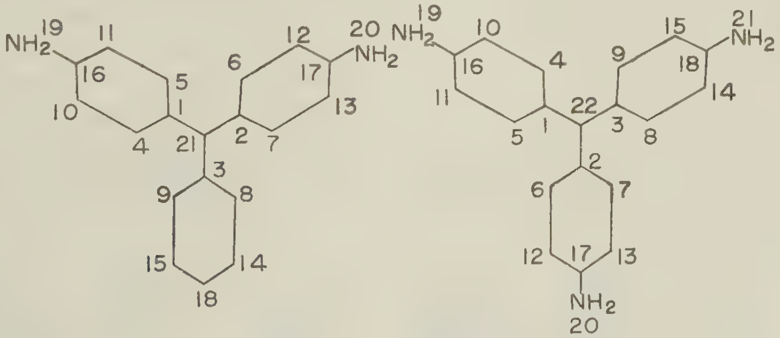

Fig. 2. The ith atom is denoted by number i in the figures of Döbner's Violet and Rosaniline.

1) Molecular Orbitals in Döbner's Violet

The molecule of Döbner's Violet consists of triphenylmethyl radical and two amino groups as shown in Fig. 1, and the symmetry group of this dye is C_{2v} as shown in Fig. 2, if assuming the planer configuration, and it has 21 atoms of which the number is shown in Fig. 2. The π MO's are, by definition, all antisymmetric with respect to the molecular plane and therefore belong to the species A_2 and B_2 as follows. From the character table of the irreducible representations of this group we have for the splitting of $\Gamma(C_{2v})$ representation

$$\begin{array}{lcccc} \text{operation} & E & C_2 & \sigma_v & \sigma_{v'} \\ \Gamma(C_{2v}) & 21 & -3 & -21 & 3 \end{array}$$

into its irreducible components

$$\Gamma(C_{2v})=9A_2+12B_2\ ,$$

Species of B_2: the molecular orbitals of species B_2 may be written in the form

$$\begin{aligned}\psi(B_2)=&c_1(\phi_1+\phi_2)+c_2(\phi_5+\phi_6)+c_3(\phi_4+\phi_7)\\&+c_4(\phi_{11}+\phi_{12})+c_5(\phi_{10}+\phi_{13})\\&+c_6(\phi_{16}+\phi_{17})+c_7(\phi_{19}+\phi^{20})+c_8\phi_3\\&+c_9(\phi_8+\phi_9)+c_{10}(\phi_{14}+\phi_{15})\\&+c_{11}\phi_{18}+c_{12}\phi_{21}\end{aligned}$$

We see $c_2=\pm c_3$, $c_4=\pm c_5$ (the double signs are to be read in the same order) and the approximate MO's are of the forms

$$\begin{aligned}\psi(B_2)=&c_1(\phi_1+\phi_2)+c_2(\phi_4+\phi_5+\phi_6+\phi_7)\\&+c_3(\phi_{10}+\phi_{11}+\phi_{12}+\phi_{13})\\&+c_4(\phi_{16}+\phi_{17})+c_5(\phi_{19}+\phi_{20})\\&+c_6\phi_3+c_7(\phi_8+\phi_9)+c_8(\phi_{14}+\phi_{15})\\&+c_9\phi_{18}+c_{10}\phi_{21}\\ \psi'(B_2)=&c_1(\phi_4-\phi_5-\phi_6+\phi_7)\\&+c_2(\phi_{10}-\phi_{11}-\phi_{12}+\phi_{13})\end{aligned}$$

Species A_2: the MO's of species A_2 have the nodal planes through atoms 21, 3, 18 and they have the form

$$\begin{aligned}\psi(A_2)=&c_1(\phi_2-\phi_1)+c_2(\phi_7-\phi_5)+c_3(\phi_6-\phi_4)\\&+c_4(\phi_{13}-\phi_{10})+c_5(\phi_{12}-\phi_{11})\\&+c_6(\phi_{17}-\phi_{16})+c_7(\phi_{20}-\phi_{19})\\&+c_8(\phi_8-\phi_9)+c_9(\phi_{14}-\phi_{15})\end{aligned}$$

but, since there is no interaction between the group of the atoms 8, 9, 14 and 15, and the other atoms, the MO's will be the form with $c_2=\pm c_3$, $c_4=\pm c_5$ (the double signs are to be read in the same order):

$$\begin{aligned}\psi(A_2)=&c_1(\phi_2-\phi_1)+c_2(\phi_6+\phi_7-\phi_5-\phi_4)\\&+c_3(\phi_{12}+\phi_{13}-\phi_{10}-\phi_{11})\\&+c_4(\phi_{17}-\phi_{16})+c_5(\phi_{20}-\phi_{19})\\ \psi'(A_2)=&c_1(\phi_4-\phi_5+\phi_6-\phi_7)\\&+c_2(\phi_{10}-\phi_{11}+\phi_{12}-\phi_{13})\\ \psi''(A_2)=&c_1(\phi_8-\phi_9)+c_2(\phi_{14}-\phi_{15})\end{aligned}$$

Thus the secular equation of π MO can be reduced and the determinants of $5(A_2)$, $2(A_2)$, $2(A_2)$, $10(B_2)$ and $2(B_2)$ ranks are obtained. In the case of $5(A_2)$, equation (3) gives

$$\begin{aligned}-xc_1+2c_2&=0\ ,\\-xc_2+\ c_1+c_3&=0\ ,\\-xc_3+\ c_2+c_4&=0\ ,\\-x_4+2c_3+c_5&=0\ ,\\-xc_5+\ c_4&=0\ .\end{aligned}$$

Eliminating the coefficients c_r, we have

$$\begin{vmatrix}-x&2&0&0&0\\1&-x&1&0&0\\0&1&-x&1&0\\0&0&2&-x&1\\0&0&0&1&-x\end{vmatrix}=-x^5+6x^3-7x=0$$

As this equation gives five roots x_i $(i=1, 2, 3, 4, 5)$, there are 5 MO's of specy A_2, with energies $\varepsilon_i=\alpha+\beta x_i$. The ratios of the coefficients c_r for each of these are obtained by substituting the appropriate x_i back into the linear equations, and their absolute magnitudes are determined by the normalized condition of MO;

The values of x_i and the corresponding values of c_r are given in Table II, III and IV.

2) Molecular Orbitals in Rosaniline

As shown in Fig. 2, the spatial symmetry of Rosaniline is D_{3h}, if we assume the planer configuration as before, and it has 22 atoms of which the number is shown in the figure. MO's are of species A_1'', A_2'' and E'' as shown in the following. From the character table and the character of $\Gamma(D_{3h})$ representation

operation	E	$2IC_6$	$2C_3$	σ_h	$3U$	$3\sigma_v$
$\Gamma(D_{3h})$	22	−1	1	−22	−4	4

we have the splitting of $\Gamma(D_{3h})$ representation into its irreducible components;

$$\Gamma(D_{3h})=2A_1''+6A_2''+7E''.$$

The MO's of these species have the form

$$\psi(A_1'')=c_1(\phi_4-\phi_5+\phi_6-\phi_7+\phi_8-\phi_9)$$
$$+c_2(\phi_{10}-\phi_{11}+\phi_{12}-\phi_{13}+\phi_{14}-\phi_{15})\,,$$
$$\psi(A_2'')=c_1\phi_{22}+c_2(\phi_1+\phi_2+\phi_3)$$
$$+c_3(\phi_4+\phi_5+\phi_6+\phi_7+\phi_8+\phi_9)$$
$$+c_4(\phi_{10}+\phi_{11}+\phi_{12}+\phi_{13}+\phi_{14}+\phi_{15})$$
$$+c_5(\phi_{16}+\phi_{17}+\phi_{18})+c_6(\phi_{19}+\phi_{20}+\phi_{21})\,.$$

As the MO's of specy E'' occur in degenerated pairs, there is a certain freedom in the choice of the form of MO (though the energy of each pair is uniquely determined) and we will use the following form:

$$\psi_1(E'')=c_1(\phi_1+\omega\phi_2+\omega^2\phi_3)+c_2(\phi_4+\omega\phi_6+\omega^2\phi_8)$$
$$+c_3(\phi_5+\omega\phi_7+\omega^2\phi_9)$$
$$+c_4(\phi_{10}+\omega\phi_{12}+\omega^2\phi_{14})$$
$$+c_5(\phi_{11}+\omega\phi_{13}+\omega^2\phi_{15})$$
$$+c_6(\phi_{16}+\omega\phi_{17}+\omega^2\phi_{18})$$
$$+c_7(\phi_{19}+\omega\phi_{20}+\omega^2\phi_{21})\,,$$
$$\psi_2(E'')=\psi_1^*(E'')\,.$$

where $\omega=\exp(2\pi i/3)$ and $\psi_1^*(E'')$ is the conjugated complex of $\psi_1(E'')$. In the case of specy E'' it is obvious that $c_2=\pm c_3$, $c_4=\pm c_5$ and we have the form:

$$\psi_1(E'')=c_1(\phi_1+\omega\phi_2+\omega^2\phi_3)$$
$$+c_2(\phi_4+\phi_5+\omega\phi_6+\omega\phi_7+\omega^2\phi_8+\omega^2\phi_9)$$
$$+c_3(\phi_{10}+\phi_{11}+\omega\phi_{12}+\omega\phi_{13}$$
$$+\omega^2\phi_{14}+\omega^2\phi_{15})$$
$$+c_4(\phi_{16}+\omega\phi_{17}+\omega^2\phi_{18})$$
$$+c_5(\phi_{19}+\omega\phi_{20}+\omega^2\phi_{21})$$
$$\psi_1'(E'')=c_1(\phi_4-\phi_5+\omega\phi_6-\omega\phi_7+\omega^2\phi_8-\omega^2\phi_9)$$
$$+c_2(\phi_{10}-\phi_{11}+\omega\phi_{12}-\omega\phi_{13}$$
$$+\omega^2\phi_{14}-\omega^2\phi_{15})$$

and now

$$\psi_2(E'')=\psi_1^*(E'')\,,\quad \psi_2'(E'')=\psi_1'^*(E'')\,.$$

As described above, the spatial symmetry o the molecule leads to secular determinants o $2(A_1'')$, $6(A_2'')$, $5(E'')$ and $2(E'')$ ranks. Th values of x and c_r are readily obtained. Th results are given in Table V, VI and VII.

§ 3. Electron Densities and Bond Orders in Döbner's Violet and Rosaniline

It must be re-emphasized that the abov values of the energy parameter, x, and th AO coefficient, c_r, have been calculated on th assumption that all the nitrogen atoms an the carbon atoms have the same value o coulomb imtegral. Under this assumption, le us calculate the electron densities and mobil bond orders in the ground state. These ar defined by

$$q_r=\sum_{occ} c_r{}^2,\quad p_{rs}=\sum_{occ} c_rc_s \qquad (4$$

respectively, where the summations are taken over all the electrons in the occupied orbitals As there are 22π electrons in Dobner's Viole cation, each of the 10 MO's of positive x wil contain 2 electrons while there are 2 electron in the MO for which $x=0$. On the othe hand, as there are 24π electrons in the Rosaniline cation, 10 MO's of positive x (4 of them have no degeneracy, 3 pairs are doubly degenerated) and 2 MO's of $x=0$ (doubly degenerated) are occupied by 2 electrons each.

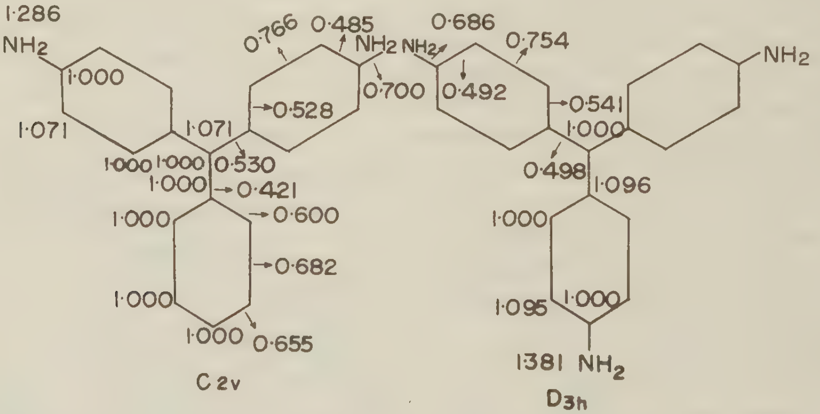

Fig. 3. Molecular diagrams of Döbner's Violet and Rosaniline. Values in the left hand side of the figures are those of π charge densities and the values denoted by an arrow are those of bond orders.

Summing over these orbitals, we obtain the values given in Fig. 3 for the electron densities and bond orders. It is intresting to note that π electron density is the highest on the atoms of terminal groups, even though no allowance has been made in the calculations for the greater electron affinity of nitrogen than carbon. This suggests two things. Firstly, this piling up of the electrons may reduce the electron affinity of nitrogen atoms and, hence, it may not be a poor approximation to set the coulamb integrals of nitrogen atoms equal to those of carbon atoms. Seondly, the basic strength of terminal groups vhich depends on the σ charge density of itrogen atoms, has some correlations with π harge density of the atoms. If the terminal roups becomes more basic, the non-bonding electrons (lone pair) of nitrogen are decreas-d by the induction effects of alkyl groups ttaching to the nitrogen atom.

4. Perturbation Treatments

In Döbner's Violet, f level (the highest oc-upied orbital) corresponds to the one with $x=0$ in A_2 species of C_{2v}, and g level (the low-st vacant orbital) corresponds to the one vith $x=--0.320359$ in B_2 species of C_{2v}. Electronic transition from one to another is llowed from symmetry consideration. It is lso readily known that in Rosaniline the lectronic transition between f level which is he one with $x=0$ in E'' of D_{3h} and g level which is the one with $x=--0.414214$ in A_2 of he same group is allowed from symmetry.

Up to this point, the common coulmb in-egral α is used for all atoms, but this is, of ourse, not correct, as nitrogen is more lectronegative than carbon, it has certainly ower value of α. Matsen[6] has indicated hat in the case of aniline the value of $\alpha_N-\alpha_c=\Delta\alpha_1=-4.8$ eV, is compatible with the spec-roscopic data. Here, too, the value of -4.8 eV, is used for $\Delta\alpha_1$, in both of Döbner's Vio-et and Rosaniline, where amino groups are he substituents for benzene rings. The value f resonance integral β is taken to be -3 eV.

By the first order perturbation theory the erturbed energy levels are given by

$$\mathcal{E}'=\mathcal{E}+\Delta\mathcal{E}\,, \qquad (5)$$

vhere $\Delta\mathcal{E}$ is given from the perturbed one lectron Hamiltonian H' as follows,

$$\Delta\mathcal{E}=(\psi(R)|H'|\psi(R)) = \sum_i c_i^2\Delta\alpha_i+\sum_{i,j} c_ic_j\Delta\beta_{ij}\,. \qquad (6)$$

In this expression, the second term can be estimated by the relation[3]

$$2\beta_{ij}=E_d-E_s + \frac{((1-p)/p)^2(k_s/k_c)^2-(k_s/k_d)}{1+(k_s/k_d)((1-p)/p)}(x_s-x_d)^2, \qquad (7)$$

where E_d and E_s are the bond energies -146 and -83 Kcal[4]; x_d and x_s are the bond lengths 1.34 and 1.54 A[5]; k_d and k_s are the force constants, $k_d=9.5\times10^5$ dyn/cm², $k_d/k_s=0.765$[3], suffixes d and s being refered to the double and the single bond respectively, and p is the bond order between the ith and jth atom. The standard value of β is taken to be -40.36 Kcal, which corresponds to the bond order of $p=2/3$, and the values of $\Delta\beta_{ij}$ are listed in Table VIII. With these values it can be shown that the effect of $\Delta\beta_{ij}$ on the calculated value of absorption energy is less than 2 Kcal. The first term of expression (6) is most important since it includes the nitrogen's large $\Delta\alpha_r$. $\Delta\alpha$'s for carbon atoms can be estimated by the following expression[7] to be also the same order as $\Delta\beta_{ij}$; in other words, the effects of $\Delta\alpha$'s other than $\Delta\alpha_1$ and $\Delta\beta$'s to the absorption energy are less than 10%:

$$\alpha_r=I_r+\left\{\frac{1}{2}\sum_{occ} c_i^2(E_r-I_r)\right\} \qquad (8)$$

where I_r is the ionization potential[8], -11.17 eV, of carbon atom from the valence state $C(sp^3, V_4)$ to $C^+(sp^2, V_3)$, and E_r is the electron affinity[8], -0.69 eV, of carbon atom in the valence state from $C^-(sp^4, V_3)$ to $C(sp^3, V_4)$. The standard value of α_r is taken to be -136.7 Kcal which corresponds to the atom with $q_r=1.00$, while $\Delta\alpha_r$'s of nitrogens are dominating terms in expression (6), the effect of the latter to the absorption energy being 23 ~ 27 Kcal, i.e. 40 ~ 50%. Therefore, we take only the main part of equation (6) into consideration, and the results obtained through

Table VIII. Values of bond orders and resonance integral differences computed by equation (7). Standard value of β is taken to -40.36 Kcal/Mol which corresponds to the bond order of 0.667.

simple perturbation with $\Delta\alpha_1 = -4.8$ eV and the resonance integral $\beta = -3$ eV are given in Table X.

§ 5. Relation between $\Delta\alpha_r$ and pK_b of Amino Groups

Various derivatives of Döbner's Violet and Rosaniline of the types II, III, IV, V and II′, III′, IV′, V′, etc. have the alkyl substituted amino groups as their end groups, and the existence of the correlation of the basic strength of these groups with the electronic absorption spectra is reasonably expected. If bases, B_i and B_j, correspond to the dye of the type I and J $(I<J)$, respectively, the terminal groups of B_j are more basic than those of B_i because of the electron donating character of NR_2 groups, and this causes the diminution of coulomb integrals of these groups, that is, if α_i and α_j are the coulomb integrals of the terminal groups in the bases B_i and B_j, respectively,

$$|\alpha_i| > |\alpha_j| \,. \tag{9}$$

In comparing the dissociation constants of two bases B_i and B_j in a given solvent at a given temperature, we consider the equilibrium

$$B_iH^+ + B_j = B_i + B_jH^+ \,. \tag{10}$$

Longuett-Higgins[9] has pointed out that the potential energy change occuring in reaction (10) is principally due to the difference in resonance energy between the species on the right hand side of the equation and those on the left. When the difference in resonance energy between B_iH^+ and B_i is indicated by $\Delta\mathcal{E}_i$, the above postulate may be written in the equation

$$\Delta\mathcal{E}_j - \Delta\mathcal{E}_i = 2.3RT(pK_{a_i} - pK_{a_j}), \tag{11}$$

where

$$pK_a = -\log K_a;\ K_a = \frac{[H_3O^+][B]}{[BH^+]} \,.$$

pK_a corresponds to the logarithmic equilibrium constant of the reaction

$$BH^+ + H_2O = B + H_3O^+. \tag{12}$$

In comparing the coulomb integral of terminal groups in B_i with that in B_j, it is convenient to postulate that the magnitude of coulomb integral α_i of NR_2 group depends up on the σ charge density on the group, the magnitude of which being proportional to the basic strength pK_b of NR_2 groups, in orde words, coulomb integral of terminal grou NR_2 is proportional to basicity, pK_b, of amin NHR_2, where

$$pK_b = -\log_{10} K_b;\ K_b = \frac{[BH^+][OH^-]}{[B]} \,,$$

K_b corresponds to the logarithmic equil brium constant of reaction (12). Then, pK and pK_b are related each other by

$$pK_a + pK_b = 14 \,.$$

Now it can be shown that if r is an ator in a conjugated system and if coulomb integra of atom r is altered by a small amount o $\Delta\alpha_r$, then the change in resonance energy o the system is given by[10]

$$\Delta\mathcal{E} = q_r \Delta\alpha_r \,,$$

where q_r is the π electron density at th position of atom r. This may be true in th case of bases B_i and B_j, where the differen ce, $\Delta\alpha_i - \Delta\alpha_j$, in coulomb integral of NR groups causes the difference in resonanc energy in B_i and B_j, and the above postulate may be summarized in the equations

$$\Delta\alpha_i - \Delta\alpha_j = k(pK_{b_i} - pK_{b_j}), \quad (13$$

$$\Delta\mathcal{E}_i - \Delta\mathcal{E}_j = q_r(\Delta\alpha_i - \Delta\alpha_j), \quad (14$$

where pK_b is the basic strength of amin NHR_2 and its values are shown in Table IX As it seems difficult to estimate the value o k in the exact manner, it was determine empirically by the data of Crystal Violet, an the value of $k = 0.4605$ eV was obtained.

Summarizing the above consideration on th situation of electronic sturcture, we rely o the two assumptions:

1) the differences in magnitudes of pK_b o NR_2 groups owing to σ charge density do no change appreciably the π electron density while 2) the induction effect of alkyl group which changes the ionization potential of NR groups correlates with coulomb integral o the groups, α_i, and the changes in α_i and α cause the resonance energy differences $\Delta\mathcal{E}$ $\Delta\mathcal{E}_j$ as shown in the above equations.

§ 6. Computed Absorption Spectra of Vari ous Derivatives

The terminal groups in the dyes of th types I, II, III, IV, V and I′, II′ III′, IV′, V are indicated in Table IX, in which the relat ve magnitudes in coulomb integrals and basi strengths of various NR_2 groups are given.

Table IX. Valtes of coulomb integrals and pK_b in alkyl substituted amino groups.

Dyes	NR_2 group	$\Delta\alpha_i K$ cal/mol	pK_b	literature
I, I′	NH_2	−110.64	4.75	a

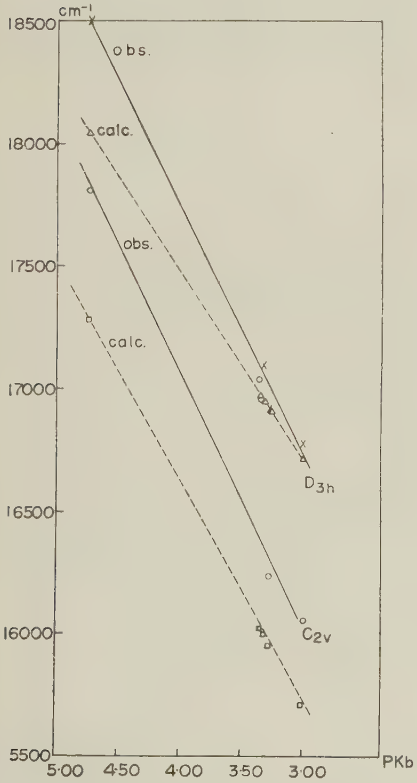

Fig. 4. The absorption frequencies, m⁻¹, of triphenylmethane dyes against the basic strength, pK_b, of their terminal groups NR_2 are shown by full lines (observed) and dotted lines (calculated).

The pK_b values in Table IX are based on activity in place of conceneration. The coulomb integral of the ith NR_2 groups is given by $\alpha_i = \alpha + \Delta\alpha_i$, where $\Delta\alpha_1$ is taken to be −4.8 eV from the data of Matsen and the other $\Delta\alpha_i$'s can be computed by equation (13). With the above values of $\Delta\alpha_i$ the predicted electronic transition energies are obtained in the same manner as in Döbner's Violet and Rosaniline by the simple perturbation method from the orbital coefficients of AO's in the present molecules which are iso-electronic with the Dye I and I′. The results are assembled in Table X.

The absorption frequencies of these dyes are compared in Table XI with experimental values in cm⁻¹ unit.

Table X. Calculated absorption energies of various derivatives in K cal/mol.

Base B_i	I	II	III	IV	V
C_{2v} Symmetry	49.42	45.79	45.71	45.60	44.90
Base B'	I′	II′	III′	IV′	V′
D_{3h} Symmetry	51.55	48.50	48.43	48.35	47.75

Table XI. Values of calculated and observed frequencies in cm⁻¹ unit.

NR_2	NH_2	$NHCH_3$	NHC_2H_5	$N(CH_3)_2$	$N(C_2H_5)_2$
Dye	I	II	III	IV	V
$\tilde{\nu}_{obs.}$	17810	17040	16960	16230	16050
$\tilde{\nu}_{calc.}$	17290	16020	15990	15960	15710
Dye	I′	II′	III′	IV′	V′
$\tilde{\nu}_{obs.}$	18510	—	17090	16920	16780
$\tilde{\nu}_{calc.}$	18040	16970	16950	16920	16710

These values are plotted in Fig. 4, where ordinate is absorption frequency in cm⁻¹ and abscissa is pK_b of NR_2 groups. It is now expected that electronic absorption energy is linear function of basic strength of terminal groups NR_2. In this diagram dyes of type II and III are somewhat deviated from the line for C_{2v} groups, but as the linear relation between absorption frequencies and basic strengths of substituents, NR_2, has been confirmed by the author[11)] in various aniline derivatives, the linearity will not be so far from the truth. Thus, it may be plausible to say that the computed transitions are in good agreement with experimental values within the error caused by slovent effects, and we may conclude that relative basic strength of alkyl substituted amino groups will be able to use as a measure of the relative magnitude in coulomb integral of the group.

The author would like to express his grati-

tude to Professor I. Oshida and Mr. Y. Ooshika for much stimulating and helpful discussions. This work was supported by the Scientific Research Fund granted by the Ministry of Education.

Structural Investigation by Means of Nuclear Quadrupole Resonance I

(Determination of Crystal Symmetry)

By Kenji SHIMOMURA

Minami Branch, Hiroshima University, Hiroshima

(Received October 13, 1956)

The number of nonequivalent directions of the z-axes of the field gradient in the crystal for every symmetry class is calculated. It is shown that we may discuss about the symmetry of the crystal and may determine the orientations of nonequivalent directions with respect to the axes of symmetry through the Zeeman analysis of nuclear quadrupole resonance line.

§ 1. Introduction

As was briefly reported[1], one may obtain the possible arrangements of resonant atoms by studying the multiplicity of pure quadrupole resonance spectrum and the intensity ratio of the multiplet. The values for the resonance frequency and asymmetry parameter of the field gradient at the resonant nucleus may give the percentage of ionic, single, and double bond character, which gives the bond distance.

A resonance line is attributed to all the resonant atoms which occupy the equivalent positions in crystal but the bond, or strictly speaking, the z-axis of the field gradient, at each equivalent position may have one of many different sorts of directions, called tentatively "*nonequivalent directions* (abbreviated to *N. E. D.*)". Since the behavior of th Zeeman splitting of nuclear quadrupole resonance line in the external magnetic field depends on the angle between the z-axis of th field gradient and the magnetic field, *N.E.D* may be determined through the investigatio of the Zeeman splitting. On the other hand since the positive and negative z-axes of th field gradient have the same behavior of Zeeman splitting, it will be noted that paralle and antiparallel directions of z-axis of the fiel gradient are not distinguished by this method Accordingly, these are called "*equivalent direction* (abbreviated to *E. D.*)". Bond direction which are usually coincident with the z-axes o the field gradient are decided through th Zeeman analysis of the resonance line, and fro these the orientation of axis of symmetry (o plane of symmetry), the molecular and crystal structure may be discussed.

§ 2. Calculations and Discussions

Since translations do not alter the bond (the z-axis of the field gradient) directions, so far as the number of *N. E. D.* is concerned, screw-axis and glide-plane are equivalent to simple axis and plane of symmetry, respectively. Consequently, the number of *N. E. D.* is the same in all space-groups which are derived from the same point-group. So it is only necessary to consider the simple space-group such as $C_1^1, C_2^1, C_{2h}^1, \ldots$ which may be built up by hanging one of the 32 point-groups at the lattice points of the simple space-lattice having appropriate symmetry characteristics.

Let the resonant atom whose coordinate is $(x_1y_1z_1)$ be covalently bonded to the partner atom whose coordinate is $(x_2y_2z_2)$, then each pair of atoms which situate at the positions which are crystallographically equivalent to $(x_1y_1z_1)$ and $(x_2y_2z_2)$ and correspond to the same coordinate of the point-group, e. g., $(x_1y_1\bar{z}_1)$ and $(x_2y_2\bar{z}_2)$, may also be bonded to each other, but the direction coefficient ratios of these bonds, such as $(x_1-x_2):(y_1-y_2):(z_1-z_2)$, are different from each other, hence the total number of *N. E. D.* at the resonant atoms which occupy the equivalent positions is generally equal to the number of coordinates of the point-group of the crystal. On the other hand, if the point-group contains the coordinates (xyz) and $(\bar{x}\bar{y}\bar{z})$, such as in the case of C_{2h}, the bond directions that correspond to (xyz) and $(\bar{x}\bar{y}\bar{z})$ are equivalent, hence in this case the number of *N. E. D.* is equal to one half the number of coordinates of the point-group.

On the other hand, when the bond lies along a special orientation, the number of *N. E. D.* will be less than the maximum number for the general case. For example, when the bond lies in a plane $z=$const. which is parallel to the (001) plane, if the point-group contains the coordinates $(xyz), (xy\bar{z})$ and the coordinates $(\bar{x}\bar{y}\bar{z}), (\bar{x}\bar{y}z)$ specifing the antiparallel bonds of the former two, respectively, it is very easy to verify that all bond directions which correspond to them are equivalent.

Generally, the special orientations in which the number of *N. E. D.* will decrease, may be constituted by 2-combinations of the following nine cases: $x=$const., $y=$const., $z=$const., $x=y$, $y=z$, $z=x$, $x=-y$, $y=-z$, $z=-x$, when each case may be repeated, where xyz are the coordinates refered to the reference axes XYZ of the space-group, and in this paper Wyckoff's notation[2] is adopted. So the number of special cases is equal to ${}_9H_2=45$ but all the independent cases among them are listed in Table I. In this Table, $x=c, x=y$, and $x=-y$ mean that the pair of atoms lie in the plane that satisfies $x_1=x_2, x_1-x_2=y_1-y_2$, and $x_1-x_2=y_2-y_1$, respectively. In such special cases, it is very easy to verify that the directions which correspond to the coordinates in Table IV in the appendix are equivalent. In these cases, the number of *N. E. D.* is equal to the total number of coordinates of the point-group divided by that which correspond to the equivalent directions. The results are listed in Table II. In each Table the second row is

		$\parallel$ $(0001)\ (11\bar{2}0)$ $(1\bar{1}00)$	$\perp$ $(11\bar{2}0)$ $(1\bar{1}00)$	$\perp(0001)$

the symbols that specify the orientation of the z-axis of the field gradient and are defined in Table I, while the third row is another expression of the orientation; $\parallel(010)$ means that the z-axis lies in a plane parallel to the (010) plane, and $\perp(010)$ means that the z-axis is perpendicular to the (010) plane.

In the above discussion the resonant atom and its partner are assumed to be placed in the general positions, but even in the special cases in which the number of the equivalent coordinates of these atoms will be less than the maximum number of generally equivalent points, we may suppose that a pair of these atoms are moved to the general positions keeping the bond direction unaltered and that the other pairs of equivalent atoms are shifted simultaneously, maintaining the equivalent condition, then the results above-mentioned may be applied to this case, while since the bond directions are not altered in this process, the number of *N. E. D.* must be unaltered before and after this process. So to these cases the above-mentioned results can be applied. And in the above discussion, the z-axis of the field gradient is assumed to coincide with the bond axis, but even when this does not hold, we may assume an imaginary partner atom on the z-axis of the field gradient, so these results are applicable to these cases also.

Accordingly we may discuss about the crystal symmetry by studying the number and the relative orientations of *N.E.D.* For example, 2-*N. E. D.* is generally possible in the case of monoclinic symmetry but the crystals of orthorhombic or tetragonal symmetry may have 2-*N. E. D.* in the special cases; in the case of orthorhombic system 2-*N. E. D.* must lie in a plane perpendicular to one of the a-, b-, and c-axes and in the case of tetragonal system 2-*N. E. D.* must be perpendicular to each other. The *N. E. D.* of the x- and y-axes of the field gradient tensor may be useful in determining the crystal symmetry, if we have few *N. E. D.* But generally speaking, in order to determine the crystal symmetry, all *N. E. D.* of the z-axes of the field gradient must be found out.

By this method crystal of low symmetry can be treated rather easily than that of high symmetry, because in the low symmetry case few *N. E. D.* are expected to be found.

While, by means of Zeeman effect there is no distinction between positive and negative directions of the z-axis of the field gradient. The equivalence of these two directions means that, judged by the Zeeman effect, all crystals will seem to have a center of symmetry. The symmetry of the crystal judged by this method will therefore be that of one of the eleven point-groups of Table III.

Table III. The relation between crystallographic symmetry and symmetry judged by the Zeeman effect.

Crystallographic Symmetry	Symmetry judged by the Zeeman Effect.
1. Triclinic System	
C_1 C_i	C_i
2. Monoclinic System

field gradient was calculated for every symmetry class. By studying the Zeeman splitting of the nuclear quadrupole resonance line one may discuss about the crystal symmetry and may determine the relative orientation of *N. E. D.* of the bond with respect to the symmetry axes of the crystal. It is concluded that, judged by the Zeeman analysis, all crystals will seem to have a center of symmetry, and that the crystal symmetry will therefore be that of one of the eleven point-groups and is quite similar to the symmetry of Laue photograph.

The author wishes to express his sincere thanks to Professor H. Tazaki for his kind guidance and Professor T. Fujiwara, Professor Y. Seiki of Hiroshima University and Professor R. Kiriyama of Ōsaka University for their helpful advices and encouragement. This work has been partly supported by the Scientific Research Expenditure of the Ministry of Education.

Appendix

The coordinates of the point-group that correspond to the *E. D.* in the special cases are listed in Table IV.

Structural Investigation by Means of Nuclear Quadrupole Resonance II

(Tin Tetrabromide)

By Kenji SHIMOMURA

Minami Branch, Hiroshima University, Hiroshima

(Received November 13, 1956)

Details of the universal quadrupole resonance crystal analyzer were described, and using this apparatus the crystal structure of SnBr was studied at room temperature (15°～20°C). The $SnBr_4$ molecule is an almost exact tetrahedron, and each of the four resonance lines is assigned to each bromine atom situated at the apexes of the tetrahedron, and the value of asymmetry parameter of the field gradient at the bromine nucleus is less than 0.025. The crystal has monoclinic symmetry and one of the Sn-Br bond in one molecule is perpendicular to the *b*-axis and the other two orient at the same angle to the *b*-axis. All atoms including Sn in a molecule have nonequivalent general positions in the crystal, and the number of molecules in a unit-cell is equal to the maximum number of equivalent coordinates of the space-group. The existence of pair of two molecules is suggested, and the origin of the splitting of the spectrum is discussed. $SnBr_4$ may be assigned to the symmetry class C_{2h}. The crystal symmetry of the low temperature phase is assigned to the cubic or hexagonal class.

§ 1. Introduction

The energy levels of interaction between a nuclear quadrupole moment Q and electric field V in a crystal for nuclear spin $I=3/2$ are[1]

$$E_{m=\pm 1/2}=-\frac{eQ}{4}q_{zz}\left(1+\frac{\eta^2}{3}\right)^{1/2}, \qquad (1)$$

$$E_{m=\pm 3/2}=\frac{eQ}{4}q_{zz}\left(1+\frac{\eta^2}{3}\right)^{1/2}, \qquad (2)$$

where η is an asymmetry parameter and is defined as

$$\eta=\left|\frac{q_{xx}-q_{yy}}{q_{zz}}\right| , \quad q_{xx}=\frac{\partial^2 V}{\partial x^2} , \quad q_{yy}=\frac{\partial^2 V}{\partial y^2} , \quad \text{etc.},$$

and x, y, z are the principal axes of the field gradient tensor, and z-axis is usually chosen so that

$$|q_{zz}|>|q_{yy}| , \quad |q_{xx}| .$$

If the static magnetic field is applied, the 2-fold degeneracy of the pure quadrupole energy levels is removed, and $E_{\pm 3/2}$ and $E_{\pm 1/2}$ are split into the energy levels $E_{+3/2}$, $E_{-3/2}$ and $E_{+1/2}$, $E_{-1/2}$, respectively. Consequently each resonance line for a given nucleus is split into four components (Fig. 1).

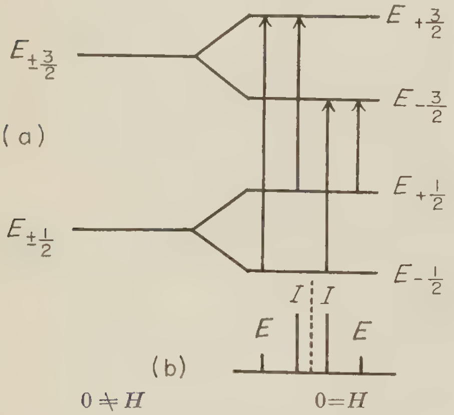

Fig. 1. (a) The energy diagram showing Zeeman splitting in the external magnetic field.
(b) Diagram illustrating the spacings of Zeeman lines. I and E denote the internal and external components, respectively.

The splitting depends on the orientation of the magnetic field with respect to the electric field gradient at that nucleus. In the special orientation of the magnetic field which satisfies the following relation

$$E_{+3/2}-E_{+1/2}=E_{-3/2}-E_{-1/2} , \tag{3}$$

the inner component lines coalesce to a single line. For $I=3/2$, this relation is satisfied when[2)]

$$\sin^2\theta=\frac{2}{3-\eta\cos 2\phi} , \tag{3'}$$

where θ, ϕ are the polar coordinates of the magnetic field with respect to the principal axes xyz (Fig. 2).

The relations between the multiplicity and the intensity ratio of the pure quadrupole resonance lines and crystal structure have been discussed in the previous paper[3)] whose notation will be employed here.

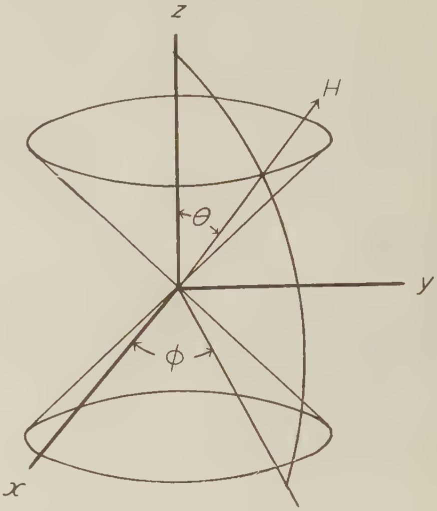

Fig. 2. Diagram illustrating a pair of zerosplitting cones. H denotes a direction of the magnetic field when the zerosplitting is observed. θ is called zerosplitting angle.

In this experiment, the method used in the author's previous measurement[4)] of the angle between the two nonequivalent directions[3)] of the bond in iodine crystal was employed, the apparatus, however, being improved in order to yield more exact determination of the bond angles.

The nuclear quadrupole resonance spectrum[5)6)] of $SnBr_4$ consists of three lines grouped together with a fourth line at noticeably lower frequency and there is a striking similarity[6)] in the spectra of $SnBr_4$, $SnCl_4$[7)], $GeCl_4$[7)], and $SiCl_4$[7)] which suggests that these substances may be isomorphous.

Since most of Group IV tetrahalides are liquid at room temperature and moreover easy to hydrolyze when exposed to moisture, the analysis of the crystal structure is difficult in the usual way.

§ 2. Determination of Structure

(a) Determination of field gradient orientation

Since Eq. (3′) does not contain the magnitude of the static magnetic field H, the zerosplitting angle θ is independent of the magnitude of the magnetic field, while, when $\eta\neq 0$, θ depends on ϕ, but when $\eta=0$, zerosplitting angle θ does not depend on ϕ and is equal to 54°44′. In a general case, zerosplitting is observed when the magnetic field orientates at angle θ that satisfies Eq. (3′), to the z-axis. The locus of zerosplitting direction is a circular cone ($\eta=0$) or roughly elliptical one ($\eta \neq 0$) about the z-axis. This cone is called "*zerosplitting cone*".

Let XYZ be the orthogonal coordinate system fixed to the crystal where Z-axis is chosen to be the rotational axis of the crystal. Let the laboratory coordinate system $X'Y'Z'$ be so chosen that Z'- and X'-axes lie in a horizontal plane, that Y'-axis is perpendicular to the $Z'X'$-plane, and that Z'-axis coincides with the Z-axis. The crystal is rotated about Z, and the external magnetic field H is rotated in a horizontal $Z'X'$-plane. Θ, Φ are the polar coordinates of H with respect to the XYZ axes (Fig. 3).

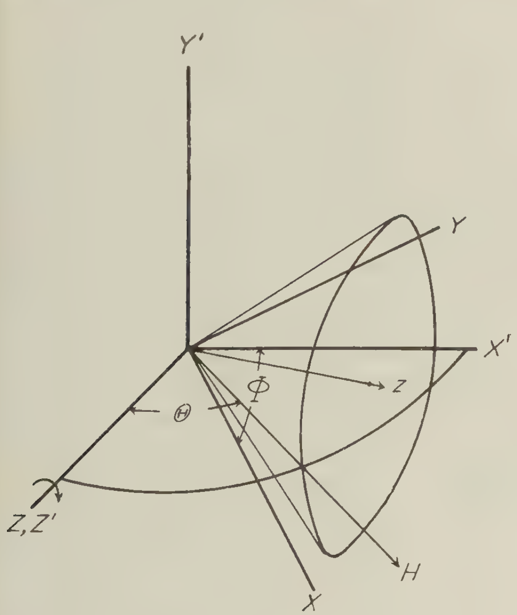

Fig. 3. The relative orientation of the two coordinate systems YYZ, $X'Y'Z'$. H represents the direction of the magnetic field which satisfies the zerosplitting condition (3′). Θ, Φ are the polar coordinates of H with respect to the XYZ system.

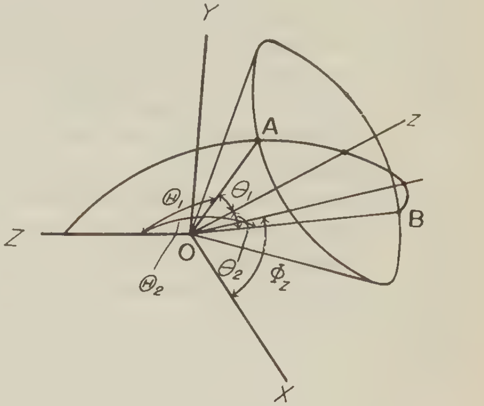

Fig. 4. The relation between zerosplitting cone and the plane which contains the z-axis and satisfies Φ=const.

When any independent values of Θ and Φ are chosen, any relative orientation of H with respect to the XYZ axes may be obtained. Consequently, in principle, the location of any zerosplitting direction is possible by this method. In order to determine the direction of the z-axis of the field gradient from the zerosplitting cone, let us suppose a plane that contains the z-axis and satisfies Φ=const. (Fig. 4), then this plane will intersect the zerosplitting cone along the two directions **OA** and **OB** which make the angles θ_1 and θ_2 with the z-axis, respectively. Since these two directions satisfy $\phi_1=\phi_2$, it is concluded that $\theta_1=\theta_2$ from Eq. (3′). Accordingly, the z-axis must lie in a locus of direction bisecting the angle between the intersecting lines of the zerosplitting cone with plane Φ=const. In the case of Θ=const. (Fig. 5) the same procedure may be applied when $\eta=0$, but

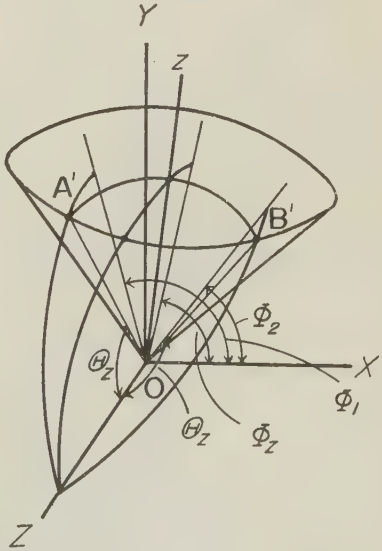

Fig. 5. The relation between zerosplitting cone and the surface which contains the z-axis and satisfies Θ=const.

when $\eta \neq 0$, this procedure is rather approximate, because the surface Θ=const. is not a plane. But in either of the following cases when (1) the z-axis is nearly perpendicular to the Z-axis, (2) either x- or y-axis lies nearly in a plane Φ=const., and (3) η is small and zerosplitting cone may be considered to be a spherical cone, we have good reason to do this. Thus, the orientation of the z-axis is determined from the two loci.

An alternate method was used to obtain the direction of the z-axis. The direction of H is made to coincide with the X'-axis, and then the crystal is rotated until the z-axis comes to be perpendicular to H (Fig. 6). This is easily found by the characteristic spectrum, i.e., the four components of Zeeman lines that are ascribed to one of the *N.E.D.**[3] coalesce into two lines. In that case the z-axis is expected to lie in the $Z'Y'$-plane. Let the crystal be rotated further by 90°, then the z-axis lies in the $Z'X'$-plane. And next, let the magnetic field be rotated in the $Z'X'$-plane, then the zerosplitting directions **AO**, **A′O** and the direction **BOB′** that is perpendicular to the z-axis are easily found. Consequently, the direction of the z-axis may be decided as a line perpendicular to **BOB′** or as the bisector of the angle $\angle$**AOA′**.

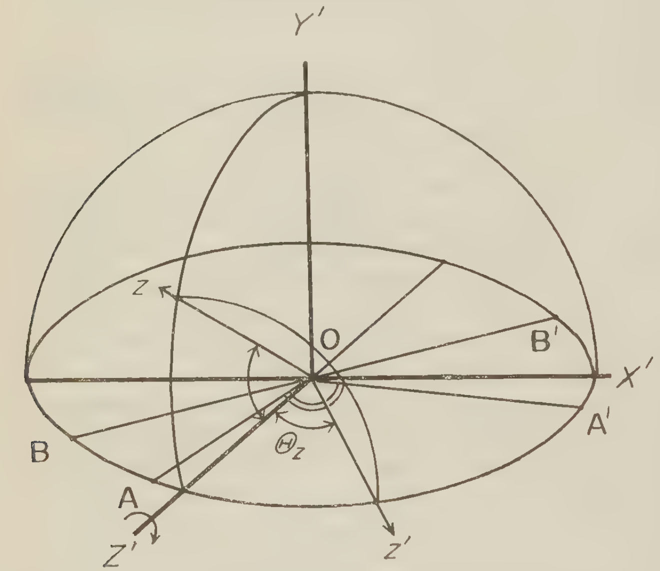

Fig. 6. Diagram illustrating an alternate way determining the direction of field gradient. z, z' denote the directions of the z-axis when it lies in the $Z'Y'$-, $Z'X'$-planes, respectively, hence $\angle Z'Oz' = \angle Z'Oz = \Theta_z$.

Let the z-axis be specified by the polar coordinates $(\Theta_z \Phi_z)$ where the angle Θ_z is measured from the Z-axis, and values for angle Φ_z is determined from a divided circle mounted on the shaft of the crystal holder. An excellent agreement was found between the results obtained by the two methods. But in the present experiment the former was chiefly employed.

(b) **Calculation of angle**

The angle α between the two directions $(\Theta_1 \Phi_1)$ and $(\Theta_2 \Phi_2)$ is calculated from the following equation:

$$\cos\alpha = \sin\Theta_1 \sin\Theta_2 \cos(\Phi_1 - \Phi_2) + \cos\Theta_1 \cos\Theta_2 . \qquad (4$$

(c) **Determination of orientation of two-fold axis of symmetry (or a line perpendicular to the plane of symmetry)**

Nonequivalent directions are systematically arranged about the axis of symmetry, which can be determined from the nonequivalent directions. In this paper we are concerned only with 2-fold axis of symmetry. This symmetry axis should bisect the angle between two proper *N.E.D.* of the z-axes, or be perpendicular to them, and it is easily found by plotting the directions of the z-axes on a globe. Three possible types of orientations of the axis of symmetry, i.e., **U**, **V** and **W** (Fig. 7) are calculated by the following equations where **U** and **V** are the internal and external

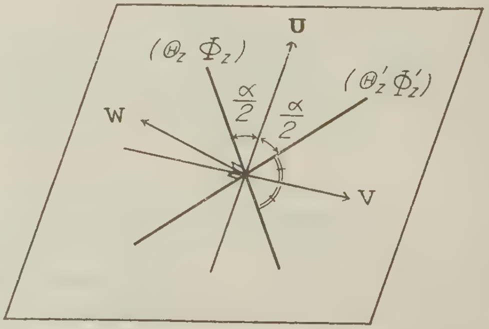

Fig. 7. Three possible types of 2-fold symmetry axis. $(\Theta_z \Phi_z)$, $(\Theta_z' \Phi_z')$ are the two proper *N.E.D.* of the z-axes.

---

* "*Nonequivalent directions of the z-axes of the field gradient tensor*" is abbreviated to *N.E.D.*

isectors of the angle between the two direcions of the z-axes $(\Theta_z\Phi_z)$, $(\Theta_z'\Phi_z')$, respectively, nd **W** is a perpendicular to them,

U:

$$\frac{\sin\Theta_z\cos\Phi_z+\sin\Theta_z'\cos\Phi_z'}{2\cos(\alpha/2)}=\sin\Theta_{\text{sym.}}\cos\Phi_{\text{sym.}}\,,$$

$$\frac{\sin\Theta_z\sin\Phi_z+\sin\Theta_z'\sin\Phi_z'}{2\cos(\alpha/2)}=\sin\Theta_{\text{sym.}}\sin\Phi_{\text{sym.}}\,,$$

$$\frac{\cos\Theta_z+\cos\Theta_z'}{2\cos(\alpha/2)}=\cos\Theta_{\text{sym.}}\,, \tag{5}$$

V: + should be replaced by − in the above equations.

W:

$$\frac{m_1n_2-m_2n_1}{\sin\alpha}=\sin\Theta_{\text{sym.}}\cos\Phi_{\text{sym.}}\,,$$

$$\frac{n_1l_2-n_2l_1}{\sin\alpha}=\sin\Theta_{\text{sym.}}\sin\Phi_{\text{sym.}}\,,$$

$$\frac{l_1m_2-l_2m_1}{\sin\alpha}=\cos\Theta_{\text{sym.}}\,,$$

$$l_1=\sin\Theta_z\cos\Phi_z\,,\quad m_1=\sin\Theta_z\sin\Phi_z\,,$$

$$n_1=\cos\Theta_z\,,\quad l_2=\sin\Theta_z'\cos\Phi_z'\,,\quad \text{etc.}, \tag{6}$$

where α denotes the angle between the two directions $(\Theta_z\Phi_z)$, $(\Theta_z'\Phi_z')$; and $(\Theta_{\text{sym.}}\Phi_{\text{sym.}})$ represents the direction of the symmetry axis.

(d) Determination of η

The angle θ between the z-axis $(\Theta_z\Phi_z)$ and the generating line of zerosplitting cone is calculated from Eq. 4. Using the maximum and minimum values for θ, η is determined from the formula[2)]

$$\eta=\frac{3(\sin^2\theta_{\text{max.}}-\sin^2\theta_{\text{min.}})}{\sin^2\theta_{\text{max.}}+\sin^2\theta_{\text{min.}}}\,. \tag{7}$$

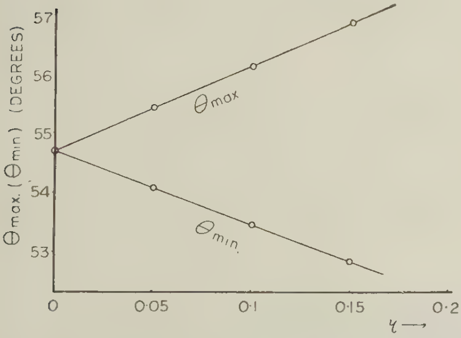

Fig. 8. $\theta_{\text{max.}}$ $(\theta_{\text{min.}})$ as a function of η. This graph was obtained by putting $\phi=0$ $(\phi=\pi/2)$ into Eq. (3).

The alternate method for obtaining the value of η is shown in Fig. 8. From the value of $\theta_{\text{max.}}$ or $\theta_{\text{min.}}$, the value of η may be determined. This method is easier than the former.

§ 3. Experimental Procedure

$SnBr_4$ was prepared by dropping bromine on tin metal, and was distilled at 201°C and sealed in a glass cylinder[8)] (diameter 2.5 cm) with a bottom tapered to a capillary tube of about 15 cm long (inside diameter 1 mm). The single crystal was obtained by descending the container slowly (at about 1 cm/hour) into water through a vertical furnace (at about 75°C) which has a large temperature gradient.

The apparatus was a frequency-modulated superregenerative detector of the CV6×2 push-pull Lecher-wire tuned type[6)], and the absorption lines for Br^{81} were observed on a persistent-screen cathode-ray oscilloscope. The spectrum was obtained with the sample at room temperature (15°~20°C).

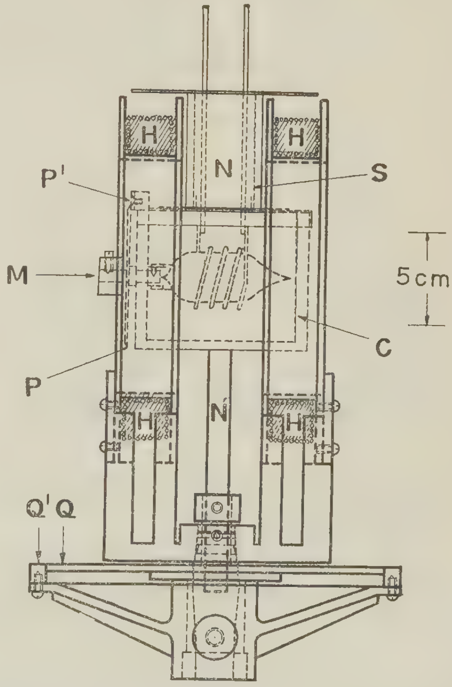

Fig. 9. The universal quadrupole resonance crystal analyzer. **H** denotes the Helmholtz coil.

As Fig. 9 shows, the crystal was set on the shaft **M** in a brass cylinder **C** which had been proved to be non-magnetic, and could be rotated about **M** as one pleases. No particular relative orientation of the sample with respect to the shaft **M** was needed in this apparatus. Values for angle Φ could be measured to

±0.1° from a divided circle **P**, which is mounted on the shaft **M**, and its vernier **P′**.

The external magnetic field, which was provided by a Helmholtz coil **H**, could be rotated about the axis of cylinder **C**, i.e., **N**-**N′** and the values for angle Θ could be measured to ±1′ from a divided circle **Q** and its vernier **Q′**.

Copper static shield **S** was used in order to eliminate the electrostatic effect on the Lecher-wire produced by the rotation of the Helmholtz coil. In order to keep the effect of still surviving faint magnetism constant during the rotation of the external magnetic field, axial symmetry was given to **C** and non-magnetic substance was used as much as possible.

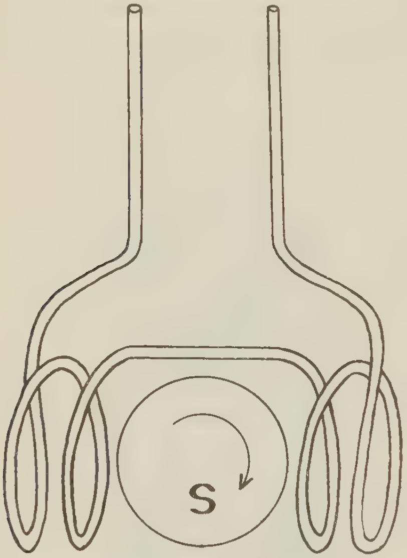

Fig. 10. The special coil used at the second step of the experiment. The sample S is rotated as this figure shows.

In the present experiment, two kinds of hf coils were used. At the first step, the axis of hf coil of usual type was taken nearly parallel to the rotation axis **M**, and the zerosplitting directions were observed on each line of $SnBr_4$. The intensity of the resonance line varies as the square of the sine of the angle between the rf magnetic field and the z-axis of the field gradient, accordingly, if the z-axis is nearly parallel to the hf coil axis (and therefore to the rotation axis **M**), the Zeeman line that is ascribed to it may be missed. In order to remove such apprehension, at the second step of the experiment another hf coil was used, the axis of which was taken perpendicular the rotation axis **M** (see Fig. 10). Then th zerosplitting line that was observed with di ficulty at the first step, became comparativel strong, and the variation of its intensity wit rotation of the sample was reduced, hence th possibility of missing the zerosplitting lin might be deminished. At the second step the experiment, the intensity variation of th resonance line with rotation of the sample i the absence of the external magnetic field wa observed. This results give a rough estimat of orientation of the z-axis of field gradient.

§ 4. Results Obtained

The pure quadrupole resonance absorptio of polycrystalline $SnBr_4$ in the absence o external magnetic field shows $M=4$ an $m_1:m_2:m_3:m_4=1:1:1:1$. Consequently one obtains the following five cases from Eqs (1), (2), and (3) of the previous paper[3] (see Table I). In the seventh column of Table I

Table I. Possible arrangements of **Br** atoms which satisfy Eqs. (1), (2), and (3).

Case	n_1	n_2	n_3	n_4	N	p_{ij}
a	4	0	0	0	1	$p_{11}=p_{12}=p_{13}=p_{14}=1$
b	3	1	0	0	2	
c	2	2	0	0	2	$p_{11}=p_{12}=p_{21}=p_{22}=2$
d	2	1	1	0	3	$p_{11}=p_{12}=2,\ p_{21}=p_{31}=4$
e	1	1	1	1	4	$p_{11}=p_{21}=p_{31}=p_{41}=4$

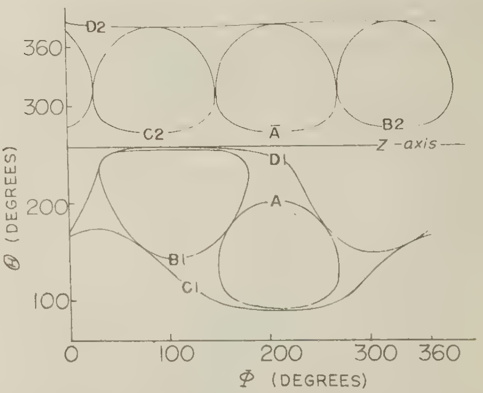

Fig. 11. Zerosplitting-direction-patterns of Zeeman lines of $SnBr_4$. Θ, Φ are polar coordinates with respect to the orthogonal coordinate axes XYZ fixed to the sample. Equivalent patterns are omitted in order to avoid confusion. **A**, **B1**, **B2**, etc. represent the zerosplitting-directions of Zeeman lines at the nuclei $\mathbf{Br_A}$, $\mathbf{Br_{B1}}$, $\mathbf{Br_{B2}}$, etc., respectively.

the arrangements of atoms that do not satisfy the intensity relation are not included. The quartet lines of $SnBr_4$ (in the absence of external magnetic field) are called ***A***, ***B***, ***C***, and ***D*** from the higher to the lower frequency.

Let the bromine atoms that contribute to the line ***B***, etc., be labeled as $\mathbf{Br_{B1}}$, $\mathbf{Br_{B2}}$, etc., briefly, where the latter subscript is used to discriminate the *N.E.D.* At the first step of the determination of zerosplitting direction on each line, it has been shown that ***A*** has only one *N.E.D.*, while $\mathbf{Br_{B1}}$ and $\mathbf{Br_{B2}}$ contribute to the line ***B***; $\mathbf{Br_{C1}}$, $\mathbf{Br_{C2}}$ to the line ***C***; and $\mathbf{Br_{D1}}$ to the line ***D***. While at the second step $\mathbf{Br_{D2}}$ has also been proved to contribute to the line ***D***.

These experimental results are shown in Fig. 11 in which the closed or unclosed contour shows zerosplitting direction of each line. The orientations of the *z*-axes are plotted on a globe. As is shown in Plate 1, an axis of 2-fold symmetry (or a plane of symmetry) can be found.

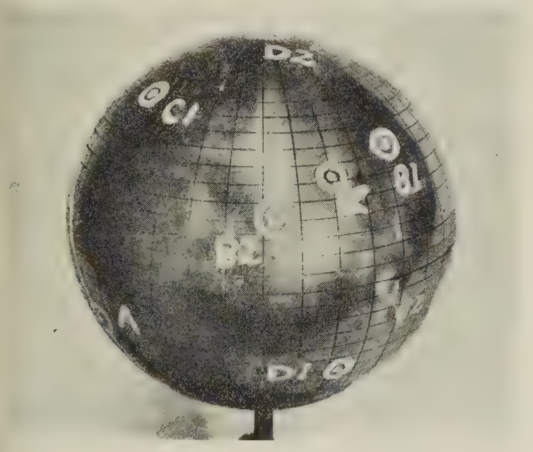

Plate 1. Plotting of directions of the *z*-axes of the field gradient on a globe. **A, B1, B2**, etc. represent the directions of the *z*-axes of the field gradient at the nuclei $\mathbf{Br_A}$, $\mathbf{Br_{B1}}$, $\mathbf{Br_{B2}}$, etc., respectively.

The intensity variation with rotation of the crystal at the second step of the experiment is shown in Fig. 12.

In the temperature range between about 10°C and the dry-ice temperature two closely spaced lines were observed; the resonance frequency being 161.15 Mc, 160.95 Mc for Br^{81} at 12°C. The higher frequency resonance line is three times more intense than the lower one (Fig. 13). This spectrum is noticeably different from those of the SnI_4 type crystals in the two points, namely the spacing and the intensity distribution of the doublets. These lines seem to be in good agreement with an earier measurement[5]. This spectrum suggests the existence of another phase of the crystal structure, which is tentatively called β-phase, while the high temperature phase so far studied mainly is called α-phase. When the β-phase of the crystal is heated near room temperature, an increase in volume occurs often resulting in the fracture of the glass container. This fact seems to correspond to the phase transformation.

In the temperature range between the liquid nitrogen and liquid air temperature, the striking four-lines spectrum indicates that the crystal has the same structure as that of the α-phase.

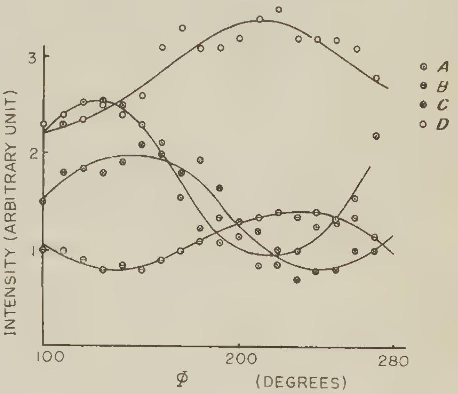

Fig. 12. The intensity variation of resonance lines with rotation of the sample in the hf field as shown in Fig. 10. The relative intensity of each line has no significance since each line was measured under different conditions, e.g., different quenching frequencies.

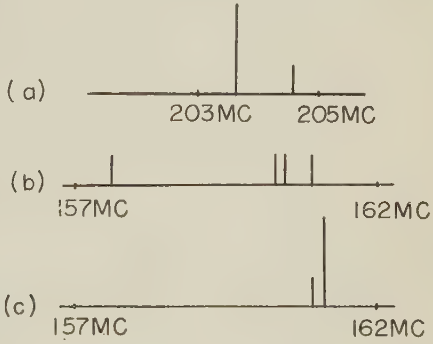

Fig. 13. Resonance spectra of SnI_4 and $SnBr_4$. (a) SnI_4, (b) α-$SnBr_4$, (c) β-$SnBr_4$.

§ 5. Discussions

The number of *N.E.D.* of the lines *A*, *B*, *C*, and *D* are 1, 2, 2, and 2, respectively. Accordingly the single crystal must have been perfect, since otherwise the line *A* could not have only one *N.E.D.* Moreover, one might expect no missed line, since at the second step, only $\mathbf{Br}_{\mathrm{D2}}$ was newly added and moreover $\mathbf{Br}_{\mathrm{A}}$, $\mathbf{Br}_{\mathrm{B1}}$, $\mathbf{Br}_{\mathrm{B2}}$, $\mathbf{Br}_{\mathrm{C1}}$, $\mathbf{Br}_{\mathrm{C2}}$, $\mathbf{Br}_{\mathrm{D1}}$ that had already been found at the first step and were expected to absorb weakly this time, were also observed, and since the positions of maxima and minima of each resonance line in Fig. 12 are compatible with Fig. 11. Accordingly, one may conclude that the crystal has monoclinic symmetry, because each line has 2-*N.E.D.*9) generally, and as Plate 1 shows, the crystal has only one 2-fold symmetry axis; i.e., *b*-axis, or a plane of symmetry.

And the fact that *A* has only 1-*N.E.D.* shows that cases (c), (d), and (e) are impossible, because in these cases the line *A* also must have more than 2-*N.E.D.* Consequently only case (a) is possible; each bromine and **Sn** atoms in a $\mathrm{SnBr_4}$ molecule situate at their own crystallographically general positions which are nonequivalent to each other, because each atom of $\mathrm{SnBr_4}$ molecule must possess the same number of equivalent positions in a unit cell from the relations $p_{11}=p_{12}=p_{13}=p_{14}=1$ and five atoms including **Sn** in the molecule cannot situate simultaneously at their own special positions10) having fewer equivalent points than the maximum number of generally equivalent ones in the monoclinic crystal. So the number of molecules in a unit-cell is equal to the maximum number of equivalent positions of the space-group of the crystal. If the number of molecules per unit-cell is determined from the density and dimensions of the unit-cell which are obtained by the X-ray method, the space-group may be discussed.

The angles between any two **Sn-Br** bond directions calculated from Eq. 4 using the data obtained from Fig. 11 are listed in Table II, where the value in parenthesis is the supplementary angle of the other. These two possibilities of the bond angle are due to the fact that the Zeeman effect cannot distinguish between the positive and negative directions of the *z*-axis of the field gradient. In order to determine the true one of these two possibilities one must rely on other data. Since the gas molecule of $\mathrm{SnBr_4}$ has been found to be an exact tetrahedron11), one may expect that this molecule is nearly an exact tetrahedron in the solid state also.

Table II. The angles between all the **Sn–Br** bonds in the crystal.

Sn	$\mathbf{Br}_{\mathrm{A}}$	$\mathbf{Br}_{\mathrm{B1}}$	$\mathbf{Br}_{\mathrm{B2}}$	$\mathbf{Br}_{\mathrm{C1}}$	$\mathbf{Br}_{\mathrm{C2}}$	$\mathbf{Br}_{\mathrm{D1}}$
$\mathbf{Br}_{\mathrm{A}}$						
$\mathbf{Br}_{\mathrm{B1}}$	70°19′ (109°41′)				Bond Angle	
$\mathbf{Br}_{\mathrm{B2}}$	70° 7′ (109°53′)	39°36′ (140°24′)			α $(180°-\alpha)$	
$\mathbf{Br}_{\mathrm{C1}}$	69°11′ (110°49′)	109°11′ (70°49′)	122°52′ (57° 8′)			
$\mathbf{Br}_{\mathrm{C2}}$	70°13′ (109°47′)	56°43′ (123°17′)	110°10′ (69°50′)	55°56′ (124° 4′)		
$\mathbf{Br}_{\mathrm{D1}}$	109°14′ (70°46′)	70°28′ (109°32′)	54°22′ (125°38′)	71°38′ (108°22′)	39° 2′ (140°58′)	
$\mathbf{Br}_{\mathrm{D2}}$	70°43′ (109°17′)	55°13′ (124°47′)	71°19′ (108°41′)	139°54′ (40° 6′)	109° 0′ (71° 0′)	122°35′ (57°25′)

Taking this into consideration, we find from Table II that each of the groups $\mathbf{Br}_{\mathrm{A}}$, $\mathbf{Br}_{\mathrm{B1}}$, $\mathbf{Br}_{\mathrm{C1}}$, $\mathbf{Br}_{\mathrm{D1}}$ and $\mathbf{Br}_{\bar{\mathrm{A}}}$, $\mathbf{Br}_{\mathrm{B2}}$, $\mathbf{Br}_{\mathrm{C2}}$, $\mathbf{Br}_{\mathrm{D2}}$ belongs to each molecule where the symbols **A**, $\bar{\mathbf{A}}$ mean that the atoms that contribute to the resonance line *A* have *E.D.* of the *z*-axis. This fact is more easily verified in Fig. 11, where the contours that correspond to $\mathbf{Br}_{\mathrm{A}}$, $\mathbf{Br}_{\mathrm{B1}}$, $\mathbf{Br}_{\mathrm{C1}}$, $\mathbf{Br}_{\mathrm{D1}}$ (or $\mathbf{Br}_{\bar{\mathrm{A}}}$, $\mathbf{Br}_{\mathrm{B2}}$, $\mathbf{Br}_{\mathrm{C2}}$, $\mathbf{Br}_{\mathrm{D2}}$)

ontact with each other, which means that $r_A Br_{B1} Br_{C1} Br_{D1}$, etc., may be an almost xact tetrahedron and that the value of η may e small, because two times of the zerosplitting angle $\theta = 54°44'$ corresponding to $\eta = 0$, is qual to 109°28′ which is the tetrahedral bond ngle. The relative orientation of each **Sn-Br** ond with respect to the b-axis is obtained by sing Eq. 5. The results are given in Fig. 14.

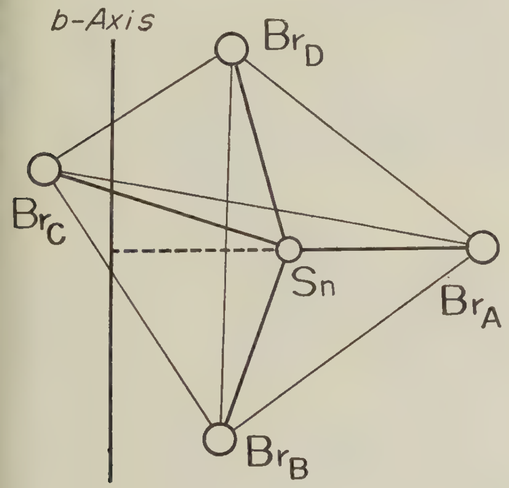

Fig. 14. Relative orientation of $SnBr_4$ tetrahedron with respect to the b-axis.

$\angle \mathbf{Br_A}\text{-}\mathbf{Sn}\text{-}\mathbf{Br_B} = 109°47' \pm 6'$,

$\angle \mathbf{Br_A}\text{-}\mathbf{Sn}\text{-}\mathbf{Br_C} = 110°18' \pm 31'$,

$\angle \mathbf{Br_B}\text{-}\mathbf{Sn}\text{-}\mathbf{Br_C} = 109°40' \pm 29'$,

$\angle \mathbf{Br_D}\text{-}\mathbf{Sn}\text{-}\mathbf{Br_A} = 109°16' \pm 2'$,

$\angle \mathbf{Br_D}\text{-}\mathbf{Sn}\text{-}\mathbf{Br_B} = 109°\ 7' \pm 25'$,

$\angle \mathbf{Br_D}\text{-}\mathbf{Sn}\text{-}\mathbf{Br_C} = 108°41' \pm 19'$,

$\mathbf{Sn}\text{-}\mathbf{Br_C}$, $\mathbf{Sn}\text{-}\mathbf{Br_D}$, $\mathbf{Sn}\text{-}\mathbf{Br_B}$, $\mathbf{Sn}\text{-}\mathbf{Br_A}$ orient at the angles $62°2' \pm 9'$, $61°18' \pm 24'$, $19°48' \pm 14'$, and $90°0' \pm 20'$, respectively, to the b-axis.

From Fig. 14 we may conclude that the molecule is an exact tetrahedron within the experimental accuracy, and that the predominant configuration of electron of covalent bond of **Sn** atom is $4s\,(4p)^3$.

As in the case of SnI_4[11)12)], the **Sn-Br** bond length in the solid state is assumed to be nearly equal to that of the gas molecule, i.e., 2.44Å[11)], and considerable amount of double ond character[6)] may be expected, nevertheless, it is concluded that the value of η at the r_A nucleus does not exceed 0.025, from Fig. using the value of zerosplitting angle of ig. 15. The small value of η is ascribed to he 3-fold symmetry character of the $SnBr_4$ olecule about the $\mathbf{Sn}\text{-}\mathbf{Br_A}$, etc. Consequently, we may conclude that each **Sn-Br** bond length is nearly equal. As Fig. 14 shows $\mathbf{Sn}\text{-}\mathbf{Br_A}$ is perpendicular to the b-axis (this is the reason why the line A has only 1-$N.E.D.$)[9)], while $\mathbf{Sn}\text{-}\mathbf{Br_C}$ and $\mathbf{Sn}\text{-}\mathbf{Br_D}$ have almost the same angle between the b-axis, and the plane $\mathbf{Br_B Br_C Br_D}$ may be almost parallel to the b-axis.

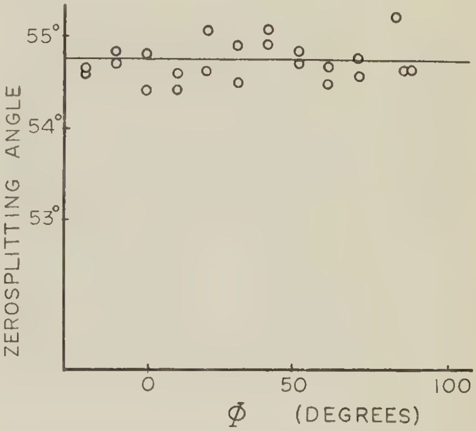

Fig. 15a. The zerosplitting angle θ as a function of Φ. The straight line at 54°44′ corresponds to $\eta = 0$.

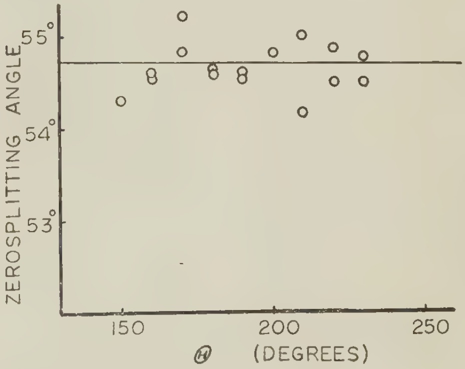

Fig. 15b. The zerosplitting angle θ as a function of Θ.

Unfortunately, the nuclear quadrupole resonance itself always introduces into the Zeeman analysis the effect of adding a center of symmetry to the crystal.[9)] It is therefore impossible on the basis of the Zeeman analysis alone to distinguish between C_s, C_2, and C_{2h}. But the resonance spectrum may discriminate these point-groups. The resonance frequency of $\mathbf{Br_D}$ atom is considerably lower (1.8%) than those of $\mathbf{Br_A}$, $\mathbf{Br_B}$, and $\mathbf{Br_C}$. The spacing of the multiplets is too large to be ascribed only to the difference of the nuclear sites* in the crystal. So it is concluded that the bond character of $\mathbf{Br_D}$ may be slightly different from those of $\mathbf{Br_A}$, $\mathbf{Br_B}$, and $\mathbf{Br_C}$.

The electric field gradient, that is produced primarily by the valence electron, at a given nucleus may be affected by the change in ionic character of the bonds due to electrostatic interactions[1)13)] between neighbouring ions. The consideration on the feature of the spectrum consisting of three lines grouped together with a fourth line at noticeably lower frequency indicates that the arrangement of surrounding molecules must have approximately three-fold symmetry character about the $\mathbf{Sn}$-$\mathbf{Br_D}$ bond. As concluded before, this substance has monoclinic symmetry, which has not three-fold axis, so we may deduce the existence of *pair of tetrahedral molecules*, whose interactions with each other are more prominent than those with the other neighbouring molecules, and which contribute three-fold symmetrical fields to each other. The three-fold symmetrical field will be given by the two neighbouring tetrahedral molecules whose $\mathbf{Sn}$-$\mathbf{Br_D}$ bond-directions are coincident. The models which are compatible with the striking pure quadrupole spectrum and with the relative orientation of the $SnBr_4$ tetrahedron with respect to the b-axis, are shown in Fig. 16. In the model (a) of Fig. 16, the base of each tetrahedron, i.e., $\mathbf{Br_A}$-$\mathbf{Br_B}$-$\mathbf{Br_C}$-$\mathbf{Br_A}$, sites opposite to that of the other one, and the edges $\mathbf{Br_A}\rightarrow\mathbf{Br_B}$, $\mathbf{Br_B}\rightarrow\mathbf{Br_C}$ and $\mathbf{Br_C}\rightarrow\mathbf{Br_A}$ of one tetrahedron are antiparallel to that of the other one, respectively, while in the other model (b), the two $\mathbf{Br_D}$ atoms in a pair of tetrahedrons face to each other along the line connecting the two $\mathbf{Sn}$ atoms. This pair of molecules which satisfy the relative orientation with respect to the b-axis can be realized in the crystal which has C_{2h} symmetry among the three possible symmetry class mentioned above.

While, in SnI_4[12)14)], GeI_4[12)14)], and SiI_4[12)14)] which have structures of the type (a) of Fig. 16, six $\mathbf{I}$ atoms which form the facing planes of the two tetrahedrons contribute to the low frequency line of the doublets[6)]. Hence, on the basis of the existence of pair of molecules of the type (a) the resonance frequencies of $\mathbf{Br_A}$, $\mathbf{Br_B}$, and $\mathbf{Br_C}$ may be expected to be lower than that of $\mathbf{Br_D}$ independently of the crystal structure. This conclusion is opposite to the spectrum, so we prefer the model (b). And moreover in the β-phase the stronger resonance line has higher frequency than the other, and this may also be interpreted by the use of the model (b).

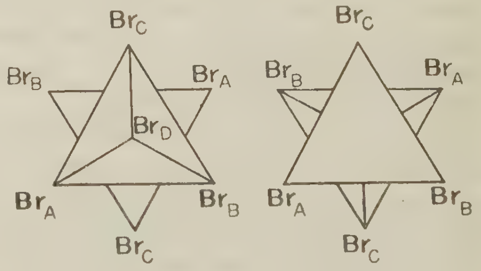
While, in order to estimate the influence of the partner molecule in contrast with that of the other neighbouring molecules, let us consider the difference of the values of the following quantity at each resonant nucleus

$$u=\left|\frac{eQq}{(eQq)_{\mathrm{atom}}}\right|^{*}$$

where q is the magnitude of the field gradient at the resonant nucleus and $(eQq)_{\mathrm{atom}}$ is the atomic coupling constant.

Using the data on the resonance frequencies, one finds that Δu, the difference of the value of u at $\mathbf{Br_D}$ and the mean value of those at $\mathbf{Br_A}$, $\mathbf{Br_B}$, and $\mathbf{Br_C}$, is 9.7×10^{-3}. On the other hand, in SnI_4 in which the $\boldsymbol{A}$, $\boldsymbol{B}$, and $\boldsymbol{C}$ lines coalesce into a single line, Δu is 4.2×10^{-3}. Accordingly, Δu, the intermolecular interaction of $SnBr_4$, is about the same order of that of SnI_4.

On the other hand, Δu in the β-phase is 6.1×10^{-4}. This small value of Δu in the β-phase indicates that the origin of Δu in the α-phase is not due to the covalent bond between the pair of molecules but due to electrostatic interaction between neighbouring ions tending to lower the energy of the ionic form



(a) (b)

Fig. 16. Proposed models of pair of molecules.

---

* The moderate spacings of the lines, $\boldsymbol{A}$, $\boldsymbol{B}$, and C, are ascribed to the nonequivalency of sites of the atoms, $\mathbf{Br_A}$, $\mathbf{Br_B}$, and $\mathbf{Br_C}$, which have almost the same bond character.

* On the estimation of the unbalanced p-electron, eQq in the numerature is usually evaluated from the mean value of the resonance frequencies of component lines of the multiplets.

of each **Sn**-**Br** bond, because if the former is the true origin of Δu, the same order of magnitude of Δu is expected also in the β-phase as in the α-phase.

The arrangements of molecules which are shown in Fig. 16 are possible in the space-groups of C_{2h}^2, C_{2h}^4, C_{2h}^5, and C_{2h}^6, and are impossible in the C_2 symmetry class. Fig. 17 shows an illustration of the arrangements of molecules.

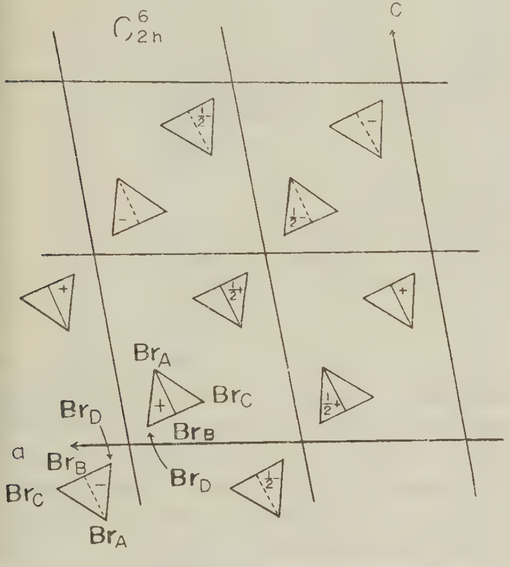


Fig. 17. An illustration of arrangement of $SnBr_4$ tetrahedrons. The b-axis is taken upwards from the plane of the paper, while the directions of the a- and c-axes which cannot be determined from this experiment, are drawn arbitrarily.

From the analysis of the spectrum of the β-phase, one may reasonably conclude that $p_{11}=3$, and $p_{12}=1$, and that the structure must have cubic or hexagonal symmetry. The bond direction connecting the central **Sn** atom with one of the four **Br** atoms in one molecule is coincident with three-fold symmetrical axis of this crystal, and the other three bromine atoms occupy the three equivalent positions about the three-fold axis. The small value of Δu in the β-phase is interpreted as follows; the neighbouring molecules distributed about the three-fold axis contribute the same order of magitude of intermolecular interaction as that between the pair of molecules.

A. E. Nordenskjöld[15] (1863) showed that the crystals form rhombic pyramids with axial ratios a : b : c = 0.556 : 1 : 1.487. But we cannot give orthorhombic symmetry on the basis of Zeeman analysis. This substance is so hygroscopic that the treatment in the air is very difficult, and the optical study has not yet been made with any success by us. The study of the crystal structure by the optical and X-ray methods will be performed in near future.

Microwave Studies of the Internal Motion and the Structure of Methyl Amine

By Tetsuji NISHIKAWA*

Department of Physics, Faculty of Science, University of Tokyo, Tokyo, Japan

(Received January 19, 1957)

This is the final report of a series of papers from this laboratory on the internal motion and the structure of methyl amine. Most of the observed lines including $J=1\leftarrow0$, $K=0\leftarrow0$ lines were analyzed in the frequency range between 4 and 50 kMc/sec. The barrier height of internal rotation has been determined to be 691.1 cm^{-1} as well as the molecular structure, $d_{\mathrm{CN}}=1.474$ A, $\angle\mathrm{HNC}=112°10'$, $\angle\mathrm{HNH}=105°50'$, $\angle\mathrm{HCH}=109°30'$ and the angle between CN and methyl axis$=3°30'$ on the assumption that $d_{\mathrm{CH}}=1.093$ A and $d_{\mathrm{NH}}=1.014$ A. These results were compared with the barrier height and the structure of other $\mathrm{CH_3\,MH}_n$ type molecules, methyl alcohol and methyl mercaptan.

The inversion doubling of the observed lines was also analyzed satisfactorily. The quadrupole coupling constant of N^{14} along the charge symmetry axis has been obtained as -3.6 ± 0.3 Mc/sec, with the direction of the axis, 90°±8, from the methyl axis.

§ 1. Introduction

Methyl amine is a unique molecule in microwave spectroscopy because of the remarkable effects of both internal rotation and inversion. The spectrum was observed in the frequency range between 4 and 34 kMc/sec by several workers[1,2,3]. Since the spectrum is very much complicated by the internal motion, former analyses were entirely incomplete. A previous study[1]**, however, showed that the internal rotation of the molecule can be treated by a theory similar to those of Dennison and others for methyl alcohol[4,5,6], with an additional treatment on the coupling between the internal rotation and inversion. The molecular structure calculated from frequencies of several lines by use of the theoretical method was reported by Itoh[7]. After these previous studies, the frequency range of observation has been extended to the millimeter wave region, where many important lines for the complete analysis, such as $J=1\leftarrow0$ line, have been found.

§ 2. Experimental Results

The spectrometer used and the frequencies of the lines previously observed were already reported in SNI. Since the spectrum of methyl amine consists of many lines due to complicated transitions, it was important to study the Stark effects of the lines precisely. All the observed lines can be classified into five classes according as they show whether

1) the first-order Stark effect with stronger outer components, 1(o),
2) the first-order effect with stronger inner components, 1(i),
3) the second-order Stark effect with positive Stark shift, 2(+),
4) the second-order effect with negative Stark shift, 2(−), or
5) the first-order effect similar to 1(o) in a weaker field ($\lesssim 100$ V/cm), and nearly the second-order effect, 2(+), in a stronger field, 1→2.

A high sensitivity Stark-modulation spectrometer for the millimeter wave region was also constructed. A frequency multiplier using a commercial crystal mixer, 1N 26, driven by a K-band klystron, 2K 33, was employed as the power source. The conversion loss of the multiplier was estimated to be less than 15 db for the second harmonics. A K-band waveguide absorption cell of one meter long sealed by teflon sheets of 1 mil thick was used. The Stark electrode was supported by teflon plates of 20 mils thick in a usual manner. The loss was as small as 0.7 db/ft at 48 kMc/sec. A detector current of more than 50 μA was ob-

tained at the output end of the absorption cell. About one hundred lines were found in the region between 40 and 50 kMc/sec. Their observed frequencies and Stark effects are listed in Table I.

After a careful study, some additional lines have also been found in the frequency range between 11 and 28 kMc/sec; they are given in Table II.

§ 3. Theoretical Consideration

The energy level of methyl amine type molecule may be written as

$$W^{JK\mu n\pm}=W_0^{JK\mu n\pm}+\tilde{W}^{JK\mu n\pm} \tag{1a}$$

and $$W_0^{JK\mu n\pm}=W^{JK}+W^{K\mu n}+W^{n\pm}\,, \tag{1b}$$

where J and K are the usual rotational quantum numbers, n is the quantum number of torsional vibration, and $\mu(=0,\ \pm1)$* is the quantum number of hindered rotation; + or − indicates the inversion state, i.e. whether it corresponds to the triplet or singlet nuclear spin state of the two hydrogen nuclei in the amino group.

In equation 1(b), W^{JK} expresses the rotational energy when the molecule is assumed to be a rigid symmetric rotor, $W^{K\mu n}$ is the energy of internal rotation, and $W^{n\pm}$, which is also affected by K and μ because of the interaction with the internal rotation, is the energy of inversion. $\tilde{W}^{JK\mu n\pm}$ in equation 1(a) is the perturbation energy due to asymmetry.

From the theory developed by Itoh[7], W^{JK}, $W^{K\mu n}$, and $W^{n\pm}$ can be expressed by

$$W^{JK}=\frac{A+B}{2}(J(J+1)-K^2)-CK^2\,, \tag{2}$$

$$W^{K\mu n}=VR^{K\mu n}\,, \tag{3}$$

$$W^{n\pm}=\pm\frac{1}{2}(-1)^K\Delta_0\int_0^{2\pi}Q^{K\mu n*}(x)Q^{K\mu n}(x-\pi)dx\,, \tag{4}$$

where

$$A=\frac{h^2}{8\pi^2I_x}\,,\qquad B=\frac{h^2I_y}{8\pi^2(I_y^2+D^2)}\,,$$

$$C=\frac{h^2}{8\pi^2}\left(\frac{I_y+I_z}{I_yI_z-D^2}-\frac{I_y}{I_y^2+D^2}\right),$$

$$V=\frac{h^2}{8\pi^2}\frac{I_yI_z-D^2}{I_2(I_yI_1-D^2)}$$

I_x, I_y, and I_z are the moments of inertia about x, y and z axes, and D is the product of inertia with respect to y and z axes, z axis being parallel to the symmetry axis of methyl group, y axis being comprised in the bisecting plane of HNH angle, and the origin being taken at the center of masses of the molecule. I_1 is defined as $I_1=I_z-I_2$, where I_2 is the moment of inertia of methyl group about its symmetry axis. $R^{K\mu n}$ and $P^{K\mu n}(x)=e^{iKx}Q^{K\mu n}(x)$ are respectively the eigen value and the eigen function of the internal rotation which were introduced by Koehler and Dennison[4], whereas $\alpha=\frac{2\pi^2}{h^2}H_0\frac{I_1I_2}{I_z}$ and $\sigma=-\frac{I_1}{I_z}K$ in their equation are replaced by $\alpha'=\frac{2\pi^2}{h^2}H_0\left(\frac{I_2(I_yI_1-D^2)}{I_yI_z-D^2}\right)$ and $\sigma'=-\left(1-\frac{I_2\sqrt{I_y^2+D^2}}{I_yI_z-D^2}\right)K$. The potential barrier is assumed to be a sinusoidal form, $\frac{H_0}{2}(1-\cos 3x)$. The energy of inversion doubling can be calculated from equation (4), where the constant, Δ_0, would correspond to the hypothetical inversion splitting if the coupling between inversion and internal rotation were absent.

The perturbation energy $\tilde{W}^{JK\mu n\pm}$ in equation (1.a) consists of the terms due to the K, $K\pm1$ off-diagonal elements of the Hamiltonian and of the terms due to the K, $K\pm2$ elements. It can be expressed by

$$\begin{aligned}\tilde{W}^{JK\mu n\pm}&=\tilde{W}^{K}_{K\pm1}+\tilde{W}^{K}_{K\pm2}\\&=S^2\left[\frac{\left(K-\frac{1}{2}\right)^2(J-K+1)(J+K)(I^{K-1\mu n}_{K\ \ \mu n})^2}{W_0^{JK\mu n\pm}-W_0^{JK-1\mu n\pm}}+\frac{\left(K+\frac{1}{2}\right)^2(J-K)(J+K+1)(I^{K+1\mu n}_{K\ \ \mu n})^2}{W_0^{JK\mu n\pm}-W_0^{JK+1\mu n\pm}}\right]\\&+\frac{1}{4}(A-B)^2\left[\frac{(J+K)(J+K-1)(J-K+1)(J-K+2)}{W_0^{JK\mu n\pm}-W_0^{JK-2\mu n\pm}}I(^{K-2\mu n}_{K\ \ \mu n})^2\right.\\&\left.+\frac{(J-K)(J-K-1)(J+K+1)(J+K+2)}{W_0^{JK\mu n\pm}-W_0^{JK+2\mu n\pm}}(I^{K+2\mu n}_{K\ \ \mu n})^2\right],\end{aligned} \tag{5}$$

where $S=\frac{h^2}{8\pi^2}\frac{D}{I_y^2+D^2}$ and $I^{K'\mu n}_{K\ \mu n}=\int_0^{2\pi}Q^{K\mu n*}(x)Q^{K'\mu n}(x)dx$.

$W_0^{JK0n\pm}$ is equal to $W_0^{J-K0n\pm}$, so that the asymmetry of the molecule yields the K-type doublet for $\mu=0$ and $K\neq0$ states as in a rigid asymmetric rotor. When the effect of internal rotation is not so large as in the ground torsional state in methyl amine, the magnitude of the doublet splitting is approximately given by Wang's formula8),

---

* $K-\tau+\mu=1$ (mod. 3), where $\tau(=1, 2, 3)$ is the quantum number used by Dennison and others.

$$\Delta W=\frac{A-B}{2}\left(\frac{\delta}{1-\frac{1}{2}\delta}\right)^{K-1}$$
$$\times\frac{(J+K)!}{16^{K-1}(J-K)!(K-1)!(K-1)!}\ . \qquad (6)$$

The asymmetry parameter δ is

$$\delta=\frac{A-B}{C-A}\ . \qquad (7)$$

It must be noted that the denominator of the $K\leftrightarrow K\pm 2$ interaction term in equation (5) is sometimes too small to use the perturbation method. For example, if $\mu=0$, the perturbation energy due to $K=1\leftrightarrow -1$ interaction is replaced by

$$\Delta W_{J\ \ 10n}^{J-10n}=\frac{A-B}{2}I_{\ 10n}^{-10n}J(+1)\ , \qquad (8)$$

from equation (6), including the effect of internal rotation.

For $\mu=\pm 1$, Burkhard and Dennison5) showed that the energy level $W^{JK\mu n\pm}$ always degenerates to the level $W^{J-K-\mu n\pm}$ belonging to a degenerate symmetry class, E, while the degeneracy of K and $-K$ levels for the same J, μ, n, and inversion state is already removed by the tunneling effect due to the internal rotation even in the symmetric top approximation. However, in some cases as $|K|=1$, ΔW in equation (6) may be as large as the magnitude of $W_0^{JK\mu n\pm}-W_0^{J-K\mu n\pm}$. In such case, the energy level $W^{JK\mu n\pm}$ must be calculated by solving a secular equation,

$$\begin{vmatrix} W_0^{JK\mu n\pm}-W & \frac{\Delta W}{2} \\ \frac{\Delta W}{2} & W_0^{J-K\mu n\pm}-W \end{vmatrix}=0 \qquad (9)$$

Again, the perturbation energy due to $K=1\leftrightarrow -1$ interaction must be excluded from equation (5), when its effect is taken account by means of equation (9).

The selection rules for allowed transitions are $\Delta J=0$ or ± 1, $\Delta K=0$ or ± 1, $\Delta n=0$, $\Delta\mu=0$, and $+\leftrightarrow+$, or $-\leftrightarrow-$.

§ 4. Analysis of the Spectrum

a) Assignment of the series

Eight well-defined series of lines have been found in the observed range; seven of them, p_1, p_2, q_1, q_2, r_1, r_2 and s_1, were already reported in SNI, the remaing one, s_2, having been found later in the millimeter wave region.

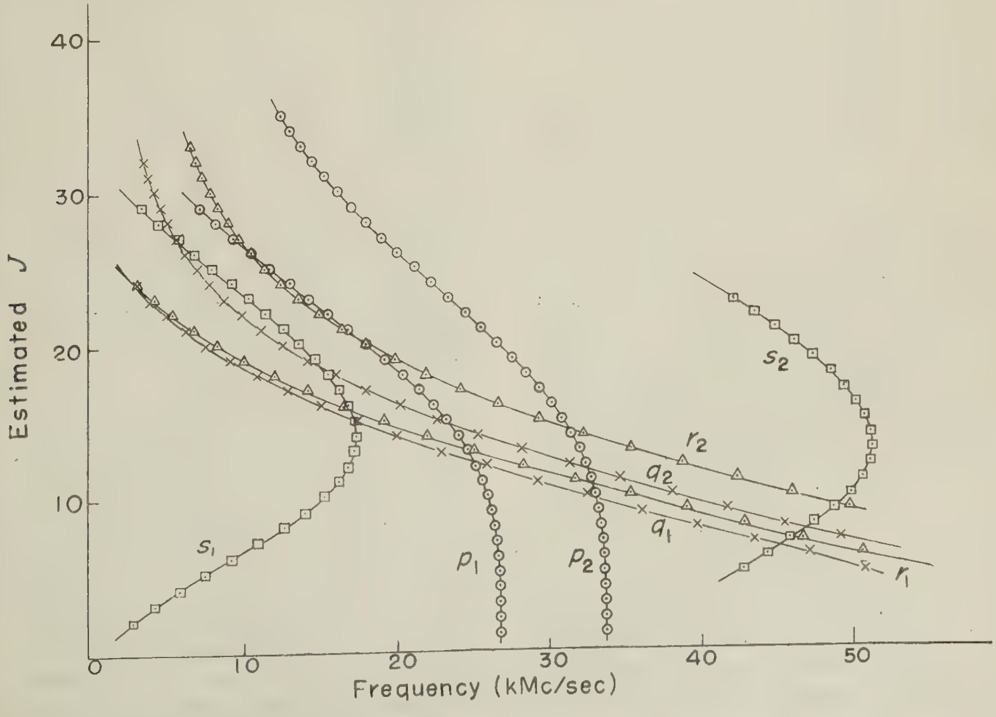

Fig. 1. Frequencies of the lines of series plotted against their rotational quantum number J. J values are only approximate except for p series.

The Stark effect for p series is 1(o), that for q series is 1→2, and those for r and s series are 2(+).

These series correspond to the transitions, $\Delta J=0$ and $\Delta K=\pm 1$, and member lines of a series correspond to successive J values. The frequencies of the observed lines are plotted against estimated J values in Fig. 1. Among the observed series the initial lines were observed only for p_1 and p_2 series. The frequencies of initial lines of theoretically possible series were calculated as functions of the barrier height as shown in Fig. 2 of SNI. The first-order Stark effect of p series indicates that the series belongs to the transitions between degenerated levels of internal rotation, $\mu=\pm 1$. From the study of the Stark pattern of a few low J lines of p_1 series and also from the intensity consideration, p series were previously assigned to the transition $J \leftarrow J$, $K=1\leftarrow 0$, $\mu=1\leftarrow 1$, and $n=1\leftarrow 1$; p_1 correspond to the stronger inversion partner, $+\leftarrow +$ while p_2 to the weaker partner, $-\leftarrow -$.

The Stark pattern of some low J lines of series have also been resolved, and the mea frequency of the initial lines of s_1 and series can be estimated to be nearly 20 kMc sec. If one takes the barrier height of abou 700 cm^{-1} which is infered from the assignmen of p series, s series can be uniquely assigne to the transitions, $J \leftarrow J$, $K=0\leftarrow 1$, $\mu=0\leftarrow$ and $n=1\leftarrow 1$; s_1 to $+\leftarrow +$ and s_2 to $-\leftarrow -$.

On the other hand, the initial lines of q an r series are in the higher frequency regio than the observed range, and a few sets c assignments are possible. The previous ten tative assignments in SNI, however, wer found to be incorrect, and the present assign ments are given in Table III. The most im portant difference lies in the assignment of for q series. Even by the crude theory in SNI, it could be expected that the frequencies of member lines of $\mu=0$, $K=1\leftarrow 0$ series ($n=0$) would greately deviate from the frequency of the initial line (80∼90 kMc/sec). Thus q series was assigned to this transition, though its peculiar Stark effect (1→2) was rather inconsistent with the assignment. The Stark effect of $\mu=0$ lines should be simple second-order as observed in s series.

Table III. Assignments of series.

Series	Assignment			Frequency of initial line		Inversion state	Magnitude of inversion doubling	
	$K' \leftarrow K$	μ	n	Obs. (Mc/sec)	Calc. (Mc/sec)		Obs.(Mc/sec)	Calc.(Mc/sec
p_1	1←0	1	1	26734*	26734	+	6903*	6903
p_2	1←0	1	1	33637*	33637	−		
q_1	1←0	−1	0	—	70428	−	∼5000	8641
q_2	1←0	−1	0	—	79069	+		
r_1	1←0	0	0	—	79171	+	∼10000	10690
r_2	1←0	0	0	—	89861	−		
s_1	0←1	0	1	∼2000	2743	+	∼36000	38064
s_2	0←1	0	1	∼38000	40807	−		

If the $K=1\leftrightarrow -1$ interaction in $\mu \neq 0$ lines is taken into account, however, it is found that the frequencies of member lines of $\mu=-1$, $K=1\leftarrow 0$ series ($n=0$) also deviate to the lower frequency region from the frequency of initial line (70∼80 kMc/sec). The Stark effect of this series should be primarily first-order, 1(o), similar to p series, but should become second-order, 2(+), because of the $K=1\leftrightarrow -$ interaction. This just accounts for the pecu liar Stark effect of q series, 1→2. From theoretical considerations, the q_1 series is as signed to be the weaker inversion partner $-\leftarrow -$, whereas q_2 series to $+\leftarrow +$. These assignments differ from the previous ones no only in respect to μ, but also to the inversion states. Since the intensities of lines in q_1 and q_2 series were almost equal in the spectrum of centimeter wave region, it was difficult in SNI to decide from the experimental results which of q_1 and q_2 series belongs to the stronger inversion state. But it has been clearly confirmed from the millimeter wave spectrum that the q_2 series belongs to the stronger state because the intensity difference of the lines becomes more significant as the

J value decreases.

Now the transitions $\mu=0$, $K=1\leftarrow 0$, and $n=0$ are assigned to r series instead of q series; r_1 is the stronger inversion partner $+\leftarrow+$ and r_2 is $-\leftarrow-$. The lines of $\mu=0$, $K=2\leftarrow 1$, and $n=1$ series, that was assigned to r series in SNI, are considered to be so weak that the series could not be taken out from the observed spectrum; its initial line lies at a very high frequency region ($\sim$100 kMc/sec) and it belongs to the excited torsional state.

b) Analysis of $4_2\leftarrow 5_{\pm 1}$ and $6_{\pm 1}\leftarrow 5_2$ lines

From the study of Stark effects some ten lines, which were expected to correspond to the transitions, $J_K=4_2\leftarrow 5_{\pm 1}$ or $6_{\pm 1}\leftarrow 5_2$ in the ground torsional state, were found. In case of $\mu=0$, these lines show either 2(+) or 2(−) Stark effect according to the lower or higher frequency partner of the K-type doublet. Lide[2] assigned the lines at 23341, 23450 and 36452 Mc/sec to $4_{22}\leftarrow 5_{14}$, $6_{15}\leftarrow 5_{23}$, and $4_{23}\leftarrow 5_{15}$ transitions, respectively. He also found their weaker inversion partners at 17476, 29312 and 30566 Mc/sec[9].

Table IV. Assignments of $\varDelta J=\pm 1$, $\varDelta K=\mp 1$ lines (I).

$J'_{K'}\leftarrow J_K$	μ	n	γ^a	Obs. freq. (Mc/sec)		Calc. freq. (Mc/sec)

a. $\gamma=0$ or 1 as $J+K_{+1}-K_{-1}$ is even or odd.

b. These frequencies are taken from reference 9.

In case of $\mu\neq 0$, however, it was very difficult to obtain a proper assignment, since all lines show similar Stark effect, 1(i), both for $\mu=+1$ and $\mu=-1$. If one takes into account the effect of $K=1\leftrightarrow -1$ interaction, however, it is shown as in the following section that the magnitudes of the Stark effect coefficient and the quadrupole hyperfine splitting would differ for each line. The consistent assignments, which have been obtained from the study of these effects, are shown in Table IV. The transitions $K=-1\leftrightarrow 2$, assigned to the lines at 13176 Mc/sec and 28533 Mc/sec, were forbidden by the crude theory neglecting the $K=1\leftrightarrow -1$ interaction. Due to this interaction, however, K is not a good quantum number and the state of $K=-1$ merges to $K=1$ state. Then the transition $K=-1\leftrightarrow 2$ becomes to be allowed. It is also noted that the magnitude of inversion doubling largely depends on the quantum number, J, through the $K=1\leftrightarrow -1$ interaction. The present assignments considerably differ from those by Lide[9]. The latter seems to have been given without proper consideration on the effect of $K=1\leftrightarrow -1$ interaction on $\mu\neq 0$ lines.

Recently, the molecular constants, A, B, C, D, V and $\varDelta_0$ have been calculated by Itoh[7] from the observed frequencies of initial lines of p series, $4_2\leftarrow 5_1$ ($\mu=0$) lines, and $6_1\leftarrow 5_2$ ($\mu=0$) lines. The results are also shown here in Table V. By use of these values, the frequencies of other $4_2\leftarrow 5_{\pm 1}$ and $6_{\pm 1}\leftarrow 5_2$ ($\mu=\pm 1$) lines as well as those of the initial lines of q, r and s series have been calculated. They agree well with the observed values as shown in Table III and IV.

Table V. Molecular parameters calculated from the observed frequencies marked by * in Table III and Table IV.

$A+B$	44329.2 Mc/sec
$\dfrac{A-B}{2}$	461.46 Mc/sec
C	10314.8 Mc/sec
S	−135. Mc/sec
V	456609. Mc/sec
$\varDelta_0$	28604. Mc/sec ($n=0$) 29358. Mc/sec ($n=1$)
$\alpha'\left(=\dfrac{2\pi^2 H_0}{h^2}\dfrac{I_2(I_y I_1-D^2)}{I_y I_z-D^2}\right)$	11.3444
$\sigma'\left(=1-\dfrac{I_2\sqrt{I_y^2+D^2}}{I_y I_z-D^2}\right)$	0.344724

c) The $J=1\leftarrow 0$ line

To verify the above analysis, it is most important to find the line for which $J=1\leftarrow 0$ and $K=0\leftarrow 0$. Edwards, Gilliam, and Gordy[10] tentatively assigned the line at 45325 Mc/sec to this transition. However, that line is definitely assigned to a member of q_2 series in the present analysis. Using the millimeter wave Stark-modulation spectrometer, the author found the line at 44286.56±0.20 Mc/sec, which showed the correct Stark effect of $J=1 \leftarrow 0$ transition. For methyl amine, the component of the dipole moment parallel to the methyl axis, $\mu_{\parallel}$, is as small as a quarter of the perpendicular component, $\mu_{\perp}$, so that the intensity of this line is very weak, perhaps as small as 10^{-7} cm^{-1}.

The fine structure due to internal rotation and inversion could not be resolved for this line ($n=0$), but two satellite lines were found, which are expected to belong to the excited torsional state, $n=1$. Their frequencies are 44214±1 and 44205±1 Mc/sec. Similar vibrational fine structures were also observed in $J=1 \leftarrow 0$ lines of other molecules with internal rotation. The method, which was presented by the author11) for the purpose of the analysis of the fine structure of methyl alcohol spectra, will also be applicable to this molecule. In order to obtain the complete analysis of the present case, at least three satellite lines have to be observed, because the line, for which $\mu=0$ and $n=1$, is expected to be observed as an inversion doublet separated by several megacycles on account of the appreciable $K, K\pm1$ perturbation energy. However, an approximate calculation shows that the value of $A+B$ including the vibrational correction should be about 40 Mc/sec larger than the observed frequency of $n=0$ line; hence $A+B \approx 44325$ Mc/sec. This value is close to the value 44329.2 Mc/sec in Table V, calculated on the basis of a rigid hindered rotor model. The difference between two values is within the error of the approximation used.

d) *K*-type doublet lines

Some lines corresponding to the transition from one to the other partner of a K-type doublet should be observed in case of $\mu=0$, as in spectra of usual rigid asymmetric rotors.

However, the tentative assignments given in SNI were incorrect. After a careful study, lines corresponding to the transitions, for which $J=6$, 7, and 10 ($|K|=1$), have been found, while their intensities are very weak ($\sim 5\times 10^{-8}$ cm^{-1} for $J=6$). Each transition consists of two lines due to the inversion doubling.

Their frequencies are theoretically given by equation (8). The values of $\Delta\nu/J(J+1)$ are listed in the third column of Table VI. Thus the value of $\frac{A-B}{2} I_{1\ \ 00}^{-100}$ is obtained as 440.0 Mc/sec from their mean value. Using the calculated value of $I_{1\ \ 00}^{-100}$ ($=0.9510$), one obtains $\frac{A-B}{2}=462.7$ Mc/sec. This value is consistent with that in Table V, 461.46 Mc/sec, calculated from the frequencies of $4_2 \leftarrow 5_1$ and $6_1 \leftarrow 5_2$ transitions.

Table VI. Assignments of K-type doublet lines ($|K|=1$).

J	$\Delta\nu$ (Mc/sec)	$\frac{\Delta\nu}{J(J+1)}$ (Mc/sec)
6	18476.	439.90
	18486.	440.15
7	24634.0	439.89
	24647.1	440.13
10	48385.	439.86
	48400.	440.00

e) Additional strong lines

The remaining strong lines, which are rather irregularly spaced in the observed range, will be assigned to the transitions, $\Delta J=\pm1$ and $\Delta K=\mp1$ ($J\gtrsim7$ and $K\gtrsim2$). The frequencies of such lines were calculated using the values of molecular parameters in Table V.

Following procedures were used for the simplicity of calculation.

1) As pointed out by Dennison and others4)-7), the energy of internal rotation, $W^{K\mu n}=VR^{K\mu n}$, is a periodic function of $\gamma=\frac{2\pi}{3}\left(\frac{I_2\sqrt{I_y^2+D^2}}{I_yI_z-D^2}K+\mu\right)$. Hence, $R^{K\mu n}$ can be expanded as a Fourier series in γ. The expansion formula,

$$R^{K\mu n}(\text{cm}^{-1})=-13.185372-0.018873\cos\gamma$$
$$+0.000012\cos 2\gamma\ , \qquad (10a)$$
$$\gamma=78°38'K+120°\mu \qquad (10b)$$

were used for $n=0$ states.

2) Itoh7) showed that the inversion energy $W^{n\pm}$ is also a periodic function of $\gamma'=\pi/3\left(\frac{I_2\sqrt{I_y^2+D^2}}{I_yI_z-D^2}K-2\mu\right)=39°19'K-120°\mu$. The overlap integral which expresses the coupling between the inversion and the internal rotation is approximately given by,

$$\int_0^{2\pi} Q^{K\mu n*}(x)Q^{K\mu n}(x-\pi)dx \quad (\text{cm}^{-1})$$
$$=0.210803\cos\gamma' - 0.000377\cos 3\gamma'$$
$$+0.000001\cos 5\gamma' \qquad (11)$$

for the ground torsional state, $n=0$.

3) The perturbation energy due to K, $K\pm1$ off-diagonal elements of Hamiltonian, $\tilde{W}^{K}_{K\pm1}$, can be neglected since their magnitudes are of the order of 10 Mc/sec.

4) The perturbation energy due to K, $K\pm2$ off-diagonal elements, $\tilde{W}^{K}_{K\pm2}$, cannot be neglected, because it may amount to a few hundred megacycles even in large K levels. The denominators of $\tilde{W}^{K}_{K\pm2}$, however, were replaced by $W^{JK}-W^{JK\pm2}$ in the present calculation. This results in errors of several ten megacycles in the calculated frequencies.

a: These lines are quoted from reference 3.

b: These lines are quoted from the private communication sent by Dr. D. R. Lide, Jr.

5) The energy of K-type doubling, $\varDelta W$, is not so small for $|K|=2$ levels that it is necessary to calculate the effect of $-K\leftrightarrow K$ interactions by equation (9) for $\mu=\pm1$ states. As K increases, $\varDelta W$ rapidly decreases by $(\delta)^K\approx(0.1)^K$ so that this effect can be neglected for $|K|\geq3$.

The calculated frequencies based upon these procedures have fitted successfully the observed frebuencies. About fifty lines, which have J ranging from 7 to 21 and K from 2 to 6, have been assigned and are listed in Table VII. The errors of two to three hundred megacycles in the calculated frequencies are not surprising in view of the approximation used, since the interactions of internal rotation with the other vibrations than torsion and inversion have been neglected, as well as other smaller interactions.

Some experimental evidence for these assignments have been given as follows:

(1) The Stark effect patterns of the stronger inversion partners of $7_3\leftarrow8_2$, $8_3\leftarrow9_2$ and $10_2\leftarrow9_3$ lines have been partially resolved. The J values of these lines could be estimated from the splittings of resolved component lines.

(2) The Stark pattern of higher J lines ($J\geq14$) could not be resolved. The Stark effect of most lines are similar to 1(i) since in case of $\mu=0$ the forbidden lines appear near the allowed lines even in a lower Stark field. The Stark pattern, however, shows an unsymmetrical feature about the center of the line in case of $\mu=0$, whereas a symmetrical feature in case of $\mu=\pm1$. This gives a check for the assignment of μ.

(3) The magnitude of K-type splitting for a $\mu=0$ line is almost independent of the energy of internal rotation and inversion. Thus the magnitude gives a good verification for the value of J and K in case of $\mu=0$.

(4) The magnitude of inversion doubling for these lines depends on K and μ, but is almostly independent of J, since the effect due to $-K\leftrightarrow K$ interaction on the inversion energy is small as theoretically expected. This confirms the choice of inversion pairs.

§ 5. Molecular Parameters

The molecular dimensions of methyl amine calculated from the rotational constants in Table V are $d_{CN}=1.474\pm0.005$ A, $\angle$CNH$=112°10'\pm1°$, $\angle$HCH$=109°30'\pm1°$, and $\angle$HNH$=105°50'\pm1°$, on the assumption of $d_{NH}=1.014$ A and $d_{CH}=1.093$ A. The direction of methyl axis does not coincide with that of CN axis and passes through the NH_2 triangle having an angle of $3°30'\pm20'$ to the CN axis. The height of potential barrier hindering internal rotation has been found to be 691.1 ± 1 cm^{-1}. This value is between the previous value from the calorimetric data[12], 1000 cm^{-1}, and that from the infrared spectrum[13], 530 cm^{-1}. Recently, Aston and others[14] reexamined the barrier height from the entropy measurement and obtained the value of 665 ± 140 cm^{-1}, which was close to the present value.

The magnitude of inversion doubling is considerably large. The Δ_0 in equation (4) (the hypothetical inversion splitting in case of no significant internal rotation) has been calculated to be 28,604 Mc/sec for $n=0$ and 29,358 Mc/sec for $n=1$. If one assumes that the reduced mass is proportional to the inverse square of the frequency of the NH_2 wagging vibration, the value of 3,300 Mc/sec is calculated from Dennison and Uhlenbeck's formula[15]. The observed inversion splitting is much larger than the calculated value, but the difference can be explained, at least qualitatively, from the large CNH angle, which facilitates the inversion motion. If one takes a fictitious ammonia type symmetric top molecule, NM_3, which has the same reduced mass as methyl amine and a MNM angle of about 110°30′ ($d_{NM}=1.014$ A), the inversion splitting is calculated to be about 30,000 Mc/sec, consistent with the observed value.

§ 6. Dipole Moment and Quadrupole Coupling Constant

a) Stark effect and dipole moment

The Stark patterns of the lines, for which $\mu=0$, $J_K=4_2\leftarrow5_1$ and $6_1\leftarrow5_2$, were measured by Lide[2]. From the Stark coefficients he gave the component of dipole moment parallel to the z axis, $\mu_{\parallel}$, to be 0.304 D and the perpendicular component, $\mu_{\perp}$, to be 1.232 D. These values are consistent with the Stark coefficient of the third and forth lines of p_1 series, which have been measured by the author.

The first-order Stark energy of $\mu=\pm1$ levels is given from the diagonal matrix element,

$$W_s=\mu_{\parallel}\frac{KE}{J(J+1)}\ , \qquad (12)$$

neglecting the perturbation term from the K, $K\pm1$ off-diagonal matrix element. However, if the effect of $-K\leftrightarrow K$ interactions is taken into account, K is no longer a good quantum number. The mixing of the wave functions ψ_{+K} and ψ_{-K} is expressed by

$$c_+\psi_{+K}+c_-\psi_{-K}\ , \qquad (13)$$

taking $c_+^2+c_-^2=1$. Hence K, which is used in equation (12), should be replaced by

$$c_+^2K-c_-^2K\ . \qquad (14)$$

The Stark coefficient, b_{JK}, for a observed line is approximately given by

$$b_{JK}=\mu_{\parallel}\left(\frac{(c_+^2-c_-^2)}{J(J+1)}K-\frac{(c'^2_+-c'^2_-)}{J'(J'+1)}K'\right)\ , \qquad (15)$$

where JK and $J'K'$ mean the final and initial states of the transition, respectively. The Stark shift, $\Delta\nu_s$, is

$$\Delta\nu_s=\frac{1}{h}b_{JK}ME\ , \qquad (16)$$

where M is the projection of $\boldsymbol{J}$ on the direction of the applied field.

The calculated Stark coefficients are compared with the observed values for $4_2\leftarrow5_1$ and $6_1\leftarrow5_2$ lines in Table VIII. The agreement gives a good verification for the present assignment.

Table VIII. Stark effect coefficient and quadrupole hyperfine splitting.

* The sign of the splitting is plus when the frequency of the stronger component is higher than that of the weaker component, and vice versa.

b) Quadrupole hyperfine structure

The quadrupole energy, W_Q, due to the nuclear quadrupole moment, Q, of N^{14} can be written by

$$W_Q = eQ\left\langle\frac{\partial^2 V}{\partial Z^2}\right\rangle_{Av} \frac{\frac{3}{4}C(C+1) - I(I+1)J(J+1)}{2J(2J-1)I(2I-1)}\,, \tag{17}$$

where

$$C = F(F+1) - I(I+1) - J(J+1)\,,$$

and

$$F = J+I\,,\ J+I-1\,,\ \cdots,\ |J-I|\,.$$

$I(=1)$ is the nuclear spin of N^{14}. The field gradient averaged over the rotational wave function, $\left\langle\frac{\partial^2 V}{\partial Z^2}\right\rangle_{Av}$, is given by

$$\left\langle\frac{\partial^2 V}{\partial Z^2}\right\rangle_{Av} = \langle\alpha_{Zx}{}^2\rangle\frac{\partial^2 V}{\partial x^2} + \langle\alpha_{Zy}{}^2\rangle\frac{\partial^2 V}{\partial y^2} + \langle\alpha_{Zz}{}^2\rangle\frac{\partial^2 V}{\partial z^2} + 2\langle\alpha_{Zx}\alpha_{Zy}\rangle\frac{\partial^2 V}{\partial x\partial y} + 2\langle\alpha_{Zy}\alpha_{Zz}\rangle\frac{\partial^2 V}{\partial y\partial z} + 2\langle\alpha_{Zz}\alpha_{Zx}\rangle\frac{\partial^2 V}{\partial z\partial x}\,, \tag{18}$$

referred to the x, y and z axes. The direction cosine matrix element $\langle\alpha_{Zz}\rangle$ is diagonal with respect to K, whereas $\langle\alpha_{Zx}\rangle$ and $\langle\alpha_{Zy}\rangle$ have only K, $K\pm1$ off-diagonal elements. Thus the last two terms vanish and the remaining cross term, $2\langle\alpha_{Zx}\alpha_{Zy}\rangle\frac{\partial^2 V}{\partial x\partial y}$ is also zero since y axis is implied in the symmetry plane which bisects HNH angle and x axis is perpendicular to this plane. Using the relations,

$$\alpha_{Zx}{}^2 + \alpha_{Zy}{}^2 + \alpha_{Zz}{}^2 = 1 \tag{19}$$

and

$$\frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} + \frac{\partial^2 V}{\partial z^2} = 0\,, \tag{20}$$

the following equation is obtained;

$$\left\langle\frac{\partial^2 V}{\partial Z^2}\right\rangle_{Av} = \frac{1}{2}\langle 3\alpha_{Zz}{}^2 - 1\rangle\frac{\partial^2 V}{\partial z^2} + \frac{1}{2}\langle\alpha_{Zy}{}^2 - \alpha_{Zx}{}^2\rangle\left(\frac{\partial^2 V}{\partial y^2} - \frac{\partial^2 V}{\partial x^2}\right). \tag{21}$$

The first term is diagonal with respect to K and the second term has only K, $K\pm2$ off-diagonal elements. The second term becomes significant when $|K|=1$, through $K=1\leftrightarrow-1$ interactions. Hence equation (21) becomes

$$\left\langle\frac{\partial^2 V}{\partial Z^2}\right\rangle_{Av} = \frac{3K^2 - J(J+1)}{(J+1)(2J+3)}\frac{\partial^2 V}{\partial z^2} \pm \delta_{|K|,1} \times \frac{J}{2J+3}\left(\frac{\partial^2 V}{\partial y^2} - \frac{\partial^2 V}{\partial x^2}\right)c_+c_-\,. \tag{22}$$

Using equations (17) and (22), the quadrupole hyperfine splitting, $\Delta\nu_Q$, for $4_2\leftarrow5_1$ lines is given by

$$\Delta\nu_Q = eQ\left[0.1865\frac{\partial^2 V}{\partial z^2} \pm 0.3744\left(\frac{\partial^2 V}{\partial y^2} - \frac{\partial^2 V}{\partial x^2}\right)c_+c_-\right], \tag{23a}$$

and for $6_1\leftarrow5_2$ lines

$$\Delta\nu_Q = eQ\left[-0.1223\frac{\partial^2 V}{\partial z^2} \mp 0.3736 \times \left(\frac{\partial^2 V}{\partial y^2} - \frac{\partial^2 V}{\partial x^2}\right)c_+c_-\right]. \tag{23b}$$

These formula have been obtained on the assumption that the doublet separation is given by the difference in frequencies between $F=J$ line and the weighted mean of $F=J\pm1$ lines, because the $F=J+1$ and $J-1$ lines are close to each other. The double sign of the second term should be the upper one when the $|K|=1$ level is the upper state ($\mu=1$ for $K=1$ and $\mu=-1$ for $K=-1$), and the lower one when the $|K|=1$ level is the lower state ($\mu=-1$ for $K=1$ and $\mu=1$ for $K=-1$).

The quadrupole coupling constants $eQ\frac{\partial^2 V}{\partial z^2}$ and $eQ\left(\frac{\partial^2 V}{\partial y^2} - \frac{\partial^2 V}{\partial x^2}\right)$ have been determined so as to give the best fit calculated values to the observed splittings. The results are

$$eQ\left(\frac{\partial^2 V}{\partial z^2}\right) = 1.8 \pm 0.2\ \text{Mc/sec}\,, \tag{24a}$$

$$eQ\left(\frac{\partial^2 V}{\partial y^2} - \frac{\partial^2 V}{\partial x^2}\right) = -5.4 \pm 0.3\ \text{Mc/sec}\,. \tag{24b}$$

The comparison between the observed and the calculated splittings are also given in Table VIII, confirming the present analysis.

It is also interesting to transform the coupling constants to the charge symmetry axis around the nitrogen nucleus. The charge symmetry axis, ζ, is naturally comprised in the bisecting plane of the HNH angle, with an angle Θ between z and ζ axes. Hence the transformation is expressed by

$$\frac{\partial^2 V}{\partial x^2} = -\frac{1}{2}\frac{\partial^2 V}{\partial \zeta^2} \tag{25a}$$

$$\frac{\partial^2 V}{\partial y^2} = \frac{3\sin^2\Theta - 1}{2}\frac{\partial^2 V}{\partial \zeta^2} \tag{25b}$$

$$\frac{\partial^2 V}{\partial z^2} = \frac{3\cos^2\Theta - 1}{2}\frac{\partial^2 V}{\partial \zeta^2}\,. \tag{25c}$$

From equation (20), (24a, b), and (25a), the coupling constant along ζ direction is

$$eQ\frac{\partial^2 V}{\partial \zeta^2} = -3.6 \pm 0.3\ \text{Mc/sec}\,. \tag{26}$$

This value is rather close to that of ammonia,

−4.10 Mc/sec.[16] The angle Θ can also be determined by a relation

$$3\frac{\cos^2\Theta-1}{3\cos^2\Theta-1}=\frac{\dfrac{\partial^2 V}{\partial x^2}-\dfrac{\partial^2 V}{\partial y^2}}{\dfrac{\partial^2 V}{\partial z^2}}=\eta\,. \tag{27}$$

The left term of this equation takes a value from 0 to $-\infty$ as Θ increases from 0 to Θ_0, and it takes a value from $+\infty$ to 3 as Θ increases from Θ_0 to 90°, as shown in Fig. 2.

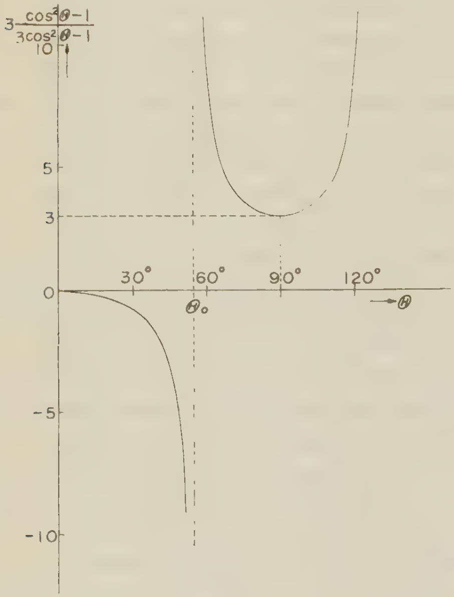

Fig. 2.

Θ_0 (∼54°45′) is the angle for which $\cos^2\Theta_0=1/3$. From the experimental values in (24a, b), η is 3.0 ± 0.2. This value gives the direction of charge symmetry axis to be 90° ± 8° to z axis.

On the other hand, we can calculate the direction of charge symmetry axis from the bond angles using the orthogonal conditions for bonding orbitals. If no ionic structure is assumed, Θ is calculated to be 105° ± 5°* from the molecular dimension described in the preceding section. Θ determined from the quadrupole coupling constant is smaller than the calculated volue, even if the experimental errors are taken into account. However, if the ionic structure or the hyperconjugation effect is considered, the symmetry exis probably in clines towards the perpendicular direction to CN axis.

§ 7. Discussion

Most of the important lines in the spectrum have been analyzed, giving the molecular parameters of methyl amine. The error of a few hundred megacycles in the calculated frequencies of lines may be attributed to higher order effects. For example, the effect of other vibrations than torsion and inversion were entirely neglected in the calculated frequencies. The assumption of a cosine form of the barrier to internal rotation, $H=H_0(1-\cos 3x)$, and a simple treatment of the coupling of internal rotation and inversion may also cause some errors in the calculation of frequencies. The remaining weaker lines, which have not been assigned, will be attributed to the excited torisonal states ($n\geq1$), to the very high rotational states ($J\geq20$, $K\geq6$), or to other isotopic species. Further study on the lines belonging to the excited torsional states would give more precise knowledge on the potential barrier to internal rotation, such as the contribution of six-fold potential barrier term.

It is interesting to compare the structure of methyl amine with other CH_3MH_n type mole-

Table IX. Molecular structure, barrier height, and dipole moment of CH_3MH_n type molecule.

cules, such as methyl alcohol[11] and as methyl mercaptan[17]. The molecular structures, barrier heights, and dipole moments of these molecules are listed in Table IX. First, the bond lengthes, d_{CM}, agree well with the sums of the Pauling's covalent radii, which are also shown in the table. Secondly, the bond angles ∠CMH are about five degrees larger than the bond angles ∠HMH in MH_{n+1} type molecules, that is ammonia, water and hydrogen sulfide corresponding to methyl amine, methyl alcohol, and methyl mercaptan, respectively. It is also noted that the CM directions are not on the symmetry axis of methyl group and that the angles between CM and methyl axes, θ's, are almost equal for these molecules. These characteristics in the angles, ∠CMH and θ, are probably explained by the repulsive effect between the MH_n group and methyl group.

Several theories on the potential barrier to internal rotation have already been given. Among them, Lassettre and Dean's method[18] on the electrostatic potential due to the dipole-dipole, dipole-quadrupole, and quadrupole-quadrupole interactions between MH and CH bonds seems to be valid for these simple molecules. They calculated the barrier height for methyl amine and methyl alcohol assuming a tetrahedral value, 109°28′, for CMH angles. The approximation is fairly good and they obtained the value of 740 cm^{-1} for methyl amine and 340 cm^{-1} for methyl alcohol, which show good agreement with the observed values. The bond angle of methyl mercaptan (∠CSH =96°20′) is considerable less than the tetrahedral value, so that their method should be slightly modified. The value of 490 cm^{-1} has been calculated by a modified Lassettre and Dean's method for methyl mercaptan, showing the consistency with the experimental value (440 cm^{-1}).

In these calculations, the direction of CH bond dipole moment was taken to be $\mathrm{C}^- \rightarrow \mathrm{H}^+$. It is also interesting to compare the observed values of the components of dipole moments with the calculated values using the molecular structures and the bond dipole moments by Pauling and others[19]. Table IX also shows good agreement between the observed and calculated values, confirming the direction of CH bond moment, $\mathrm{C}^- \rightarrow \mathrm{H}^+$. If we take the reverse direction $\mathrm{C}^+ \leftarrow \mathrm{H}^-$, the agreement is completely destroyed as shown in parenthesis. The perpendicular components, $\mu_\perp$, depend predominantly on the MH bond moments, so that the agreement also verifies the values of MH bond moments given by Pauling and others.

Acknowledgement

The author expresses his hearty thanks to Professor Koichi Shimoda for his continuous guidance and advice, and to Professors Masao Kotani and Charles H. Townes for their interests throughout this work. His thanks are also due to Dr. Takashi Itoh for his valuable discussion and help on the theoretical treatment and the numerical calculation. He is also grateful to Dr. David R. Lide, Jr. for his kind informations of his unpublished worthful results.

APPENDIX

Expansion Coefficients of *p* Series

The positions of the lines of p series are expressed by means of a power series, $\nu=\nu_0+aJ(J+1)+bJ^2(J+1)^2+\cdots$. The expansion coefficients, a, b, $\cdots$, can also be calculated from the molecular parameters. The value of a is mainly determined by the centrifugal distorsion effect, and the contribution from the asymmetry is small. Although the rigorous treatment of the centrifugal effect is difficult, a rough estimation shows that its contribution is about −0.72 Mc/sec while the contribution from the asymmetry is less than 0.1 Mc/sec. These values are compared with the observed value of a, −0.77 Mc/sec.

On the other hand, the coefficient, b, springs from $\tilde{W}^K_{K\pm2}$ and can be calculated more precisely by the second-order perturbation method. The observed and the calculated values of b are −0.0614 and −0.0601 Mc/sec, respectively.

The above discussion concerns the mean values between p_1 and p_2 series, though it is also right for the coefficients of each series.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 6, JUNE, 1957

Potential Barrier and Molecular Structure of Methyl Mercaptan from its Microwave Spectra

By Takeshi KOJIMA
Department of Liberal Arts, Toyama University, Toyama, Japan
and Tetsuji NISHIKAWA*
Department of Physics, Faculty of Science, University of Tokyo, Tokyo, Japan

(Received February 9, 1957)

The microwave spectrum of normal methyl mercaptan has been studied in the frequency range from 14 to 29 kMc/sec. The potential barrier height hindering internal rotation has been determined as $444 \pm 10\,\mathrm{cm}^{-1}$, from the analysis of the lines corresponding to the transitions involving both over-all and internal rotations. The fine structures of $J=1 \leftarrow 0$, $K=0 \leftarrow 0$ lines of the various isotopic species have also been analysed and discussed. The molecular structure of methyl mercaptan has been calculated to be $d_{\mathrm{SH}}=1.336 \pm 0.01\,\mathrm{A}$, $d_{\mathrm{CS}}=1.819 \pm 0.005\,\mathrm{A}$, $d_{\mathrm{CH}}=1.091 \pm 0.01\,\mathrm{A}$, $\angle\mathrm{CSH}=96°30' \pm 1°$, $\angle\mathrm{HCH}=109°45' \pm 30'$ and the angle between CS bond and methyl axis, $\theta=2°0' \pm 30'$.

§1. Introduction

The resent development of microwave spectroscopy has made it possible to study the internal rotation of free molecules and to determine the height of potential barrier with good accuracy. The internal rotation in methyl alcohol[1),2),3)] and methyl amine[4),5)] has been studied with precision by several workers. It will be interesting to study the mo lecular structure and the behaviour of th internal rotation of methyl mercaptan as i has the structural similarity to methyl alcoho and also in some respects to methyl amine.

The barrier height, V_0, of methyl mercapta was determined as about $510\,\mathrm{cm}^{-1}$ by Russe and others[6)] by the calorimetric method. B the microwave spectroscopic method, it wa determined to be $371 \pm 43\,\mathrm{cm}^{-1}$ by Solimen

and Dailey[7] from the relative intensities of the satellites of $J=1\leftarrow0$, $K=0\leftarrow0$ line. However, since the measurements of intensities of spectral lines can not be very accurate, it is preferable to determine the barrier height from the frequency measurement. Kilb[8] obtained the height as 247 cm^{-1} from the analysis of the doublet separation of $J=1\leftarrow0$, $K=0\leftarrow0$ line in the ground torsional state. Kojima and Nishikawa[9] also estimated the height to be 280 cm^{-1} from a tentative assignment of the series originated at 18300 Mc/sec. These studies, however, were too crude to determine the reliable value of V_0.

§ 2. Experimental Results

The spectrum of methyl mercaptan has been observed in the frequency range from 14 to 29 kMc/sec, using an ordinary Stark-modulation spectrometer with an X-band waveguide cell of three meters in length.

The sample of methyl mercaptan was prepared by adding sodium hydroxide to methyl-iso-thio-urea sulfate, and that of CH_3SD was prepared by adding deuterated sodium hydroxide.

About one hundred and forty lines and their Stark effects have been observed as listed in Table I. The observed lines are classified into four kinds corresponding to their Stark effects. The lines which show first-order Stark effects are denoted by 1(i) or 1(o), according as the inner or outer Stark components are stronger. The lines which show second-order Stark effects are denoted by 2(+) or 2(−), according as the components shift to higher or lower frequency side with increasing Stark field.

Four kinds of transmissions can be considered: (1) $\Delta J=0$, $\Delta K=\pm1$ (2) $\Delta J=\pm1$, $\Delta K=\mp1$ (3) $\Delta J=\pm1$, $\Delta K=0$ (4) $\Delta J=0$, $\Delta K=0$.

(1) $\Delta J=0$, $\Delta K=\pm1$ lines

Three series of lines belonging to this kind ($\Delta J=0$, $\Delta K=\pm1$) have been found in the observed range and are designated as p, q and r in Table I. The p series showing the Stark effect, 1(o), has its origin at about 18300 Mc/sec. The member lines could not be resolved into distinct Stark patterns because of the weakness of their intensities. The lines arise from molecules in an excited torsional state, not in the ground state as was reported in our preliminary report[9].

The origins of q and r series seem to lie far beyond the observed range. The Stark effect of q series is also 1(o), while that of r series is 2(+). From their Stark effects, the internal rotation states of p and q series must be degenerate ($\mu^*=\pm1$), and r series non-degenerate ($\mu=0$).

(2) $\Delta J=\pm1$, $\Delta K=\mp1$ lines

All of 1(i) lines and many of 2(+) and 2(−) lines belong to this kind ($\Delta J=\pm1$, $\Delta K=\mp1$). The μ's of 1(i) lines are ±1 and the μ's of 2(+) and 2(−) lines are 0. These lines are irregularly distributed over the microwave

Table II. Lines of $\Delta J=\pm1$, $\Delta K=\mp1$.

Frequency (Mc/s)	Stark Effect	Assignment μ	$J_K\leftarrow J'_{K'}$*
23339.2	1	1	$2_1\leftarrow3_0$
26994.2	1	1	$5_0\leftarrow4_1$
14764.5	1	−1	$1_1\leftarrow2_0$
29091.9	2	0	$2_{12}\leftarrow3_{03}$

18039.5	1	1	$8_2\leftarrow9_1$

* Both $K_{-1}(=K)$ and K_{+1} are listed for $\mu=0$ lines as in the spectrum of a rigid asymmetric-top molecule.

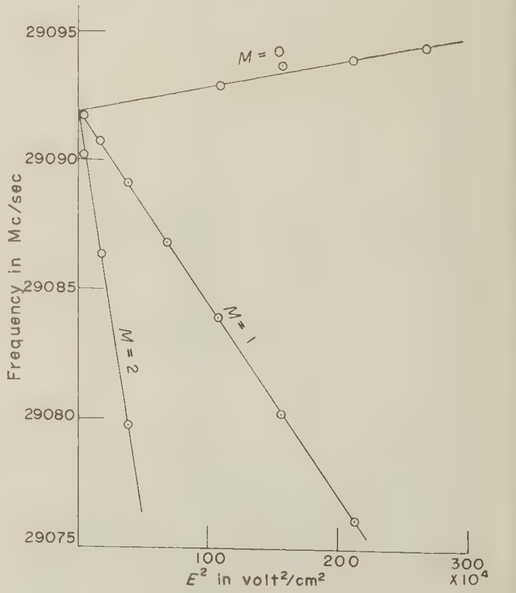

Fig. 1. Stark effect of 29091.9 line.

---

* μ is related by $\mu=-(K+\tau-1)$ mod. 3 to the quantum number, τ, used by Dennison and others. see reference 4).

region. Several low J lines, which are listed in Table II, have been resolved into Stark components for determination of J value. The frequencies of Stark components of 29091.9 line were carefully measured and plotted against the square of field strength (E^2) in Fig. 1.

(3) $\Delta J=\pm 1$, $\Delta K=0$ lines

The $J=1\leftarrow 0$ and $K=0\leftarrow 0$ line is the only one of this kind in the observed region. This line was first found by Shaw and Windle[10], and some vibrational satellites of the line were assigned by Solimene and Dailey[7], who also observed similar fine structures for several isotopic species. Their assignment for CH_3SH was confirmed by the present study, while a misassignment for CH_3SD was detected.

(4) $\Delta J=0$, $\Delta K=0$ lines

The transition from one to the other partner of a K-type doublet belongs to this kind ($\Delta J=0$, $\Delta K=0$). Six lines ($J=5$ to 10 and $K=1$) have been observed and assigned as shown in Table VI. The frequencies of these lines are proportional to $J(J+1)$ and their Stark effects are 2(+).

§ 3. Determination of the Barrier Height

The heights of potential barriers of methyl alcohol and methyl amine were determined from the series of lines which belong to $\Delta J=0$, $\Delta K=\pm 1$ transitions. Similar series of lines in the methyl mercaptan spectrum were too weak to be given the definite assignment in the observed range.

The lines which belong to $\Delta J=\pm 1$, $\Delta K=\mp 1$ transitions are more appropriate to determine the barrier height for this molecule, as their frequencies are also sensitive to the barrier height.

First, the line at 29091.9 Mc/sec could easily be assigned as $2_{12}\leftarrow 3_{03}$. The frequency can be calculated using the theory on the internally rotating molecules such as methyl alcohol and methyl amine. It is approximately given by

$$29091.9=\frac{h^2 I_z}{8\pi^2 I_1 I_2}(R^{100}-R^{000})-3\nu_0-\frac{\Delta_{J=2}}{2}$$

where I_z, I_1 and I_2 are moments of inertia of the molecule, SH group and methyl group respectively along the methyl axis. $R^{J\mu n}$ is a solution of Mathieu's equation corresponding to K, μ and n state. ν_0 is the frequency of $J=1\leftarrow 0$, $K=0\leftarrow 0$ line. $\Delta_{J=2}$ is a K-type separation at $J=2$, $K=1$ which is calculated from the lines of $\Delta J=0$, $\Delta K=0$ transitions.

The similar analysis was applied to the other six lines listed in Table II. As a result, the value of the potential barrier height was determined as 444 cm^{-1}.

The frequencies of the origins of p, q and r series were also estimated using the barrier height determined above. Their assignments are shown in Table III, while some ambiguity still remains since the origins of q and r series could not be observed.

Table III. Assignments of series.

Series	Stark Effect	Assignment	Frequency of the Origins in Mc/sec	
		$K\ \mu\ n \leftarrow K'\ \mu'\ n'$	Observed	Calculated
p	1	$5\ -1\ 2 \leftarrow 6\ -1\ 2$	18300	20000
q	1	$1\ -1\ 0 \leftarrow 0\ -1\ 0$	.....	65000
r	2	$1\ \ 0\ 1 \leftarrow 2\ \ 0\ 1$	.....	60000

We are now studying the spectrum in the millimeter wave region and have observed two series of lines showing first-order Stark effect which have their origins at about 32000 Mc/sec and 32820 Mc/sec respectively. They are assigned to be K, μ, $n=0$, 1, 1 $\leftarrow$ 1, 1, 1 and K, μ, $n=3$, -1, 1 $\leftarrow$ 2, -1, 1, respectively, confirming the above value of the barrier height. Their data and discussions will be reported later in this Journal.

The value of barrier height is also confirmed by the analysis of the vibrational fine structure of $J=1\leftarrow 0$, $K=0\leftarrow 0$ line. The vibrational satellite lines arise from molecules in different torsional states denoted by n and furthermore, the line in each torsional state splits into a doublet, $\mu=\pm 1$ and $\mu=0$, due to the internal rotation.

Kivelson[11] developed a theory of the interaction between internal rotation and vibrations to explain the similar fine structure of $J=1\leftarrow 0$ line for symmetric rotor. However, the fine structure of methyl mercaptan will occur even when we assume a rigid SH group attached at an arbitrary angle to the rigid methyl group because of asymmetry. Kilb[8] attempted to explain the doublet separation in the torsional ground state for the various isotopic species by this asymmetry effect, and he proposed that the barrier height might be 247 cm^{-1}. But it seems that he did note take account of the vibration-internal rotation interaction.

The method presented by one of us[3] (T.N.), which took into account these two effects, was applied successfully to this molecule as well as to methyl alcohol. The splitting due to the asymmetry was calculated to be of order of 0.1 Mc/sec or less for the barrier height 440 cm^{-1} in $C^{12}H_3S^{32}H$ and $C^{13}H_3S^{32}H$. Hence the vibration-internal rotation interaction is predominant as for normal methyl alcohol. The calculated and observed frequencies of $C^{12}H_3S^{32}H$ and $C^{13}H_3S^{32}H$ listed in Table IV and Table V is in good agreement. Appreciable contribution of the asymmetry effect found in the deuterated molecules will be described in § 4.

Table IV. Lines of $J=1\leftarrow0$, $K=0\leftarrow0$ of $C^{12}H_3S^{32}H$.

n	μ	Observed Frequency in Mc/sec	Calculated Frequency in Mc/sec
0	0	25290.8	(25290.8)
0	±1	25291.8	25291.8
1	0	25219.7	25219.3
1	±1	25206.8	(25206.8)
2	0	25143.6	(25143.6)
2	±1	25154.8	25154.2
3	±1	25142.2	25140.5
3	0	25126.9	25124.3

Three frequencies in parentheses were used to determine the three parameters in Kivelson's theory; $B_v=12666.3$ Mc/sec, $F_v=-61.41$ Mc/sec, and $G_v=-0.980$ Mc/sec.

Table V. Lines of $J=1\leftarrow0$, $K=0\leftarrow0$ of $C^{13}H_3S^{32}H$.

n	μ	Observed Frequency[a] in Mc/sec	Calculated Frequency[b] in Mc/sec
0	0	24389.1	24389.0
0	±1	24388.0	(24388.0)
1	0	24318.5	(24318.5)
1	±1	24306.2	24306.5
2	0	24245.0	24244.6
2	±1	24256.2	(24256.2)

a) The data are quoted from Solimene and Dailey.

b) Three parameters are $B_v=12214.45$ Mc/sec, $F_v=-53.82$ Mc/sec and $G_v=-0.937$ Mc/sec.

§ 4. Determination of the Molecular Structure

The approximate value of $\frac{1}{I_x}+\frac{1}{I_y}$ and $\frac{I_z}{I_1I_2}$ were determined from the frequencies of $J=1\leftarrow0$, $K=0\leftarrow0$ line and $\Delta J=\pm1$, $\Delta K=\mp1$ lines. Using the relations, $I_z=I_1+I_2$ and $I_1=$ I_x-I_y, the molecular structure was roughly calculated. The frequencies of the $\Delta J=0$, $\Delta K=0$ lines (transitions between the levels of K-type doublets) which are proportional to $\frac{1}{I_x}-\frac{1}{I_y}$ were also calculated and listed in Table VI.

Table VI. Lines of $\Delta J=0$, $\Delta K=0$ of $C^{12}H_3S^{32}H$.

Assignment $J_{K_{-1}K_{+1}}\leftarrow J'_{K_{-1}K'_{+1}}$	Observed Frequency in Mc/sec	Calculated Frequency in Mc/sec
$5_{14}\leftarrow5_{15}$	7846.0	7700
$6_{15}\leftarrow6_{16}$	10983.4	10800
$7_{16}\leftarrow7_{17}$	14643.1	14400
$8_{17}\leftarrow8_{18}$	18824.2	18500
$9_{18}\leftarrow9_{19}$	23526.2	23200
$10_{19}\leftarrow10_{1,10}$	28747.9	28200

To determine the exact structure of the molecule, it is necessary to determine D value which is the product of inertia in CSH plane. We have found that the contribution of the asymmetry effect to the frequency of the $J=1\leftarrow0$, $K=0\leftarrow0$, $\mu=\pm1$, $n=1$ line of CD_3SH is about 1.4 Mc/sec as shown in Table VII. The asymmetry effect is larger for CH_3SD

Table VII. Lines of $J=1\leftarrow0$, $K=0\leftarrow0$ of $C^{12}D_3S^{32}H$.

Assignment n	μ	ν[a]	Asymmetry Effect	Calculated[b] Frequency	Observed Frequency
0	0	20732.5	−0.1	20732.4	20732.0
0	±0	20733.0	−0.2	(20732.8)	20732.8
1	0	20678.9	0.0	(20678.9)	20678.9

2	±1	20627.6	0.0	(20627.6)	20627.6

a) $\nu=2B_v+2F_v(m|1-\cos3\theta|m)+2G_v(m|\Pi_z{}^2|m)$ where $B_v=10381.2$ Mc/sec, $F_v=-47.33$ Mc/sec and $G_v=-0.718$ Mc/sec.

b) The calculation was done assuming $\alpha=8.8$ and $\frac{h}{8\pi^2c}\frac{D}{B^2}=80$ Mc/sec.

because of its large D value.

We tried to determine the D value of CH_3SD from the fine structure of $J=1\leftarrow0$, $K=0\leftarrow0$ line measured by Solimene and Dailey[7] but failed. Then we have remeasured the fine structure and detected the true $n=0$ line which they missed. The measured and calculated frequencies agree very well and the D value of CH_3SD has been determined as -0.78 amu A². They are listed in Table VIII.

Table VIII. Lines of $J=1\leftarrow0$, $K=0\rightarrow0$ of $C^{12}H_3S^{32}D$.

Assignment n	μ	ν[a)]	Asymmetry Effect	Calculated[b)] Frequency	Observed Frequency
0	0	24456.7	−0.9	(24455.8	24456.0
0	±1	24457.1	−1.0	24456.1)	
1	0	24392.5	−4.8	24387.7	24388.3
1	±1	24388.1	−1.8	24386.3	24385.9
2	0	24322.0	+0.2	(24322.2)	24322.2
2	±1	24330.3	0.0	(24330.3)	24330.3
3	0	24302.2	0.0	24302.2	24302.9
3	±1	24293.8	0.0	24293.8	....

a) $\nu=2B_v+2F_v(m|1-\cos 3\theta|m)+2G_v(m|\Pi_z{}^2|m)$ where $B_v=12245.7$ Mc/sec, $F_v=-58.83$ Mc/sec and $G_v=-0.839$ Mc/sec.

b) The calculation was done assuming $\alpha=10.6$ and $\frac{h}{8\pi^2c}\frac{D}{B^2}=250$ Mc/sec.

From the D value, the angle between CS bond and methyl axis has been determined as 2°0′±30′. Then the other molecular parameters have been determined taking account of all the frequencies of $J=1\leftarrow0$ lines of various isotopic species as follows:

$$d_{SH}=1.336\pm0.01\ \text{A}$$
$$d_{CS}=1.819\pm0.005\ \text{A}$$
$$d_{CH}=1.091\pm0.01\ \text{A}$$
$$\angle CSH=96°30'\pm1°$$
$$\angle HCH=109°45'\pm30'$$

The CS bond length is very close to the sum of covalent radii, 1.82 A. It is also interesting to see that the bond angle ∠CSH is somewhat smaller than formerly reported,[7),8)] while it is about 4° larger than ∠HSH of hydrogen sulfide, (92°30′). On the other hand, the structure of the methyl group does not differ from that of methane within experimental error. The similar tendencies were also found in the structures of methyl alcohol and methyl amine.

Lassetree and Deans[12)] developed a theory, in which they pointed out that the interaction due to the quadrupole moments of CH and MH (M is O for methyl alcohol, and M is S for methyl mercaptan) bond take a considerable part in forming potential barrier to internal rotation. Since the bond quadrupole moment is approximately proportional to the square of the bond length, a larger moment is expected in SH bond than in OH bond ($d_{OH}=$ 0.95 A). Besides, since the bond angle ∠CSH is considerably smaller than the bond angle ∠COH (108°50′), the distances between the midpoints of CH and MH bond does not differ so much as expected from the difference in the CM bond lengths of the two molecules. Hence the relatively high barrier of methyl mercaptan is conceivable when we consider the quadrupole-quadrupole and the quadrupole-dipole interactions. We have obtained the barrier height of 490 cm^{-1} for this molecule by a modified Lassetree-Dean's method using the molecular structure determined above.

The components of the dipole moment parallel and perpendicular to the methyl axis have been determined as $\mu_{\parallel}=1.35\pm0.05\,D$ and $\mu_{\perp}=0.64\pm0.05\,D$ respectively from the Stark patterns of $\Delta J=\pm1$, $\Delta K=\mp1$ lines. These values are also consistent with those calculated from the bond dipole moment ($\mu_{\parallel}=1.30\,D$ and $\mu_{\perp}=0.71\,D$).

Acknowledgement

We wish to express our hearty thanks to Prof. K. Shimoda for his valuable advice and encouragement throughout this work. Also thanks are due to Mr. T. Itoh who gave us valuable discussion and to Mr. H. Hirakawa for the preparation of deuterated methyl mercaptan. This work was financially supported by grants in aid for Fundamental Scientific Research of the Ministry of Education.

Fluctuations in Amplification of Quanta with Application to Maser Amplifiers

By Koichi SHIMODA, Hidetosi TAKAHASI, and Charles H. TOWNES*

Department of Physics, Faculty of Science, University of Tokyo

(Received February 15, 1957)

Fluctuations in the amplification and absorption of waves by quantum processes are considered. Assuming for each quantum the probability (per unit time) a of producing another quantum, probability b of being absorbed, and assuming a probability c that a new quantum is introduced, a set of differential equations is obtained. By solving these equations, a complete expression for the probability of distribution of quanta is obtained, as well as expressions for the average values and fractional fluctuation.

The expressions developed are applied in particular to maser-type amplifiers, and certain fluctuations in the amplification of electromagnetic waves are pointed out which are important when their quantum character becomes significant. This condition can occur in maser-type amplifiers, where thermal and extraneous noises may be very small. For such an amplifier, a is proportional to the number of excited molecules, whereas b consists of a term proportional to the number of molecules in the ground state plus terms due to certain other losses. The noise temperature of a maser-type traveling-wave amplifier is the "effective temperature" $a(a-b)^{-1}h\nu/k$. In superregenerative and regenerative amplifiers using resonant cavities, the noise temperature is rather similar, if losses through the input coupling hole are excluded from b. In any case, the limiting noise for an ideal amplifier corresponds to a classical noise temperature of $h\nu/k$.

§ 1. Introduction

The intensity of a classical wave may increase or decrease continuously with time, or as the wave progresses. The intensity of a quantized wave, on the other hand, can change only by discrete amounts, and the extent of these changes is governed by probabilities. Hence a measurement of the number of quanta which it contains may give a variety of values. An evident example is a cosmic ray shower, in which a single initial electron may

---

[*] Fulbright Professor, May–Aug. 1956. Permanent address, Department of Physics, Columbia University.

roduce other electrons as it progresses through atter. The expectation value for the number f particles in the shower after a certain ath length may have some definite non-integral value, but the number of particles counted n the shower will of course be integral, and ay have a wide variety of values. It is his general type of fluctuation, associated ith quantum effects, with which the following discussion is primarily concerned.

A system involving stimulated emission and bsorption of low energy photons by matter ffords a particularly simple case for study f these fluctuations, since every such photon as the same energy, and the same probability er unit time of producing further absorption r emission. This case is also of interest ecause it allows discussion of the ultimate ensitivity of maser-type amplifiers, to which ome application of the theory developed below will be made. However, the equation used and their solutions apply to certain simple cases of a variety of experiments, such as fluctuations in the number of mutants of some organism[1)], in the growth of neutrons in fissionable material, in the multiplication of electrons by secondary emission, as well as variations in cosmic ray showers[2)].

§ 2. Definitions and Fundamental Equations

Consider an initial number of particles, n, each of which has a probability per unit time, a, for producing another similar particle, and a probability per unit time, b, of being absorbed or destroyed. Also let c be the constant rate at which additional particles may be added from some unspecified source. If the total number of particles, m, could increase continuously, it would then follow the equation

$$\frac{dm}{dt}=(a-b)m+c\,, \tag{1}$$

with the initial condition, $m=n$ for $t=0$. Solution of this equation, corresponding to the change in intensity of a classical wave, is

$$m=\left(n+\frac{c}{a-b}\right)e^{(a-b)t}-\frac{c}{a-b}\,. \tag{2}$$

Hence the quantity $m+\frac{c}{a-b}$ increases or decreases exponentially with time. However, since m must be integral, equation (1) does not apply precisely*, and it is convenient to consider the probability $P_{n,m}(t)$ for having a total of m particles at a time t. Since $(am+c)P_{n,m}$ is the probability per unit time that the number of particles are increased from m to $m+1$ and $bmP_{n,m}$ the probability for a decrease from m to $m-1$, the $P_{n,m}$ are related by the set of differential equations

$$\begin{aligned}\frac{dP_{n,m}}{dt}=&-[(a+b)m+c]P_{n,m}\\&+[a(m-1)+c]P_{n,m-1}\\&+b(m+1)P_{n,m+1}\end{aligned} \tag{3}$$

with initial conditions that for $t=0$, $P_{n,m}=\delta_{nm}$ Evidently, this equation is satisfied by any probability distribution corresponding to an arbitrary initial state, although the initial condition may differ from that given above.

§ 3. Distributions when Absorption or Emission Occurs Alone

Since general solutions for the set of equations (3) are rather complicated, it is instructive to first consider solutions of the simplified cases when only emission or only absorption occurs ($b=0$ or $a=c=0$ respectively). For emission only,

$$\frac{dP_{n,m}}{dt}=-(am+c)P_{n,m}+[a(m-1)+c]P_{n,m-1}\,. \tag{4}$$

Solutions satisfying the initial conditions, $P_{n,m}=\delta_{nm}$ for $t=0$ are

$$\begin{aligned}P_{n,m}(t)=&\frac{\Gamma(m+c/a)}{(m-n)!\,\Gamma(n+c/a)}e^{-at(n+c/a)}\\&\times(1-e^{-at})^{m-n}\end{aligned} \tag{5a}$$

or

$$\begin{aligned}P_{n,m}=&\frac{\Gamma(m+c/a)}{(m-n)!\,\Gamma(n+c/a)}\left(\frac{1}{K}\right)^{n+c/a}\\&\times\left(1-\frac{1}{K}\right)^{m-n}\,,\end{aligned} \tag{5b}$$

where $K=e^{at}$ is the classical growth or amplification factor from (2). When there is absorption or attenuation only,

$$P_{n,m}=\frac{n!}{m!\,(n-m)!}e^{-btm}(1-e^{-bt})^{n-m} \tag{6a}$$

or

---

* It will been seen below, in equation (11), that even when the number of particles is finite and does not increase continuously, the average number of particles still changes with time in precisely the same manner given by the classical expression.

$$P_{n,m}=\frac{n!}{m!\,(n-m)!}(K)^m(1-K)^{n-m} \tag{6b}$$

where $K=e^{-bt}$ is from (2) the classical attenuation factor.

After a very long time (6a) gives, as expected, a probability zero for finding any number of particles other than $m=0$. However, the asymptotic behavior of (5a) is more interesting. In the limit where e^{at} or K is very large,

$$P_{n,m}\to\frac{m^{n+c/a-1}e^{-m/K}}{K^{n+c/a}\,\Gamma(n+c/a)}\,. \tag{7}$$

This probability is a maximum when $m=K(n+c/a-1)$, but from it the average value of m can be shown to be $\bar{m}=K(n+c/a)-c/a$, which is identical with the classical expression (2). Furthermore when K is so large that (7) is a good approximation, the distribution does not change shape, but is a function of $\frac{m}{K}=n+c/a-1$. The fluctuations then depend, after a large amplification, only on the number n of initial particles and on c/a, which is the number of new particles introduced during the time required for the amplification to increase by a factor e.

A special property of equation (6), or of (5) when $c/a=1$, is that an exponential probability distribution remains exponential after amplification or attenuation. The latter case $c/a=1$ is important, as will be shown below, for distributions of photons where c is due only to spontaneous emission. Let there be initially a probability $p_n(0)=(1-u_0)u_0^n$ that n particles are introduced, where $u_0<1$. The probability p_m of m particles after amplification is

$$\begin{aligned}p_m&=\sum_n P_{n,m}p_n(0)\\&=\frac{(1-u_0)}{K}\sum_n\frac{m!}{n!(m-n)!}\left(\frac{u_0}{K}\right)^n\left(1-\frac{1}{K}\right)^{m-n}\\&=\frac{(1-u_0)}{K}\left(\frac{K+u_0-1}{K}\right)^m.\end{aligned} \tag{8a}$$

This is just another exponential distribution with somewhat larger spread, since u_0 is replaced by $u=\frac{K+u_0-1}{K}$, and $u\geq u_0$ when $K\geq 1$. Equation (8a) can be written in the form

$$\frac{u}{1-u}=K\left(\frac{u_0}{1-u_0}+1\right)-1\,. \tag{8b}$$

Since $\frac{u_0}{1-u_0}$ and $\frac{u}{1-u}$ represent the averag value of n and m respectively, (8b) mean that the classical relation (2) is again satisfie for the average values.

Similarly, when attenuation occurs, a distr bution $(1-u_0)u_0^n$ is changed into $(1-u)u^m$ where

$$u=\frac{Ku_0}{1-u_0(1-K)}\,. \qquad (9$$

Here $u\leq u_0$ since now $K\leq 1$. (9a) may b written as

$$\frac{u}{1-u}=\frac{Ku_0}{1-u_0} \qquad (9$$

which again corresponds to the classical re lation (2) with $a=c=0$. When $c/a=0$ in ex pressions (6a) or (6b), an exponential distri bution can be shown to again remain ex ponential after amplification, with exceptio of the unique case of $m=0$. The case o $m=0$ is exceptional when $c/a=0$, since it probability must remain constant, while pro babilities for all other values of m may be changed by the effect of amplification. These properties will prove useful in a later section

Expressions (5) and (6) giving the distri bution in the number of particles are quite general in the sense that they do not depend on the particular mechanism of attenuation or amplification. Thus if a group of particles strike a partially reflecting surface, each particle having a probability K of being re flected, the probability that m particles in al are reflected is given by (6b). Expressions (5b) and (6b) do not include time as a para meter, but simply the total amplification o attenuation, and their validity can be shown not to depend on constant values of a or b However, they do require that only emission or only absorption be present, and not both a once.

§ 4. The General Case — Moments of the Distribution and Average Fluctuation

When $K=1$, expressions (5b) and (6b) show that there is no change from the initial values of the probabilities. This is because no ampli fication or absorption has occurred, so no disturbances are introduced. However, the net amplification may also be unity in a system where both amplifying and absorbing processes occur simultaneously, and hence introduc uctuations. Hence when neither a nor b is ro, equations (5) and (6) may need con-derable modification. Since a general solution (3) in this case is complex, it is convenient examine first the various moments of the stribution and properties of the fluctuations hich can be easily deduced from them.

Behavior of the average value of m, $=\sum_m mP_{n,m}$, can be obtained by multiplying quation (3) with m, summing over m, and aking substitutions of the type,

$$\sum_m f(m)P_{n,m-1}=\sum_m f(m+1)P_{n,m}$$
$$\sum_m f(m)P_{n,m+1}=\sum_m f(m-1)P_{n,m}\,. \tag{10}$$

This gives

$$\frac{d\overline{m}}{dt}=\overline{m}(a-b)+c\,. \tag{11}$$

By a similar process, one obtains

$$\frac{d\overline{m^2}}{dt}=2(a-b)\overline{m^2}+(a+b+2c)\overline{m}+c \tag{12}$$

$$\frac{d\overline{m^r}}{dt}=\sum_{s=1}^{r}\frac{r!}{s!\,(r-s)!}\left\{\overline{m^{r-s+1}}[a+(-1)^s b]+\overline{m^{r-s}}c\right\}. \tag{13}$$

olutions of (11) and (12) are

$$\overline{m}=\left(\overline{n}+\frac{c}{a-b}\right)e^{(a-b)t}-\frac{c}{a-b} \tag{14}$$

$$\overline{m^2}=\left[\overline{n^2}-\frac{c(b+c)}{(a-b)^2}+\left(\overline{n}+\frac{c}{a-b}\right)\frac{(a+b+2c)}{a-b}\right]e^{2(a-b)t}$$
$$-\left(\overline{n}+\frac{c}{a-b}\right)\frac{(a+b+2c)}{a-b}e^{(a-b)t}+\frac{c(b+c)}{(a-b)^2}\,, \tag{15}$$

here $\overline{n}$ and $\overline{n^2}$ are values of $\overline{m}$ and $\overline{m^2}$ respectively at $t=0$. The average or expectation alue, $\overline{m}$, follows the same equation (2) which is obtained for a classical wave. It may be oted that when $\overline{n}=-\frac{c}{a-b}$ and $\overline{n^2}=\frac{c(b+c)}{(a-b)^2}$, $\overline{m}$ and $\overline{m^2}$ are constant. This equilibrium ondition can occur only when $b>a$, and will be shown below to represent thermal equiibrium in the case of photons. Furthermore, if $b>a$, (14) and (15) show that $\overline{m}$ and $\overline{m^2}$ pproach these equilibrium values after a long time.

The most significant quantity for a ready measure of fluctuations is $\frac{\overline{m^2}-\overline{m}^2}{\overline{m}^2}$. This is the quare of what is usually called the coefficient of variation or more loosely the fractional luctuation $\mathcal{E}$. $\mathcal{E}^2$ can be obtained from (14) and (15). If amplification occurs, so that $a>b$, hen after a long time the first terms of expressions (14) and (15) are the only important nes. Neglecting other terms,

$$\mathcal{E}^2=\frac{\overline{m^2}-\overline{m}^2}{\overline{m}^2}=\frac{\overline{n}\left(\frac{a+b}{a-b}\right)+\frac{ac}{(a-b)^2}}{\left(\overline{n}+\frac{c}{a-b}\right)^2}+\frac{\overline{n^2}-\overline{n}^2}{\left(\overline{n}+\frac{c}{a-b}\right)^2}\,. \tag{16}$$

number of special cases are of interest. uppose that there are a fixed number of nitial particles n, and no new ones are added, e., $\overline{n^2}=\overline{n}^2$ and $c=0$. Then

$$\mathcal{E}=\frac{1}{\sqrt{n\left(\frac{a-b}{a+b}\right)}}\,. \tag{17}$$

f amplification alone occurs ($b=0$), then $=n^{-1/2}$. The fluctuation $\mathcal{E}$ is not due to any ncertainty in the initial number n, but simply o fundamental processes in the amplification of particles. This fluctuation occurs also in amplification of an electromagnetic wave, even in the absence of thermal noise, and represents a lower limit to fluctuation of any amplifying process. If both emission and absorption occur, (17) shows that fluctuations may be appreciably larger than $n^{-1/2}$.

In many cases such fluctuations are negligible, particularly at low frequencies where the number of photons in thermal noise is large. Any degree of freedom of an electrical circuit has average energy kT and hence $kT/h\nu$

photons. Hence as long as $kT \gg h\nu$, and $(a-b)/(a+b)$ is not very small, fluctuations of this type will be negligible. On the other hand, the discussion of amplifiers of electromagnetic waves below will show that thermal noise at low frequencies is just the limiting case of the fluctuations discussed here when $kT/h\nu$ becomes large and $(a-b)/(a+b)$ becomes small as $h\nu/kT$.

A second special case of interest occurs when $c/(a-b) \gg \bar{n}$. Since $c/(a-b)$ is the number of new particles introduced during the time required for the amplification to increase by e, this condition represents the case where the initial number of particles can hardly be regarded as fixed, but is dominated by the entrance of $c/(a-b)$ new particles during the time required for an appreciable amplification. In this case

$$\varepsilon=\sqrt{\frac{a}{b}}\,. \qquad (18)$$

Note that the fluctuations are determined not by $c/(a-b)$, the number of particles entering during time for amplification, but by c/a, the smaller number which enters during the time required for appreciable emission (or absorption if $a-b \ll a$, for then $b \approx a$).

§ 5. Complete Solution for the Distribution Function

Values of the first few moments of m may be all that is usually needed for practical purposes, and these can be conveniently calculated from the set of equations (13). However, a complete solution of (3) may be useful in some cases, and will be given in the following. The solution has been obtained for the general case of arbitrary values of a, b and c by use of a generating function. However, the cases $c=a$ and $c=0$, which have the special property mentioned above, can be dealt with in a somewhat different and more physical way. Since these are also quite important cases, they will be considered in some detail.

i) Case $c=a$

It has been shown above that, when $c=$ the exponential form of probability distributi is invariant and that there is a linear relatic ship, (8b) or (9b), between the average numbe of quanta before and after either amplificati alone or attenuation alone. Hence this i variance of an exponential distribution a the same type of linear relationship mu remain valid for any combination of succe sive absorption and amplification and, as limiting case, for simultaneous absorption ar amplification. It may then be assumed tha some solution of the fundamental differenti equation

$$\frac{dp_m}{dt}=-[a(m+1)+bm]p_m + amp_{m-1}+b(m+1)p_{m+1} \qquad (19$$

has the form

$$p_m=(1-u)u^m\,. \qquad (20$$

Equation (19) is the form taken by (3) whe $c=a$. When expression (20) is substituted int (19), a factor depending on m drops out fron both sides of the equation, and a single equation independent of m is obtained:

$$\frac{du}{dt}=(1-u)(a-bu)\,.$$

Integration of this expression yields a linea relation between the average numbers o quanta, i.e.,

$$\frac{u}{1-u}=\frac{Ku_0}{1-u_0}+\frac{a}{a-b}(K-1) \qquad (21$$

where $K=e^{(a-b)t}$ is the classical amplificatio factor and u_0 is the initial value of u (fo $t=0$).

Since (20) is the probability distribution corresponding to the initial distribution $(1-u_0)u_0$ we have

$$(1-u)u^m=\sum_n P_{n,m}(1-u_0)u_0^n \qquad (22$$

or

$$\sum_n P_{n,m}u_0^n=\frac{1-u}{1-u_0}u^m=\frac{(a-b)a^m(K-1)^m}{(aK-b)^{m+1}\left[1-\frac{b(K-1)}{aK-b}u_0\right]}\left[1+\frac{\frac{(a-b)^2Ku_0}{a(K-1)(aK-b)}}{1-\frac{b(K-1)}{aK-b}u_0}\right]^m. \qquad (23$$

Since (23) holds for any u_0 (less than unity), it may be used to evaluate $P_{n,m}$ by expandin the right hand side in powers of u_0 and equating coefficients of u_0^n on each side of th uation. Such an expansion gives a convergent series when $u_0<1$, since always $\frac{b(K-1)}{aK-b}>1$. ter carrying out the expansion, one obtains the probability distribution

$$P_{n,m}=\frac{(a-b)a^m b^n (K-1)^{m+n}}{(aK-b)^{m+n+1}}\sum_{j=0}^{m \text{ or } n}\frac{m!n!}{j!(m-j)!j!(n-j)!}\left[\frac{(a-b)^2K}{ab(K-1)^2}\right]^j . \tag{24}$$

re the upper limit of the summation should be n for $n\leq m$ and m for $n\geq m$.

When $a=0$, expression (24) becomes $\frac{n!}{m!(n-m)!}K^m(1-K)^{n-m}$ for $n\geq m$, and 0 for $n<m$, agreement with the previous result (6b). Similarly, when $b=0$, (24) becomes $\frac{m!}{(m-n)!n!}$ $\frac{(K-1)^{m-n}}{K^{m+1}}$ for $m\geq n$, and 0 for $m<n$, in agreement with (5b) when $c=a$.

Case $c=0$

It has already been shown that the same type of invariance of the exponential distribution lds also when $c=0$, with the exception of the case $m=0$. Accordingly, one can proceed in way similar to that above for $c=a$, but with a few modifications. Since $m=0$ is exceptional, e probabilities may be written in the form

$$\begin{aligned} p_m&=\alpha(1-u)u^m \qquad (m\neq 0)\\ p_0&=1-\alpha u\ , \end{aligned} \tag{25}$$

sing a positive parameter α. The lowest state $m=0$ is more or less populated than is reuired by the strictly exponential distribution according as $\alpha>1$ or $\alpha<1$. One again obtains e relation between u and u_0:

$$\frac{u}{1-u}=\frac{Ku_0}{1-u_0}+K-1\ , \tag{26}$$

hich is identical with (8b). However, it should be noted that here the average number of uanta $\overline{m}$ is no longer $u/(1-u)$ but rather $\alpha u/(1-u)$ and the physical meaning of (26) is quite ifferent. The proper equation for $\overline{m}$ is

$$\overline{m}=\frac{\alpha u}{1-u}=K\frac{\alpha_0 u_0}{1-u_0}\ , \tag{27}$$

here α_0 is the initial value of α at $t=0$. Note that (27) just corresponds to (14) when $c=0$. 7) may be used to determine the additional parameter α.

From these equations, one obtains after a little calculation for $m\neq 0$

$$\sum_{n=1}^{\infty}P_{n,m}u_0^{\,n}=\frac{(a-b)^2Ku[a(K-1)+(a-bK)u]^{m-1}}{[(aK-b)-b(K-1)u_0]^{m+1}} \tag{28}$$

nd for $m=0$

$$\sum_{n=1}^{\infty}P_{n,0}u_0^{\,n}=\frac{b(K-1)u_0}{(aK-b)-b(K-1)u_0}\ .$$

xpansion of the right hand side gives

$$P_{n,m}=\frac{a^m b^n (K-1)^{m+n}}{(aK-b)^{m+n}}\sum_{j=0}^{m \text{ or } n}\frac{n!(m-1)!}{j!(n-j)!(j-1)!(m-j)!}\left[\frac{(a-b)^2K}{ab(K-1)^2}\right]^j . \tag{29}$$

i) General Case

The form of $P_{m,n}$ for the general case might he conjectured from expressions (24) and (29), r it may be rigorously derived by use of a generating function. It is

$$P_{n,m}=\frac{(a-b)^{c/a}a^m b^n (K-1)^{m+n}}{(aK-b)^{m+n+c/a}}\sum_{j=0}^{m\text{ or }n}\frac{n!\Gamma(m+c/a)}{j!(n-j)!(m-j)!\Gamma(j+c/a)}\left[\frac{(a-b)^2K}{ab(K-1)^2}\right]^j, \qquad \text{(3}$$

where the sum is to m when $m\leq n$ or to n when $n\leq m$. The generating function and deta of the derivation of (30) are given in the Appendix. Expression (30) holds for any positi values of K, a, b, and c. However, there are a number of special cases listed below whi warrant separate consideration.

(a) Case $a=b$, $K=1$

Expression (30) holds for $K>1$ as well as for $K<1$. However, the equation cannot used directly for the limiting case $K=1$, that is, the case with neither amplification nor a tenuation. By the appropriate limiting process, $K=(a-b)t+1$ and $a\rightarrow b$, (30) can be broug to the following from

$$P_{n,m}=\frac{(at)^{m+n}}{(at+1)^{m+n+c/a}}\sum_{j=0}^{m\text{ or }n}\frac{n!\Gamma(m+c/a)}{j!(n-j)!(m-j)!\Gamma(j+c/a)}\left(\frac{1}{at}\right)^{2j}. \qquad \text{(3}$$

(b) Case $a=0$, $c\neq 0$

Another limiting case occurs when there is no amplification but a constant rate of generat of new quanta. Then

$$P_{n,m}=\frac{c^m(1-K)^{n+m}}{b^m}e^{-(1-K)c/b}\sum_{j=0}^{n\text{ or }m}\frac{n!}{j!(n-j)!(m-j)!}\left(\frac{bK}{c(1-K)^2}\right)^j. \qquad \text{(32}$$

(c) $K\rightarrow\infty$, $m\rightarrow\infty$, $K/m=$finite

The asymptotic behavior of (30) for large K and m is of special interest since such a cas is related to a macroscopic observation of a small number of quanta by means of very larg amplification, as in the case of photo-multiplier tubes, or perhaps in a maser amplifier.

The asymptotic form in this case is

$$P_{n,m}=\frac{1}{m}\left(\frac{a-b}{a}\frac{m}{K}\right)^{c/a}\left(\frac{b}{a}\right)^n\exp\left(-\frac{a-b}{a}\frac{m}{K}\right)\sum_{j=0}^{n}\frac{n!}{j!(n-j)!\Gamma(j+c/a)}\left[\frac{(a-b)^2}{ab}\frac{m}{K}\right]^j. \qquad \text{(33}$$

When $c=a$, the right hand side becomes a Laguerre polynomial and

$$P_{n,m}=\frac{a-b}{aK}\left(\frac{b}{a}\right)^n\exp\left(-\frac{a-b}{ab}\frac{m}{K}\right)L_n\left[-\frac{(a-b)^2}{ab}\frac{m}{K}\right]. \qquad \text{(34}$$

When $a\gg b$, the highest term of the sum in (33) prevails and the distribution is nearly identical with the one given by (7). However, as the ratio b/a increases, the peak becomes broader and the value of $P_{n,m}$ does not vanish at $m=0$ corresponding to the fact that there is always some probability that all particles vanish during the process.

(d) Equilibrium

The distribution reaches an equilibrium after a long time only if $a<b$. $P_{n,m}$ may be evaluated in this case either by setting $dP_{n,m}/dt=0$ in the fundamental equation (3) and solving the equation by a mathematical induction, or by letting K approach zero in the general solution (30). This gives

$$P_{n,m}=(1-a/b)^{c/a}\frac{\Gamma(m+c/a)(a/b)^m}{m!\Gamma(c/a)} \qquad (35)$$

which is independent of n and finite for a values of m, since $a<b$.

Finally, attention should be called to th generality of the expression of the type (30 In case $c=a$ and $c=0$, it can be shown tha any succession of absorption and emissio leaves the exponential form of distributio invariant and leads to a linear relation betwee $u/(1-u)$ and $u_0/(1-u_0)$. The expression co tains two independent parameters K and $a/$ and represents the most general linear relatio between $u/(1-u)$ and $u_0/(1-u_0)$. Hence follows that the forms (24) and (29) represe the general case involving any arbitrary su cession of absorption, amplification, or mixtu of both, provided appropriate values of K a a/b are used.

The same argument does not apply to t

eneral case represented by (30), but it will e shown in the appendix, that this is true ven in this case, that is, when both a and depend on time, but c/a remains constant.

6. Applicability of Results to Maser-type Amplification

Equation (3) and solutions discussed above pply well to a group of photons which may ncrease or decrease in number as a result of ormal absorption, stimulated emission, or pontaneous emission. Consider some atomic r molecular system which may exist in one f two nearby levels, between which photons nay induce transitions. The probability of bsorption of a photon by a molecule in the ower state is the same as that for emission timulated by the photon from a molecule in he upper state. Under normal conditions, an nsemble of such molecules is in thermal quilibrium, there are more molecules in the ower than in the upper state, and hence the nsemble attenuates a wave packet of photons. However, spontaneous emission also occurs and is responsible for maintaining the thermal radiation of photons by the molecules. Moreover, if an abnormal ensemble can be created n which there are more molecules in the upper than in the lower state, a wave packet of photons passing through such an ensemble will be amplified rather than attenuated. This type of phenomenon occurs in a maser$^{3)}$, and gives promise of allowing construction of amplifiers which are exceptionally free of noise. To show that equation (3) applies to such amplifiers, two somewhat idealized cases will be discussed.

Consider first a cavity with perfectly reflecting walls and containing molecules of the type described above with n_a molecules in the upper state and n_b in the lower state. For simplicity, suppose that the response of these molecules is independent of frequency over the range of frequencies considered, which includes the frequency of a normal mode of the cavity. If there are m photons of this frequency in the cavity, the probability of one of the photons being absorbed per unit time is proportional to m and to n_b or hence has the form Amn_b, where A is a constant. The probability per unit time for a photon to be produced by stimulated emission is correspondingly Amn_a.

Spontaneous emission may also provide new photons. When an excited atomic or molecular system interacts with one of the normal modes of an electromagnetic field in some enclosure, the probability for emission of a photon (of the same frequency as that of the normal mode) is proportional to $n+1$, where n is the number of quanta present in the mode. The finite probability for emission when $n=0$ represents spontaneous emission, or the effect of zero-point fluctuations of the electromagnetic field which have one-half the energy of one quantum. Hence the spontaneous emission is given by An_a.

From the above, it may be seen that the number of photons in a perfectly reflecting cavity containing molecules of the type discussed will follow equations (3) with $a=An_a$, $b=An_b$, and $c=a$. If the walls are not perfectly reflecting, but absorb and emit photons, they may be replaced in principle by perfectly reflecting walls and a suitable number of molecules n_a and n_b in the upper and lower states. Hence, with appropriate modification of the effective number of molecules involved, a cavity with absorbing walls is equivalent to the case with perfectly reflecting walls already considered. If there is a coupling hole in the cavity, this allows photons to escape and corresponds simply to an increase in n_b or in b provided no new photons enter through the coupling hole. If a signal is introduced through the coupling hole, this corresponds to an increase in c, the rate of introduction of new photons, so that $c>a$. However, as will be seen below, some care must be taken to allow for possible interference of the waves of incoming and outgoing photons in this case.

As a second example, consider a packet of m photons traveling along a waveguide filled with material containing the molecules in question with a density n_a of molecules in the upper state and a density n_b in the lower state. For simplicity, let the wave associated with the m photons be a packet of constant amplitude and finite length, with Δt the time required for the entire packet to pass a given point in the waveguide. Now the probability of one of the photons being absorbed per unit time is again proportional to m and to n_b, or $A'mn_b$. The probability per unit time for production of a photon by stimulated emission is correspondingly $A'mn_a$. Again for simplicity, the molecular systems will be assumed to respond uniformly over a wide range of frequencies so that A' is independent of frequencies to be considered.

The ratio of induced emission to spontaneous emission may be seen from the discussion above to be determined by the ratio of the energy density associated with photons to twice that of zero-point fluctuations of the normal modes which have appropriate frequencies to produce emission.

A waveguide may be considered an enclosure, and the energy density of normal modes calculated, by assuming it has some arbitrary long length. Or, such a calculation may be circumvented by use of the well known relation for the power flow P of noise along a waveguide.

$$P = kT\Delta\nu\ , \tag{36}$$

where $\Delta\nu$ is the bandwidth to which the amplifying system responds. Since each normal mode has energy kT (when $kT \gg h\nu$, which may be assumed for this derivation), and each mode may be considered as two traveling waves moving in opposite directions, it can be seen from (36) that the power which might be considered to flow in one direction due to zero-point vibration is

$$P_0 = \frac{h\nu\,\Delta\nu}{2}\ .$$

The power flow due to the wave packet of m photons is $\frac{mh\nu}{\Delta t}$. Now a wave packet of duration Δt has a frequency spectrum with the power per unit bandwith given as a function of frequency by

$$\Phi(\nu)d\nu = \Phi(\nu_0)\left[\frac{\sin(\nu-\nu_0)\pi\Delta t}{(\nu-\nu_0)\pi\Delta t}\right]^2 d\nu\ . \tag{37}$$

Integration of (37) gives the total power flow and allows evalution of $\Phi(\nu_0)$

$$\frac{mh\nu}{\Delta t} = \int \Phi(\nu)d\nu = \frac{\Phi(\nu_0)}{\Delta t}$$

since $\int_{-\infty}^{\infty} \frac{\sin^2 x}{x^2}dx = \pi$. Hence the ratio of stimulated to spontaneous emission at the frequency ν is

$$r = \frac{\Phi(\nu)\Delta\nu}{2P_0} = \frac{\Phi(\nu)}{h\nu} = m\left[\frac{\sin(\nu-\nu_0)\pi\Delta t}{(\nu-\nu_0)\pi\Delta t}\right]^2.$$

Under the optimum condition, which occurs when $\nu=\nu_0$, $r=m$. Thus if the stimulate emission is given by $A'mn_a$ as indicated abov the spontaneous emission is $A'n_a$. This co responds to the case $c=a$ in (3). If emissio and absorption of photons by the waveguid walls occur, they may be again regarded a due to some equivalent number of absorbin or emitting molecules, so that the above dis cussion applies, but with modified number n_a and n_b of molecules in the two states.

Photons in Equilibrium

If there is an equilibrium distribution o particles, so that $dP_{n,m}/dt=0$ for all $P_{n,}$ then according to (35)

$$P_{n,m} = (1-a/b)^{c/a}\frac{\Gamma(m+c/a)}{m!\,\Gamma(c/a)}(a/b)^m\ .$$

If new photons are introduced into the system only as a result of spontaneous or stimulate emission then, as shown above, $c/a=1$, and (35) becomes

$$P_{n,m} = (1-a/b)(a/b)^m\ . \tag{39}$$

This is just the probability distribution for thermal equilibrium of photons with the molecules, since $a/b=e^{-h\nu/kT}$ where T is the temperature of the molecules.

§ 7. Fluctuations in a Traveling-wave Maser

Fluctuations in an amplifier of the maser type may now be related to the coefficients a, b, and c. In many cases, fluctuations which determine the limiting sensitivity of such an amplifier depend only on the ratio a/b, which is conveniently expressed in terms of an effective temperature T_e defined by

$$\frac{a}{b} = \exp\left(\frac{-h\nu}{kT_e}\right)\ . \tag{40}$$

Here $h\nu$ is the energy gap between upper and lower levels and k is Boltzmann's constant T_e may be positive or negative depending on the relative magnitude of a and b, but the fluctuations are primarily dependent on the absolute value of T_e.

Consider first the waveguide case, where for amplification to occur $a>b$. From (16) if exactly n photons are introduced into the amplifier, after a large amplification a measure of the fractional fluctuation is

$$\varepsilon^2 = \frac{\overline{m^2}-\overline{m}^2}{\overline{m}^2} = \frac{n\left(\frac{a+b}{a-b}\right)+\frac{ac}{(a-b)^2}}{[n+c/(a-b)]^2}\ . \tag{41}$$

Since in the present case $c=a$,

$$\mathcal{E}^2=\frac{n\dfrac{1+e^{h\nu/kT_e}}{1-e^{h\nu/kT_e}}+\dfrac{1}{(1-e^{h\nu/kT_e})^2}}{[n+(1-e^{h\nu/kT_e})^{-1}]^2}\,. \qquad (42)$$

If $h\nu/k|T_e|\gg 1$, (42) becomes

$$\mathcal{E}^2\approx\frac{1}{n+1} \qquad (43)$$

nd the probability distribution is given by 7) with $c=a$, or

$$P_{n,m}\approx\frac{1}{K}\left(\frac{m}{K}\right)^n\frac{e^{-m/K}}{n!}\,. \qquad (44)$$

quation (43) and (44) represent the behavior f a perfect amplifier, where the absolute alue of the temperature approaches zero and nly emission processes occur ($b\to 0$). In this ase there remain fluctuations due to quantum ffects. The fractional variations which occur pproach zero when the number of quanta to e amplified is large, which is normally the ase for very low frequencies. It should be oted that the effective temperature need not e actually zero to approach a perfect amplifier, but $k|T_e|$ must be small compared with he energy $h\nu$ of one quantum. In the case f 1-centimeter radiation, $k|T_e|=h\nu$ when $T_e|\approx 1.5$°K. $|T_e|$ in an ammonia maser[3], or example, can be smaller than this value, ince ammonia molecules in a well focused eam flowing into the cavity are predominanty in the upper inversion state and $a\gg b$.

In the other extreme case where a is almost qual to b, or $h\nu/k|T_e|\ll 1$,

$$\mathcal{E}^2\approx\frac{2nh\nu/k|T_e|+1}{(nh\nu/k|T_e|+1)^2}\,. \qquad (45)$$

A measure of the minimum detectable number f quanta under such conditions can be obtained rom the equations (14) or (21). After large mplification

$$\overline{m}=\left(\overline{n}+\frac{a}{a+b}\right)K \qquad (46)$$

here K is the classical amplification factor $e^{(a-b)t}$. For the signal to equal background oise

$$n_{\min}=\frac{a}{a-b}\approx\frac{k|T_e|}{h\nu}\,, \qquad (47)$$

f $a\approx b$ or $h\nu/k|T_e|\ll 1$. This value reresents just the magnitude of thermal noise t a temperature $|T_e|$. The thermal power evel in the same time interval Δt as the input ignal may be expressed by $P_t=k|T_e|\Delta\nu_e$, here $\Delta\nu_e$, the effective bandwidth corresponding to the length of wave packet of the signal, is $1/(\Delta t)$ by (37). The thermal noise level in terms of number of photons in time Δt is then

$$n_t=\frac{P_t\Delta t}{h\nu}=\frac{k|T_e|}{h\nu}\,.$$

Thus the signal level which doubles the background output of an amplifier has just the magnitude of the usual thermal noise at temperature $|T_e|$. From (45), if the number of photons is s times the thermal noise level, $n=sk|T_e|/h\nu$, the fluctuation is given by

$$\mathcal{E}^2=\frac{2s+1}{(s+1)^2}\,. \qquad (48)$$

Hence the signal level must be considerably larger than $k|T_e|/h\nu$ before the fractional fluctuations become small.

The probability distribution for this case is obtained from (33) as

$$P_{n,m}=\frac{1}{m_0}\,e^{-(s+m/m_0)}I_0\!\left(2\sqrt{\frac{m}{m_0}s}\right). \qquad (49)$$

where m_0 is the average number of quanta for the background noise only, and I_0 is the modified Bessel function of order zero. Note that equations (48) and (49) agree precisely with the classical expressions for the fluctuation of power for the waves obtained by superposition of a sinusoidal wave and a thermal noise.

It is important to note that $|T_e|$ may have very little to do with any ordinary idea of the temperature of the amplifying system. Suppose, for example, that the waveguide walls are at absolute zero temperature, but absorb photons. Suppose also that the material inside the waveguide is at a very small negative temperature, so that for it $b=0$, and one might expect to have an ideal amplifier. However, absorption of photons by the waveguide adds to the net value of b, and if this absorption is of sufficient size, the entire system may have b almost equal to a, so that $|T_e|$ would be extremely large and the amplifier very noisy.

§ 8. Regenerative Amplifier Using a Cavity

In the case of a resonant microwave cavity containing amplifying materials, the same equations (14) and (15) for $\overline{m}$ and $\overline{m^2}$ apply, but their physical significance is somewhat different. m then represents the total number of photons in the cavity, which does not give directly the magnitude of the energy delivered by the amplifier. Furthermore, if a signal is fed into the cavity continuously, c must represent both this signal and spontaneous emission. Two general types of operation of an amplifier using a cavity are important:

1) Superregenerative amplification where $a>b$ and amplification results from an exponentially increasing pulse initiated by the signal. The exponentially increasing pulse is quenched, and the build-up from the input signal is then repeated in a so-called quenching cycle.

2) Stable amplification where $a<b$. This gives continuous amplification without any exponential build-up.

Consider first the case of a stable amplifier made up of a perfectly conducting cavity with input and output coupling holes and containing material with active molecules or atoms which responds uniformly to electromagnetic radiation at all frequencies of interest. If photons are put into the cavity, they will be absorbed in the material or escape from the input coupling holes. They may also stimulate emission and create new photons. As a result, their average number $\overline{m}$ will decay (since $a<b$) in accordance with the expression

$$-\frac{d\overline{m}}{dt}=(b-a)\overline{m}=(b_u+b_i+b_o-a)\overline{m}\ , \qquad (50)$$

where b_u represents loss in the material, b_i and b_o losses through the input and output coupling holes respectively. The loaded Q for the cavity is easily shown to be $Q=2\pi\nu/(b-a)$. Similarly the unloaded Q, and Q's for the coupling holes are $Q=2\pi\nu/(b_u-a)$, $Q_i=2\pi\nu/b_i$, and $Q_o=2\pi\nu/b_o$. Here Q_u may be negative, since the active material would have $a<b$ to provide amplification or the equivalent of a negative resistance.

Assume now an input signal of power P_i per unit frequency interval. Standard theory for cavity resonators, which may be extended to the case where Q_u is negative, gives for the power per unit bandwidth emerging from the output

$$P_o=P_i\frac{2\pi\nu QR(\nu)}{Q_iQ_o}\ , \qquad (51)$$

where $R(\nu)$ is the resonant expression

$$R(\nu)=\left(\frac{1}{2\pi\nu Q}\right)\frac{1}{\left(\frac{1}{2Q}\right)^2+\left(\frac{\nu-\nu_0}{\nu_0}\right)^2} \qquad (52)$$

with ν_0 the resonance frequency of the cavity. Similarly, power reflected back to the input waveguide is

$$P_r=P_i\frac{2\pi\nu QR(\nu)}{4}\left[\left(\frac{1}{Q}-\frac{2}{Q_i}\right)^2+4\left(\frac{\nu-\nu_0}{\nu_0}\right)^2\right] \qquad (53)$$

and the energy stored in the cavity as a result of the input signal is

$$W_i=P_i\frac{Q}{Q_i}R(\nu)\ . \qquad (54)$$

The gain of this type of amplifier is, from (51)

$$G=\frac{P_o}{P_i}=\frac{2\pi\nu Q}{Q_iQ_o}R(\nu) \qquad (55)$$

which becomes

$$G=\frac{4Q^2}{Q_iQ_o}=\frac{4b_ib_o}{(b-a)^2} \qquad (56)$$

at the resonance frequency, $\nu=\nu_0$.

It is important now to note the difference in the reemission of an input signal from the cavity, and the escape of spontaneous emission from the coupling holes. If the input signal is a long train of coherent waves $\left(\Delta\nu<\frac{\nu_0}{2Q}\right)$, then there is an interference between the wave which is reflected from the input coupling hole without entering the cavity, and that which enters the cavity and is reemitted from the input hole. For example, in the case of a "matched" input, where $1/Q=2/Q_i$ equation (53) shows that there is no power reflected from the input when $\nu=\nu_0$. Hence in this case none of the power W_i accumulated in the cavity can escape from the input hole which might lead one to suppose that $b_i=0$ However, the spontaneous emission within the cavity undergoes no interference of this type and is emitted from the input according to the value $b_i=\frac{2\pi\nu}{Q_i}$ indicated above. Because of these same interference effects, it is also not immediately clear what values of c should be attributed to the input signal. There are $P_i/h\nu$ photon/sec. per unit bandwidth flowing towards the cavity input, but since the wave reflected directly from the input is indistinguishable from that reemitted from the cavity through the input coupling, the number of photons actually entering the cavity is subject to various interpretations.

For use of equation (3) and its solutions, the effective value of c corresponding to a certain input power P_i is the rate at which photon vould have to be released in the cavity to roduce an equivalent total number of photons r an equivalent power output. Now if c_i hotons/sec. are released within the cavity, t can be shown by standard methods that hey produce the total output power which s $h\nu c_i\frac{Q}{Q_o}$. Letting this power equal the total utput power due to the input as given by 51), the equivalent rate of introduction of hotons by the input signal is

$$c_i=\int P_0(\nu)d\nu=\frac{2\pi P_i}{hQ_i}=\frac{P_i b_i}{h\nu}\,. \tag{57}$$

Fluctuations in the power output may now e obtained from expressions (14) and (15). he result is somewhat different from that f equation (16) because, in the case of a table amplifier, $a<b$ and the exponentials in 14) and (15) decrease with time so that, under onstant conditions

$$\bar{m}=\frac{c}{b-a}\,,$$

$$\overline{m^2}=\frac{c(b+c)}{(b-a)^2}\,,$$

$$\mathcal{E}^2=\frac{\overline{m^2}-\bar{m}^2}{\bar{m}^2}=\frac{b}{c}\,. \tag{58}$$

ubstituting appropriate values into (58) one as

$$\mathcal{E}^2=\frac{b}{a+c_i}=\frac{b}{a+\dfrac{2\pi P_i}{hQ_i}}\,. \tag{59}$$

ere it is assumed that P_i is constant over he frequency range for which $R(\nu)$ is of apreciable magnitude. For an amplifying system f reasonably large gain, $a\approx b$, so that

$$\mathcal{E}^2=\frac{1}{1+\dfrac{2\pi P_i}{ahQ_i}} \tag{60}$$

nd for $\mathcal{E}$ to be small, $\dfrac{2\pi P_i}{ahQ_i}\gg 1$.

As in the waveguide amplifier, there are ackground noise fluctuations due to spontaneus emission even when no signal is present. or the output power to be doubled as a esult of an input signal, c_i must equal a, or rom (57)

$$\frac{2\pi P_i}{hQ_i}=a\,. \tag{61}$$

terms of a noise temperature T_n for the mplifier, this gives

$$P_i=kT_n=\frac{ahQ_i}{2\pi}=\frac{ah\nu}{b_i}\,. \tag{62}$$

Since $b=b_i+b_u+b_o$, and $a\approx b$ for large amplification, (62) becomes

$$T_n=\frac{bh\nu}{k(b-b_u-b_o)}\,. \tag{63}$$

An effective temperature $T_e(<0)$ for the molecular system can be defined which includes all gains and losses except those due to the input coupling, that is

$$\frac{a}{b_u+b_o}=\exp\left(-\frac{h\nu}{k|T_e|}\right). \tag{64}$$

Hence, when $h\nu\ll k|T_e|$, the noise temperature (63) is simply

$$T_n=|T_e| \tag{65}$$

and if $h\nu\gg k|T_e|$, the limiting noise temperature becomes, from (63) and (64),

$$T_n=\frac{h\nu}{k}\,. \tag{66}$$

Now a noise temperature $T_n=h\nu/k$ is based on the classical assumption that the flow of power per unit bandwidth is $kT\Delta\nu$. An amplifier with this ideal noise temperature is capable, as is the ideal waveguide amplifier, to "detect a single photon." This may be demonstrated from the fact that the noise temperature $h\nu/k$ corresponds to a rate of power flow $h\nu\Delta\nu$ in a bandwidth $\Delta\nu$, or to $\Delta\nu$ quanta per unit time. But an amplifier of bandwidth $\Delta\nu$ can amplify a pulse of minimum length $1/\Delta\nu$ which would then contain just one photon at this minimum detectable power level.*

From (63) and (64), it may be noted that the lowest noise temperature is obtained for an amplifier by making the output coupling very small, and that the limiting noise temperature when $b_o=0$ just corresponds to the effective temperature of the active material. Furthermore, as in the case of a waveguide amplifier, additional coupling holes or losses in the cavity can produce a very high noise temperature even when the cavity and its active material are at low temperatures. Of course it is also possible to dispense with the output coupling entirely and use the wave reflected from the input as the amplified signal.

---

* This does not mean the possibility of unambiguously observing a single photon as an individual pulse.

§ 9. Superregenerative Amplifier Using a Cavity

To consider the noise properties of a superregenerative cavity amplifier, assume that the rate of induced emission a is zero until time $t=0$, when suddenly a is made larger than b so that an exponential build-up of energy in the cavity is begun. There are on the average n photons in the cavity at $t=0$. Then equation (14) describes the growth of the number of photons in the cavity during the amplification period. For large gain $(a-b)t \gg 1$ and the average number of photons in the cavity after amplification lasting time t_1 is

$$\overline{m}=\left(\overline{n}+\frac{c_i}{a-b}+\frac{a}{a-b}\right)e^{(a-b)t_1}, \tag{67}$$

where c_i is again given by (57). Since the initial number of photons n is determined by the input power before $t=0$, it is from equation (14) for $a=0$

$$\overline{n}=\frac{c_i}{b}, \tag{68}$$

where a term with exponential decay factor may be neglected. Whether the contribution of initial number of photons due to input signal before $t=0$, or that of continuing flow of photons during build-up denominates depends on the relative size of $1/b$ and $1/(a-b)$, assuming c_i is same for $t<0$ and $t>0$.

Putting (68) into (67), one obtains

$$\overline{m}=\left[\frac{c_i}{b}+1\right]\frac{a}{a-b}e^{(a-b)t_1}. \tag{69}$$

Or, if the the cavity is operated as a stable regenerative amplifier until $t=0$ with $a=a_0<b$ and after that a is suddenly increased so that $a>b$, $\overline{n}$ is equation (67) is given by

$$\overline{n}=\frac{1}{b-a_0}(c_i+a_0) \tag{68a}$$

instead of (68). Then one obtains from (67)

$$\overline{m}=\frac{b(a-a_0)}{(a-b)(b-a_0)}\left[\frac{c_i}{b}+1\right]e^{(a-b)t_1} \tag{69a}$$

The background noise due to spontaneous emission when no photon is introduced from coupling holes is given by the second term, $+1$, in the brackets of (69) and (69a). The threshold signal is that which gives the same amount of output or the same number of quanta $\overline{m}$ as the background noise. Then

$$\frac{ci}{b}=1 \quad \text{or} \quad \frac{b_iP_i}{bh\nu}=1$$

and the noise temperature of the amplifier at the resonance is

$$T_n=\frac{P_i}{k}=\frac{h\nu}{k}\frac{b}{b_i}. \tag{70}$$

It may be noted that the noise temperature in a superregenerative amplifier is essentially the same form as (63) in a regenerative amplifier, and that more detailed discussion is allowed by the application of general solutions developed in § 5.

The discussion of noise and the number of quanta in the cavity has dealt with a continuous range of frequencies. The amplifier gain of course varies with frequency, but in any small part of its bandwidth the signal to noise ratio is equivalent. The gain varies as

$$\left[\left(\frac{1}{2Q}\right)^2+\left(\frac{\nu-\nu_0}{\nu_0}\right)^2\right]^{-1}$$

and at maximum, $\nu=\nu_0$, it is

$$G=\frac{4ab_ib_0}{b(a-b)^2}e^{(a-b)t_1} \tag{71}$$

for the case described by equation (69), and

$$G=\frac{4(a-a_0)b_ib_0}{(b-a_0)(a-b)^2}e^{(a-b)t_1} \tag{71a}$$

for the case to which equation (69a) applies.

These results differ somewhat from the conclusions of Gordon, Zeiger, and Townes,[33] partly because the earlier work did not take into account spontaneous emission from the molecules. Although this random spontaneous emission is generally small compared with the stimulated emission occuring in the cavity, it is amplified and therefore may become an important source of noise. Consider, for example, a group of molecules which are entirely in the upper state. Let them be in a cavity made of lossless and hence non-radiative material and let no photons enter through the coupling hole. One might then suppose that no noise would exist in the cavity. This is true only if there is no spontaneous emission $(c=0)$. Actually $c=a$ and if the system is stable, the noise level is given by $\overline{m}=a/(b-a)$, which is equivalent to the input noise temperature $b/b_i\cdot(h\nu)/k$.

Other differences between the present results and those of Gordon, Zeiger, and Townes come from the fact that they consider effects of thermal radiation which may enter the amplifier through input or output coupling holes

Although this type of noise is quite important in some cases, it is not fundamental o the amplification process, and has been neglected in the above discussion. Appropriate design of input and output circuits can in most cases prevent such noise which is not essentially associated with the signal from entering the amplifier.

Many varieties of design are possible for maser-type amplifiers, each of which needs analysis for a precise evaluation of sensitivity. However, the above results for certain idealized cases should indicate qualitatively the results which may be obtained, and illustrate the application to maser amplifiers of the general expressions for fluctuations developed in the former sections.

In conclusion we would like to acknowledge a helpful correspondence on the subject of noise between one of the authors and Mr. Marcel Muller.

Appendix. Derivation of Solution (30)*

The equation (3) will be solved here by use of a generating function for the most general case that a and b are functions of time and c/a is any positive constant.

The generating function for $P_{n,m}$ is very similar to (23) and is defined by

$$f_n=\sum_m P_{n,m}x^m\,. \qquad \text{(A1)}$$

By substituting (A1) into (3), one obtains a partial differential equation satisfied by $f_n(x,t)$:

$$\frac{\partial f_n}{\partial t}=(1-x)(b-ax)\frac{\partial f_n}{\partial t}-c(1-x)f_n \qquad \text{(A2)}$$

This is linear in f_n and may be solved by standard methods. The characteristic equation for (A2) is given by

$$\frac{-dx}{(1-x)(b-ax)}=dt=\frac{-df_n}{c(1-x)f_n} \qquad \text{(A3)}$$

The desired solution of (A2) is obtained by solving (A3) with the initial conditions: $x=x_0$ and $f_n=x_0{}^n$ for $t=0$, and then eliminating x_0.

The equation (A3) may be solved by putting

$$y=\frac{1}{1-x} \qquad \text{(A4)}$$

Then (A3) becomes

$$\frac{-dy}{(b-a)y+a}=dt=\frac{-y\,df_n}{cf_n}\,. \qquad \text{(A5)}$$

The left part of the equation (A5) is

$$dy/dt=(a-b)y-a \qquad \text{(A6)}$$

which is linear in y. The solution is given by

$$y=e^{\int(a-b)dt}\left(\int -ae^{-\int(a-b)dt}dt+y_0\right) \qquad \text{(A7)}$$

where y_0 is the initial value of y for $t=0$, i.e.

$$y_0=\frac{1}{1-x_0}$$

Using the notations

$$K=e^{\int(a-b)dt}\,, \qquad \text{(A8)}$$

$$G=K\int\frac{a}{Kdt}\,, \qquad \text{(A9)}$$

(A7) is written in the form

$$y=Ky_0-G \qquad \text{(A10)}$$

Evidently, K is the classical amplification factor.

f_n is obtained from the right part of (A5), i.e.

$$\frac{1}{f_n}\frac{df_n}{dt}=-\frac{c}{y} \qquad \text{(A11)}$$

By (A7), the equation takes the form

$$\frac{1}{f_n}\frac{df_n}{dt}=-\frac{c}{a}\frac{a}{K}\Big/\left(-\int\frac{a}{K}dt+y_0\right) \qquad \text{(A12)}$$

Integrating (A12), one obtains

$$f_n=\left(-\int a/K\,dt+y_0\right)^{c/a}\times\text{const}$$
$$=(-G/K+y_0)^{c/a}\times\text{const.} \qquad \text{(A13)}$$

Considering the initial condition $f=x_0{}^n=(1-1/y_0)^n$ at $t=0$, (A13) becomes

$$f_n=\left(1-\frac{G}{Ky_0}\right)^{c/a}\left(1-\frac{1}{y_0}\right)^n \qquad \text{(A14)}$$

Eliminating y_0 by use of (A10), the generating function is finally given by

$$f_n=\left(\frac{y}{y+G}\right)^{c/a}\left(1-\frac{K}{y+G}\right)^n$$
$$=\left(\frac{1}{1+G(1-x)}\right)^{c/a}\left(\frac{1+(G-K)(1-x)}{1+G(1-x)}\right)^n \qquad \text{(A15)}$$

Expansion of the numerator and denominator in powers of x gives

---

* A derivation similar to that indicated here was obtained independently by Dr. L. R. Walker and kindly communicated to one of the authors.

$$P_{n,m}=\frac{G^m(G-K+1)^n(K-1)^{m+n}}{(G+1)^{m+n+c/a}}$$
$$\times\sum_{j=0}^{m\text{ or }n}\frac{n!\Gamma(n+m+c/a-j)}{(n-j)!\,j!\,(m-j)!\,\Gamma(n+c/a)}\left[\frac{(G+1)(G-K)}{G(G-K+1)(K-1)^2}\right]^j. \qquad \text{(A16}$$

Or, if (A15) is put into a form like that of (23) and similarly expanded, one obtains a mor convenient expression

$$P_{n,m}=\frac{G^m(G-K+1)^n(K-1)^{m+n}}{(G+1)^{m+n+c/a}}$$
$$\times\sum_{j=0}^{m\text{ or }n}\frac{n!}{j!\,(n-j)!\,(m-j)!}\,\frac{\Gamma(m+c/a)}{\Gamma(j+c/a)}\left[\frac{K}{G(G-K+1)}\right]^j. \qquad \text{(A17}$$

When a and b are constant, K and G are given by

$$K=e^{(a-b)t},$$
$$G=\frac{a}{a-b}(e^{(a-b)t}-1)=\frac{a}{a-b}(K-1) \qquad \text{(A18)}$$

and substituting this into (A17), one obtains the expression (30) as a result.

Magnetic Susceptibility of Iron-Nickel Alloys in Liquid and Solid States

By Yasuaki NAKAGAWA

Department of Physics, Faculty of Science, University of Tokyo

(Received March 2, 1957)

The magnetic susceptibilities of various Fe-Ni alloys have been measured through their melting points up to 1600°C. The susceptibilities of the alloys with less than 60 % Ni increase discontinuously on melting, while those of the alloys with more than 60 % Ni decrease. The temperature variation of the susceptibilities is approximately expressed by the Curie-Weiss law in the liquid state as well as in the solid state, but the Curie constants and the paramagnetic Curie temperatures of liquids are in general different from those of solids.

These results can be explained by assuming that the atomic magnetic moments remain unaltered and that the magnetic interaction varies with the interatomic distance as indicated by the Bethe-Slater curve. The change of susceptibility at the melting point is solely due to the difference in interatomic distance between the liquid and the solid.

It is expected, in some cases, that the especially strong dependence of the magnetic interaction on the interatomic distance results in an appreciable change of interaction with temperature through the thermal expansion. It can account for the anomalously large Curie constants of pure γ-Fe and Fe-rich alloys in the solid state.

§1. Introduction

As reported previously¹⁾, the magnetic susceptibilities of various transition metals and alloys decrease or increase on melting, depending on whether the interatomic interactio favours parallel alignment of atomic magneti moments or not. This result may indicate hat the interaction is always weaker in liquid han in solid. Some Fe-rich alloys with face-entred cubic lattice, however, form excep-ions to the simple rule mentioned above, *i.e.* their susceptibilities increase on melting though they are ferromagnetic at low temperatures. These exceptions can be also explained, if the Bethe-Slater interaction curve is taken into ccount*.

The magnetic interaction is expressed as a function of the ratio R of the interatomic distance D to the diameter of $3d$-shall δ, as shown in Fig. 1. The value of the interaction has a maximum at $R=R_m$ and vanishes at $R=R_0$. If $R_0<R<R_m$, the interaction is ferromagnetic and may become larger on melting, since R may be larger in liquid than in solid.

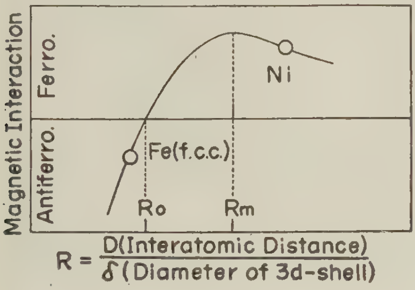

Fig. 1. Interaction Curve.

In the Fe-Ni system, the values of R for Ni-rich alloys are larger than R_m, while those for Fe-rich alloys are smaller. It was supposed in the previous paper[1)] that the susceptibility of the alloy with about 65% Ni might remain unaltered at the melting point, since this alloy might correspond to the maximum point on the Bethe-Slater curve. This supposition, however, was based upon rough measurements on merely three alloys. In the present paper, detailed experimental data on Fe-Ni alloys will be reported together with further discussions about the Bethe-Slater curve.

Up to the present, several investigations on the susceptibility of solid Fe-Ni alloys have been reported. Wohlfarth[3)] discussed the experimental data of Peschard[4)] and of Fallot[5)] on the basis of the collective electron theory of ferromagnetism. This theory, however, seems less satisfactory for Fe-Ni alloys than for Ni-Cu or Ni-Co alloys. At the present stage, the collective electron theory is unlikely to be suitable to account for the properties of the ferromagnetic metals which have more than two holes in $3d$-shell per atom. Thus the Heitler-London theory will be used in the present discussion though it also encounters some difficulties.

§ 2. Experimental Procedures and Results

The experimental method is the same as that described previously[1)]. The susceptibilities of nine different alloys ranging in composition from 10 to 89% of Ni were measured through their melting points up to 1600°C. These alloys were prepared by T. Nagashima by melting pure Fe and Ni together in a vacuum induction furnace for the purpose of other investigations[6)]. The impurities in Fe and Ni used and the composition of alloys are listed in Table I and Table II respectively.

Table I. Impurities in electrolytic Fe and Ni used
(Spectroscopic analysis)

	Al	Ca	Co	Cu	Fe	Mg	Mn	Ni	Pb	Si
Fe	trace	trace	trace	0.01	—	0.001	0.01	0.001	trace	none
Ni	0.1	trace	0.1	0.01	0.1	0.1	none	—	none	trace

(in weight %)

As can be seen in the phase diagram[7)], all alloys investigated are face-centred cubic at high temperatures. The susceptibilties of Fe-Ni alloys at low temperatures show anoma-

---

* After publishing the previous paper, the author found Weil's[2)] experimental data on the susceptibilities of some liquid alloys of transition elements. Among these alloys, those of homogeneous solid solutions such as Cu-Mn, Cu-Ni and Ag-Mn are interesting in view of the change of susceptibility on melting. Weil's results can be also accounted for by the general rule given in the previous paper.

Table II. Composition of specimens
(Chemical analysis)

Specimen	No. 1	2	3	4	5	6	7	8	9

+: Value of susceptibility measured during cooling.
↑: Melting point (Mean value of liquidus and solidus temperature).

lously large values owing to the transformation into the body-centred cubic phase.

Figure 2 shows the experimental results on the temperature variation of the susceptibilities per gram. The change of susceptibility on melting, $\Delta\chi=\chi_l-\chi_s$, is plotted against composition in Fig. 3 together with its relative value $\Delta\chi/\chi_s$. $\Delta\chi$ changes its sign at about 60% Ni, as has been supposed.

The susceptibilities of these alloys are approximately expressed by the Curie-Weiss law,

$$\chi=C'/(T-\theta)\,, \qquad (1)$$

in the liquid state as well as in the solid ate. The Curie constants per gram C' and e paramagnetic Curie temperatures θ are termined from the straight lines shown in ig. 2. C_s' and θ_s are those of solid, while $'$ and θ_l are those of liquid. Each of them is lotted as a function of composition in Fig. 4. nstead of C', the Curie constant per mole is shown for convenience. C is equal to $'M$, where M is the 'mean' atomic weight f the alloy. The C vs composition curve, however, is not essentially different from the C'vs omposition curve, since there is no large diference in atomic weight between Fe and Ni. It should be mentioned that remarkable supercooling of liquid was observed in all casse. As shown in the previous paper[1], the magnetic behaviours of supercooled liquids are not different from those of ordinary liquids. Thus the values of C_l and θ_l can be determined precisely enough.

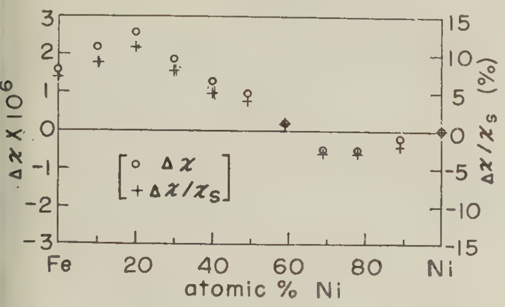

Fig. 3. Change of Susceptibility on melting.
$\Delta\chi=\chi_l-\chi_s$.
χ_l: Susceptibility per gram of liquid at melting point.
χ_s: Susceptibility per gram of solid at melting point.

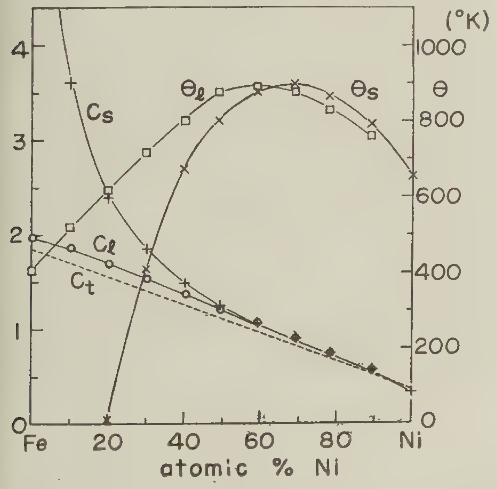

Fig. 4. Curie constant per mole C and paramagnetic Curie temperature θ.
Solid: ——+—— C_s ——×—— θ_s
Liquid: ——○—— C_l ——□—— θ_l
Theoretical: -------------- C_t

For pure Fe and Ni, the data reported before[1] are used. The susceptibility of Ni, however, shows a large deviation from the Curie-Weiss law at high temperatures, and so the Curie constant and the paramagnetic Curie temperature of liquid Ni are quite uncertain.

The very small deviations from the Curie-Weiss law for the alloys are somewhat systematic: the $1/\chi$ *vs* T curves for Ni-rich alloys are concave downwards, while those for Ferich alloys are convex.

It is to be noted that Peschard's[4] and Fallot's[5] results on the susceptibilities of Fe-Ni alloys in the solid state are in good agreement with those reported here.

§ 3. Theoretical Interpretation

The experimental results summarized in Fig. 4 may be explained on the basis of the following assumptions:

(I) The magnetic susceptibilities of these alloys can be treated with Weiss' molecular field theory.

(II) The atomic magnetic moments of Fe and Ni in Fe-Ni alloys are 3 and 1 Bohr magneton respectively, not depending on the composition of alloys. These moments remain unaltered on melting.

(III) The magnetic interaction varies with the ratio R of the interatomic distance D to the diameter of $3d$-shell δ, as indicated by the Bethe-Slater curve (Fig. 1). In order to treat the liquid and the solid together, the cubic root of atomic volume is used as the value of D, being larger in liquid than in solid. In cases where the slope of the Bethe-Slater curve is very steep, the interaction varies appreciably with temperature owing to the thermal expansion.

Discussions about these assumptions will be presented in the next section.

It is deduced from the assumption (I) that the susceptibility per mole χ_M can be expressed as

$$\chi_M=C_t/(T-C_tW)\,, \qquad (2)$$

where C_t is the 'theoretical' Curie constant and W the coefficient of molecular field. For a pure metal,

$$C_t = \frac{N\mu^2}{3k}4S(S+1)\,, \qquad (3)$$

where N is the Avogadro number, μ the Bohr magneton, k the Boltzmann constant and S the resultant spin of the atom. According to the assumption (II), S is equal to 3/2 for Fe and 1/2 for Ni.

For the Fe-Ni alloys,

$$C_t = (1-x)C_{Fe} + xC_{Ni}\,, \qquad (4)$$

where C_{Fe} and C_{Ni} are the 'theoretical' Curie constants of Fe and Ni respectively, and x is the atomic concentration of Ni. The values of C_t, given by Eq. (4), are shown in Fig. 4 with a dotted line.

If the molecular field coefficient W is independent of temperature, it is found easily that $C = C_t$ and $\theta = C_t W$ by comparing Eq. (2) with Eq. (1). This is the case of the alloys with more than 50% Ni, since both C_s and C_l are about equal to C_t as shown in Fig. 4. Thus the change of susceptibility at the melting point is solely due to the difference in W between liquid and solid.

This difference may be explained on the basis of the assumption (III). As has been suggested by Bozorth[8)], the Curie temperature θ, instead of W, is expressed as a function of $R(=D/\delta)$. Since it has been assumed that the values of R for the alloys depend linearly on the composition, the θ *vs* composition curve should be analogous to the Bethe-Slater curve. According to Slater[9)], the value of R for pure Ni is about 10% larger than that for pure Fe (with face-centred cubic lattice). On the other hand, R may be about 1% larger in liquid than in solid owing to the volume expansion on melting[10)]. Thus the increase in R due to melting corresponds to that due to 10% increase in Ni content. Therefore, the θ_l *vs* composition curve must coincide with the θ_s *vs* composition curve if the former is shifted along the composition axis by about 10%. This conclusion is in agreement with the experimental result on the alloys with more than 50% Ni, as shown in Fig. 4.

For the alloys with less than 50% Ni, however, the above theory is not satisfactory, because C_s is much larger than C_t while C_l is not so different from C_t. In this case the temperature dependence of W should be taken into account.

Since it is expected that these alloys in t solid state correspond to the steep range the Bethe-Slater curve, even the small chan in interatomic distance, caused by the therm expansion, can produce an appreciable effe on the magnetic interaction. This effect w first treated by Néel[11)].

The temperature dependence of W can expressed approximately by the formula,

$$W = W_0 + (dW/dT)_0(T-T_0)\,, \qquad \text{(5}$$

near an arbitrary temperature T_0. By su stituting (5) in (2), one obtains again the Curi Weiss law [Eq. (1)], where

$$C = \frac{C_t}{1-C_t(dW/dT)_0}\,, \qquad \text{(6}$$

and

$$\theta = T_0 - \frac{T_0 - C_t W_0}{1-C_t(dW/dT)_0}\,. \qquad \text{(7}$$

If T_0 is chosen to be equal to θ, Eq. (7) be comes

$$\theta = C_t W_0\,. \qquad \text{(8}$$

When the value of $C_t(dW/dT)_0$ approache unity, the apparent Curie constant C become much greater than the 'theoretical' one C This is the case of the alloys with less tha 50% Ni in the solid state. The value o $(dW/dT)_0$, calculated from the experimenta Curie constant $C(=C_s)$ by using Eq. (6), be comes larger with decreasing Ni content.

The value of $(dW/dT)_0$ can be also estimat ed from the change of ferromagnetic Curi point with hydrostatic pressure. It is interest ing to note that the two results are closel similar.

The interaction W is expressed as a func tion of the interatomic distance D which de pends on both temperature T and pressure *i.e.*

$$W = f\{D(p,\,T)\}\,, \qquad \text{(9}$$

The ferromagnetic Curie point, equal to θ i Eq. (8), is given implicitly as a solution o the equation,

$$\theta = C_t f(p,\,\theta)\,. \qquad \text{(10}$$

Therefore,

$$\frac{d\theta}{dp} = \left[\frac{C_t(\partial f/\partial p)_T}{1-C_t(\partial f/\partial T)_p}\right]_{T=\theta}. \qquad \text{(11}$$

From Eq. (9) it is found that

$$\frac{(\partial f/\partial p)_T}{(\partial f/\partial T)_p} = \frac{(\partial D/\partial p)_T}{(\partial D/\partial T)_p} = \frac{-\kappa/3}{\alpha}\,, \qquad \text{(12}$$

where κ is the compressibility and α the linear thermal expansion coefficient. Since $(\partial f/\partial T)_p$ is equal to $(dW/dT)_0$ in Eq. (6), one obtains finally,

$$\frac{d\theta}{dp} = -\frac{\kappa}{3\alpha}\left(\frac{C}{C_t}-1\right). \qquad (13)$$

If the values of κ and α at the Curie point re known, $d\theta/dp$ can be calculated from the experimental Curie constant $C(=C_s)$.

For the 70 Fe–30 Ni alloy, for example, it may be estimated that $\alpha=1.3\times10^{-5}$ (per degree) and $\kappa=0.55\times10^{-6}$ (per atm.), and the value of C_s/C_t is about 1.31 as shown in Fig. 4. Thus $d\theta/dp=-4.4\times10^{-3}$ (degrees/atm.). On the other hand Patrick[12] has shown by a direct measurement that $d\theta/dp=-5.8\times10^{-3}$ degrees/atm.). It may be said that these two values are in good agreement with each other. Patrick has also shown that $d\theta/dp$ decreases with increasing Ni content and becomes nearly zero for the 32 Fe–68 Ni alloy, as can be expected from the present susceptibility data.

These results are consistent with the Bethe-Slater curve. Moreover, the curvature of the Bethe-Slater curve can account for the experimental fact that the $1/\chi$ *vs* T curves for Fe-rich alloys are slightly convex downwards.

It is to be mentioned here that the susceptibility data on Fe-Co and Co-Ni alloys, reported in the previous paper[1], can be also explained by the above assumptions. The atomic moment of Co is assumed to be 2 Bohr magnetons, *i.e.* $S=1$ in Eq. (3). The 'theoretical' Curie constants C_t for these alloys are given by a similar equation to (4). For the Co-Ni alloys both C_l and C_s are not so different from C_t. For the Fe-Co alloys, on the other hand, C_l is not so different from C_t, while C_s is much larger than C_t, just as for the Fe-Ni alloys with less than 50% Ni.

§ 4. Discussions

Although the susceptibilities of these alloys can be consistently explained by using the above-mentioned assumptions, these assumptions may be open to some objections.

(I) The assumption that the susceptibility can be simply treated with Weiss' molecular field theory is questionable in the case of the alloys containing two kinds of transition elements. In order to calculate the susceptibilities of these alloys on the basis of the Heitler-London theory, three kinds of the nearest neighbor interactions between two kinds of atoms should be taken into account. It follows from this that the susceptibilities do not obey the Curie-Weiss law except at very high temperatures. According to Néel[13], the $1/\chi$ *vs* T curve should be a hyperbola, the asymptotic line of which corresponds to the Curie-Weiss law [Eq. (2)], where the Curie constant is given by Eq. (4). It is not so hopeless, however, that a more careful treatment of this statistical problem would prove the applicability of Eq. (2) to the present case.

(II) The second assumption is based on the electronic configuration of the atoms $(3d)^n(4s)^1$, where n is equal to 7 for Fe, 8 for Co and 9 for Ni*. Although the lowest-energy configuration of these atoms in the isolated state is expressed as $(3d)^{n-1}(4s)^2$, the former configuration can be more stable than the latter in the metallic state. According to Pauling[15], there is no large difference in cohesion among various transition metals of Fe-group, and Cu $[(3d)^{10}(4s)^1]$ is much more cohesive than Zn $[(3d)^{10}(4s)^2]$. These facts indicate that the number of $3d$-electrons per atom is not an important factor in cohesion and that the configuration $(4s)^1$ is more stable than the configuration $(4s)^2$.

This conclusion is based on the assumption that the number of $3d$-electrons per atom in the metallic state should be an integer. Although this assumption may be quite natural as far as the Heilter-London theory is adopted, it seems to conflict with the fact that the ferromagnetic saturation moment per atom is not equal to an integral multiple of the Bohr magneton. In the ferromagnetic state, however, the magnetic moment due to the localized $3d$-electrons might be partly compensated by that due to the non-localized $4s$-electrons**.

According to Shull and Wilkinson[17], the neutron diffraction experiments on Fe-Ni alloys in the ferromagnetic state have shown that the difference in atomic moment between Fe and Ni amounts to about 2 Bohr magnetons, being nearly independent of the composition of alloys. This result is consistent with the present theory.

---

* The magnetic resonance experiment by Bagguley and Harrick[14] has proved that the g-factor of Ni is equal to 2.0 in the paramagnetic state, *i.e.* the orbital magnetic moment is completely quenched.

** Zener[16] has considered that the non-localized $4s$-electrons participate in the ferromagnetic saturation moment of a metal. According to his theory, however, the resultant moment due to the $4s$-electrons should be parallel to that due to the $3d$-electrons.

(III) Although it may be valid that the magnetic interaction in a transition metal varies with the interatomic distance as indicated by the Bethe-Slater curve, it is very doubtful whether a 'single' Bethe-Slater curve can be applicable in common to all the transition metals and alloys.

For the Fe-Ni alloys, however, Bozorth[8] has suggested that the magnetic interaction energy, assumed to be proportional to the Curie temperature, may be expressed as a unique function of $R(=D/\delta)$*. Although Bozorth's suggestion is unlikely to be based on any plausible theory, it can well account for various experimental results, *e.g.* the change of ferromagnetic Curie point with hydrostatic pressure, the anomalous thermal expansion near the Curie point, the volume magnetostriction *etc.* The present experiment on the magnetic susceptibility is also explained by Bozorth's interaction curve, as shown in the preceding section. This interaction curve, however, cannot be applied to other metals and alloys. It may be rather fortuitous that Bozorth's suggestion has been helpful in the case of Fe-Ni alloys. In general, different interaction curves for different metals should be looked for, as proposed by Dehlinger[18].

It should be emphasized here that the anomalously large Curie constant of pure γ-Fe (face-centred cubic) can be explained by the present theory as due to the temperature dependence of the magnetic interaction. If this effect were not taken into account, very large atomic moment (6 Bohr magnetons) and very large negative interaction ($\theta=-2500$°K) would be derived from the Curie-Weiss law [Eq. (1)]. According to Wilkinson and Shull[19], however, the neutron diffraction experiment on Fe at high temperatures has shown that there is no remarkable difference in atomic moment between γ-Fe and α-Fe; the atomic momen of α-Fe may be 2 or 3 Bohr magnetons Moreover, such large negative interaction i likely to conflict with the fact that the antiferromagnetism has not been confirmed i γ-Fe*. These contradictions are overcome b the present theory: the anomalously larg Curie constant is solely due to the temperature dependence of the interaction W, an the value of W at 900°C is only slightly negative if it is calculated from Eq. (2) by using the experimental value of χ_M and the theoretical value of C_t.

§ 5. Conclusions

The magnetic susceptibilities of Fe-Ni alloys follow the Curie-Weiss law in the liquid state as well as in the solid state. The Curie constants are approximately equal to the theoretical values calculated from the atomic magnetic moments, 3 Bohr magnetons for Fe and 1 Bohr magneton for Ni, except in the case of pure γ-Fe and Fe-rich alloys in the solid state.

In this case the temperature variation of the magnetic interaction is expected to be large, resulting in the anomalously large value of the apparent Curie constant. This effect can be related quantitatively to the especially sensible change of ferromagnetic Curie points of these alloys with hydrostatic pressure.

Since there is no difference in atomic moment between liquid and solid, the change of susceptibility on melting is only due to the difference in magnetic interaction. The interaction varies with the interatomic distance, as indicated by the Bethe-Slater curve, and the interatomic distance is larger in liquid than in solid.

The alloys with less than 60% Ni, corresponding to the left-hand side of the maximum on the Bethe-Slater curve, show an increase in susceptibility on melting, and the opposite in true for the alloys with more than 60% Ni. Thus the slope of the Bethe-Slater curve can be found out experimentally by using the susceptibility change on melting.

---

* According to Néel[13], the molecular field coefficient W can be expressed as a function of $D-\delta$ for various transition metals and alloys. His interaction curve, however, seems to be inconsistent with the experiment on the change of ferromagnetic Curie point with hydrostatic pressure.

* According to Corliss, Hastings and Weiss [*cf.* reference 20)], a weak antiferromagnetism with low Néel temperature (~80°K) is suggested for pure γ-Fe by extrapolation of the properties of the Fe-Mn system.

The author wishes to express his sincere anks to Professor S. Kaya for his valuable ggestions and encouragement. The author also indebted to Mr. T. Nagashima of lectrotechnical Laboratory for his kindness in pplying the specimens.

Electronic Structure of Simple Homonuclear Diatomic Molecules

I. Oxygen Molecule

By Masao KOTANI, Yukio MIZUNO, Kunihusa KAYAMA
Department of Physics, University of Tokyo, Tokyo
and Eiichi ISHIGURO
Department of Physics, Ochanomizu University, Tokyo

The wave functions of the ground state and several lower excited states of O_2 and O_2^+ are calculated non-empirically at $R=2.3$ a.u. by LCAO MO method, where all sixteen electrons are taken into consideration and Slater type $1s$, $2s$, and $2p$ atomic orbitals are used. For the ground state of O_2, various approximate treatments are investigated. Further, for $^1\Delta_g$, $^1\Sigma_g^+$, $^1\Sigma_u^-$, $^3\Sigma_u^+$, and $^3\Sigma_u^-$ states, improved calculations are performed by mixing several configurations. By using the wave functions thus obtained, dissociation energy D_e, excitation energies ΔE, molecular quadrupole moment Q, magnetic hyperfine structure parameters $\langle\psi^2(0)\rangle$ and $\langle P_2/r^3\rangle$, oscillator strengths f, diamagnetic second order Zeeman term $\chi_{\text{dia.}}$, and polarizabilities $\alpha_{//}$ and $\alpha_\perp$ are calculated and compared with the observed values. The results are found to be improved appreciably by mixing a small number of configurations. Finally, several of the wave functions of the O_2 ground state are analyzed by the population analysis method developed by Mulliken.

§ 1. Introduction

Since the classical work of Heitler-London-Sugiura on the hydrogen molecule, mechanism of chemical binding and the electronic structure of molecules in general have been understood in principle. Useful concepts in molecular quantum theory, such as electron pair bond, hydridization, valence states of atoms in molecules, were introduced in early days, and have been extensively employed in theoretical interpretation of molecular electronic structure. However, on account of the mathematical difficulty of quantum mechanics of many electron systems, the early developments were of more or less semi-empirical nature except in the case of the hydrogen molecule, and very often in the formulation of the theory some drastic approximations had to be introduced, which were not easy to justify; particularly the neglect of non-orthogonality of orbitals localized on two adjacent atoms, which was made commonly in the generalization of Heitler-London method to more complex molecules, has been criticized by Slater and others.

Under these circumstances, rigorous, non-empirical treatment of molecules with more than two electrons seems to be highly desirable. The possibility of calculating quantum-mechanically properties of molecules with a fairly large number of electrons within manageable amount of labour has been shown by the recent developments of molecular orbital theory; success of MO SCF calculations of CO_2, H_2O, N_2 etc., extensive studies of configuration interaction by Parr, Craig and Ross, members of Slater's laboratory in M.I.T.1), and others have encouraged us to undertake purely non-empirical, detailed study of simple molecules of the first row atoms and their hydrides. We chose Li_2 and O_2 as objects of our first study; the reason of this choice is as follows: Li_2 is the simplest molecule having 2-quantum σ bond, which may have characteristics quite different from those of $1s$ bond in H_2, while O_2 is particularly rich in spectroscopic and other data, including microwave data on magnetic hyperfine structure of $O^{17}O^{16}$. In the first and second papers of this series, the results of our study of O_2 and Li_2 will be reported, and the third paper will contain summarizing discussions on these and similar diatomic molecules.

The calculation which is described in this series of papers is based on the so-called MOCI method. Taking all electrons into account, we calculate energies of the ground and lower excited states, on different choice of configurations, and comparing the results, discuss the relative merits of various approximation procedures. Further we evaluate various physical quantities such as electronic quadrupole moment, electric polarizability, transition probability, constants in microwave hfs spectra, etc., with different wave functions.

As is well-known, wave functions in Heitler London approach can be covered by MOC procedure, as long as in the former method the same atomic orbitals are used irrespectively of the degree of ionization of atom concerned, and in this way we shall be abl to discuss, among others, the relative superiority between Heitler-London and molecula orbital methods.

Very interesting results, particularly on excitation energies, have recently been obtained by Moffitt2), Mulliken3), Ohno-Itoh4) and others on the assumption that atoms will preserve their properties of their different states even in molecules. In orbital approximation this requires the use of different atomic orbitals according as the amount of charge which happens to be located on the atom concerned. This sort of refinement of Heitler-London method is not covered by our MOCI procedure. However, their methods are either semi-empirical, or involve approximations, which make the exact estimate of their effect more or less difficult.

To develop the theory on unambiguous basis, it seemed to us inevitable to carry out MOCI calculation, taking, at least, important configurations constructed out of $1s$, $2s$, and $2p$ AO's. We hope that, even for those interested in such refined approaches of HL type as mentioned above, our results will provide reliable data useful for their study.

MOCI study of the oxygen molecule has already been made by Meckler5). Meckler used Gaussian type atomic orbitals, while we employ Slater type ones, as building blocks of molecular orbitals. Further he did not consider the configurations in which $2s$ core electrons are excited. We shall show that $2s$ excitation is by no means negligible.

§ 2. Construction of Molecular Orbitals

The two oxygen nuclei will be denoted by A and B and the AO's of atoms A and B are denoted by χ_a and χ_b respectively. Since the electronic configuration of the ground state of an oxygen atom is $(1s)^2(2s)^2(2p)^4$, we confined ourselves to $1s$, $2s$, and $2p$ type AO's. Further, we adopted for these AO's the normalized Slater-type AO's, namely,

$$
\left.\begin{aligned}
&1s_a(1)=(\delta_1{}^3/\pi)^{1/2}\exp(-\delta_1 r_{a1})\ ,\\
&2s_a(1)=(\delta_2{}^5/3\pi)^{1/2}\, r_{a1}\exp(-\delta_2 r_{a1})\ ,\\
&\left.\begin{matrix}2p\sigma_a(1)\\ 2p\pi_a{}^+(1)\\ 2p\pi_a{}^-(1)\end{matrix}\right\}=(\delta_2{}^5/\pi)^{1/2} r_{a1}\exp(-\delta_2 r_{a1})\left\{\begin{matrix}\cos\theta_{a1}\\ \sin\theta_{a1}\exp(+i\varphi_1)\\ \sin\theta_{a1}\exp(-i\varphi_1)\ .\end{matrix}\right.
\end{aligned}\right\}\qquad(1)
$$

$_b$(1)'s are defined in a similar way. Here $_{a1}$, r_{b1}, θ_{a1}, θ_{b1}, and φ_1 have meanings as hown in Fig. 1, and δ_1 and δ_2 are the orbital xponents. For the orbitals 2*s*, 2*pσ*, and 2*pπ* ne same value of the orbital exponent, δ_2, is ssumed. Throughout this paper, unless othervise noticed, we shall use the atomic units,

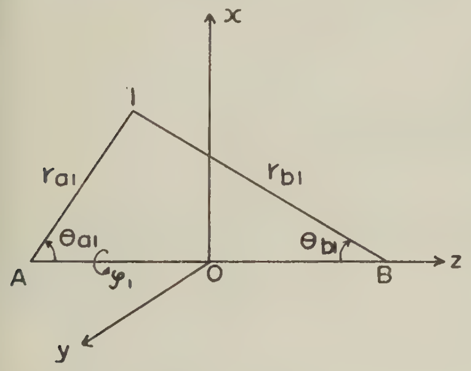

Fig. 1. Diagram of notation of coordinates.

(energy: 27.206 e.v., length: 0.5292Å). The equilibrium internuclear distance *R* of the O_2 molecule in its ground state $^3\Sigma_g{}^-$ is 2.282 a.u., and according to Slater's rule δ_1 and δ_2 are equal to 7.70 and 2.275 respectively. But the molecular integrals involving Slater-type AO's (1) are expressed in terms of $\alpha=\delta_1 R$, $\beta=\delta_2 R$, and *R*. Hence, for convenience of numerical work, we have chosen the following values, $\alpha=17.75$, $\beta=5.25$, and $R=2.30$ a.u. The corresponding values of δ_1 and δ_2 are 7.717 and 2.283 respectively.

From the AO's (1) we set up the unnormalized symmetry orbitals

$$
\left.\begin{aligned}
(\sigma 1s)_{g,u}&=1s_a\pm 1s_b\ ,\\
(\sigma 2s)_{g,u}&=2s_a\pm 2s_b\ ,\\
(\sigma 2p)_{g,u}&=2p\sigma_a\pm 2p\sigma_b\ ,\\
(\pi^\pm 2p)_{g,u}&=2p\pi_a{}^\pm\mp 2p\pi_b{}^\pm\ .
\end{aligned}\right\}\qquad(2)
$$

Orthogonalized molecular orbitals (OMO's) can be constructed as linear combinations of these symmetry orbitals in various ways; OMO's most commonly used are those of the following form, which we shall call "Schmidt-orthogonalized molecular orbitals*" (abbreviated as Schmidt-OMO's)

$$
\left.\begin{aligned}
\sigma_{1g}&=\alpha_{11}(\sigma 1s)_g\ ,\\
\sigma_{2g}&=\alpha_{21}(\sigma 1s)_g+\alpha_{22}(\sigma 2s)_g\ ,\\
\sigma_{3g}&=\alpha_{31}(\sigma 1s)_g+\alpha_{32}(\sigma 2s)_g+\alpha_{33}(\sigma 2p)_g\ ,\\
\pi_g{}^\pm&=\gamma_g(\pi^\pm 2p)_g\ ,\\
\sigma_{1u}&=\beta_{11}(\sigma 1s)_u\ ,\\
\sigma_{2u}&=\beta_{21}(\sigma 1s)_u+\beta_{22}(\sigma 2s)_u\ ,\\
\sigma_{3u}&=\beta_{31}(\sigma 1s)_u+\beta_{32}(\sigma 2s)_u+\beta_{33}(\sigma 2p)_u\ ,\\
\pi_u{}^\pm&=\gamma_u(\pi^\pm 2p)_u\ .
\end{aligned}\right\}\qquad(3)
$$

In the above equations, the coefficients α_{ij}, β_{ij}, γ_g, and γ_u are determined by the conditions of orthonormality and are given in Table I.

Table I. Values of coefficients α, β, and γ in OMO[a)].

α_{11}	0.70710 59	β_{11}	0.70710 76
α_{21}	−0.16451 50	β_{21}	−0.18141 32
α_{22}	0.64420 46	β_{22}	0.85443 12
α_{31}	0.01656 28	β_{31}	−0.05226 28
α_{32}	−0.15659 10	β_{32}	0.40917 14
α_{33}	0.63726 88	β_{33}	0.94154 01
γ_g	0.76305 78	γ_u	0.66189 67

a) See Eq. (3).

The evaluation of the molecular integrals involving the AO's (1) is laborious, but the method of integration and the numerical values of them are already published and need not be repeated here.[6),7)] Then the molecular integrals concerning the unnormalized symmetry orbitals are evaluated easily. Finally we have calculated from these the integrals involving Schmidt-OMO's. These values have been published in another paper[12)].

§ 3. Methods of Calculation

The number of electrons contained in the O_2 molecule is sixteen, and the Hamiltonian of our problem is

---

* Such procedure of orthonormalization as employed in (3) is known as Schmidt method among mathematicians. See, for example, R. Courant und D. Hilbert: Methoden der Mathematischen Physik I, p. 34.

$$H=-\frac{1}{2}\sum_{i=1}^{16}\Delta_i-\sum_{i=1}^{16}\left(\frac{8}{r_{ai}}+\frac{8}{r_{bi}}\right)+\sum_{i>j}^{16}\frac{1}{r_{ij}}+\frac{64}{R}\,. \tag{4}$$

Since this Hamiltonian has $D_{\infty h}$ symmetry, its eigenfunctions are bases of an irreducible representation of $D_{\infty h}$ group and may be classified by the quantum numbers Λ, I, and v, specifying the component of the orbital angular momentum of the electrons along the internuclear axis, the character of the inversion at the center, and the character of the reflection at any plane passing through both nuclei (for the case of $\Lambda=0$), respectively. A set of these quantum numbers Λ, I, and v is abbreviated as Ω. Moreover, as the Hamiltonian (4) is free from spin operators, the total spin quantum number S and its component along a fixed axis M are good quantum numbers. Accordingly the eigenfunctions of (4) have the symmetry character specified by (Ω, S, and M). We impose this property also on the approximate solutions of (4) which are composed of Schmidt-OMO's.

As is usually accepted, we suppose that the orbital energies of Schmidt-OMO's increase in the order of σ_{1g}, σ_{1u}, σ_{2g}, σ_{2u}, σ_{3g}, $\pi_u{}^{\pm}$, $\pi_g{}^{\pm}$, and σ_{3u}, so we assume that the wave functions of the normal state and of lower excited states of the O_2 molecule are composed mainly of configurations which contain two electrons in each of σ_{1g}, σ_{1u}, σ_{2g}, σ_{2u}, and σ_{3g} orbitals and no electron in σ_{3u} orbital. Within these limitations it is sufficient to consider only six electrons accomodated in $\pi_u{}^{\pm}$ and $\pi_g{}^{\pm}$ orbitals, and the molecular states compatible with this assumption are shown in Table II.

Table II. Electronic states arising from $(\sigma_{1g})^2(\sigma_{1u})^2(\sigma_{2g})^2(\sigma_{2u})^2(\sigma_{3g})^2[\pi]^6$ [a].

a) Electron configurations are shown by specifying the unoccupied orbitals.

In Table II, electron configurations a shown by their electron holes and the state with the parenthesis are those not observe experimentally. In this paper we shall con sider those nine states shown in Table I which are the same as those considered b Fumi-Parr[8] and Itoh-Ohno[4].

We shall explain briefly the method of con structing a complete set of orthonormaliz wave functions, which have a symmetr character specified by (Λ, I, (v), S, M) an are convenient both for calculations and fo their physical understanding, from ten kin of Schmidt-OMO's given by (3)[6].

In the first place, we pick up from these ten Schmidt-OMO's all the sets of sixteen orbitals, whose products have the given sym metry (Λ, I), considering that each orbita can only accomodate at most two electrons Then we make a product function of these sixteen orbitals for each set, in which sixteen orbitals are arranged in the order to be explained later. Then by multiplying these products by various spin functions with the symmetry (S, M) and by antisymmetrizing these results, we can obtain the required wave functions with the given symmetry (Λ, I, S, M) for $\Lambda\neq0$. When $\Lambda=0$, we can easily find the required wave functions with the given symmetry (Λ, I, v, S, M) by taking the real parts (for Σ^+) or the imaginary parts (for Σ^-) of the product functions of sixteen orbitals and then performing the same procedure as for the case of $\Lambda\neq0$. In this paper the spin-free functions having the orbital symmetry Ω correctly, such as the ones mentioned above, are called "primitive functions," in the sense that they can give wave functions with the complete symmetry character only after being multiplied by the spin functions and then antisymmetrized. Generally, many primitive functions exist for a given Ω. Then they are denoted by A, B, C, $\cdots$, and the normalized forms of them are written as $\Psi_\Omega^{\rm A}$, $\Psi_\Omega^{\rm B}$, $\Psi_\Omega^{\rm C}$ $\cdots$, respectively.

Secondly we shall consider spin functions. The number of spin functions that correspond to given values of S and M is independent of M and amounts to

$$f_S{}^N=\frac{(2S+1)\cdot N!}{(N/2+S+1)!\,(N/2-S)!}\,,$$

where N is the total number of electrons. These spin functions are denoted by $\Theta_{S,M;k}$

$=1, 2, \cdots, f_S{}^N$). Let P be any permutation mong $N!$ permutations of N electrons, then $\Theta_{S,M;k}$ is expressed linearly in terms of ^{N} functions $\Theta_{S,M;k}$:

$$\mathrm{P}\Theta_{S,M;k}=\sum_{h=1}^{f_S^N}\mathrm{V}^S_{hk}(\mathrm{P})\Theta_{S,M;h}\ , \tag{5}$$

here $\mathrm{V}^S(\mathrm{P})$ is called the representation maix of the permutation group $\mathfrak{S}_N$. Further e put

$$\mathrm{U}^S(\mathrm{P})=\varepsilon_{\mathrm{P}}\mathrm{V}^S(\mathrm{P}^{-1})^{\dagger}\ , \tag{6}$$

here † means the transposition of matrix and $_{\mathrm{P}}=(-1)^{\mathrm{P}}$. Then we have antisymmetric ave functions specified by letters A, k, Ω, , and M of the following form

$$\Phi^{\mathrm{A},k}_{\Omega,S,M}=\frac{1}{(N!)^{1/2}}\sum_{\mathrm{P}}\sum_{h}\overline{U}^S_{hk}(\mathrm{P})\mathrm{P}\Psi^{\mathrm{A}}_{\Omega}\cdot\Theta_{S,M;h}\ . \tag{7}$$

Now, we consider the case of the O_2 molecule. As we must assign sixteen electrons to ten Schmidt-OMO's, each of which can accomodate at most two electrons, the number of orbitals which contain only one electron is at most four. These orbitals are called unpaired ones. The orbitals appearing in the primitive function $\Psi^{\mathrm{A}}_{\Omega}$ are divided into paired orbitals and a few (two or four) unpaired ones. In writing $\Psi^{\mathrm{A}}_{\Omega}$, we put the unpaired orbitals first and then the paired ones. For example

$$\begin{aligned}\Psi^{\mathrm{F}}_{\Sigma_g^-}=\frac{1}{\sqrt{2}}\{&\pi_g{}^+(1)\pi_u{}^-(2)\sigma_{3g}(3)\sigma_{3u}(4)\pi_g{}^-(5)\pi_g{}^-(6)\pi_u{}^+(7)\pi_u{}^+(8)\\&-\pi_g{}^-(1)\pi_u{}^+(2)\sigma_{3g}(3)\sigma_{3u}(4)\pi_g{}^+(5)\pi_g{}^+(6)\pi_u{}^-(7)\pi_u{}^-(8)\}\\&\times\sigma_{2u}(9)\sigma_{2u}(10)\sigma_{2g}(11)\sigma_{2g}(12)\sigma_{1u}(13)\sigma_{1u}(14)\sigma_{1g}(15)\sigma_{1g}(16)\ .\end{aligned} \tag{8}$$

Generally, if we assume that r paired orbitals are present in $\Psi^{\mathrm{A}}_{\Omega}$, it is invariant with respect o the interchange between electrons in each pair. The number of such permutations is 2^r nd they are expressed as

$$\mathrm{Q}=(N-2r+1, N-2r+2)^{\lambda_1}(N-2r+3, N-2r+4)^{\lambda_2}\cdots(N-1, N)^{\lambda_r}\qquad(\lambda_i=0\text{ or }1)\ . \tag{9}$$

f we select $s=\frac{N!}{2^r}$ permutations $\mathrm{P}_0, \mathrm{P}_1, \cdots, \mathrm{P}_{s-1}$ out of $N!$ permutations of N electrons, n such a way that each of all $N!$ elements can be expressed uniquely in the form $\mathrm{P}_u\mathrm{Q}$ ($u=0, 1, \cdots, s-1$), we have, in general, s mutually independent functions $\mathrm{P}_u\Psi^{\mathrm{A}}_{\Omega}$ among $!$ $\mathrm{P}\Psi^{\mathrm{A}}_{\Omega}$.

On the other hand, since 2^r elements Q are ll commutable and $\mathrm{Q}^2=1$, we can transform (Q) to the following form

$$V_{kh}(\mathrm{Q})=0\qquad(k\neq h)\ ,$$
$$V_{hh}(\mathrm{Q})=\pm1\ .$$

In this case we can assign the suffix k so that if $k\leqq g$, $V_{kk}(\mathrm{Q})=-1$ for every Q and if $k>g$, $V_{kk}(\mathrm{Q})=+1$ for at least one Q. Then it is proved that $\Phi^{\mathrm{A},k}_{\Omega,S,M}$'s for $k\leqq g$ are linearly independent, and those for $k>g$ vanish identically. The spin functions of these first g numbers must be of the form

$$\begin{aligned}\Theta_{S,M;h}&(1, 2, \cdots, N)\\&=\Theta_{S,M;h}(1, 2, \cdots, N-2r)\\&\quad\times\frac{1}{2^{1/2}}\{\alpha(N-2r+1)\beta(N-2r+2)\\&\qquad-\beta(N-2r+1)\alpha(N-2r+2)\}\\&\quad\cdots\cdots\\&\quad\times\frac{1}{2^{1/2}}\{\alpha(N-1)\beta(N)-\beta(N-1)\alpha(N)\}\\&\qquad\qquad(1\leqq h\leqq g)\ .\end{aligned} \tag{10}$$

able III. Adopted forms of spin functions Θ_h(1, 2, 3, 4)[a].

or $S=1$, $M=1$

$$\Theta_1=\frac{1}{\sqrt{2}}\alpha(1)\alpha(2)\{\alpha(3)\beta(4)-\beta(3)\alpha(4)\}$$

$$\Theta_2=\frac{1}{\sqrt{2}}\{\alpha(1)\beta(2)-\beta(1)\alpha(2)\}\alpha(3)\alpha(4)$$

$$\begin{aligned}\Theta_3=\frac{1}{2}\{&\alpha(1)\beta(2)\alpha(3)\alpha(4)+\beta(1)\alpha(2)\alpha(3)\alpha(4)\\&-\alpha(1)\alpha(2)\alpha(3)\beta(4)-\alpha(1)\alpha(2)\beta(3)\alpha(4)\}\end{aligned}$$

r $S=0$, $M=0$

$$\Theta_1=\frac{1}{2}\{\alpha(1)\beta(2)-\beta(1)\alpha(2)\}\{\alpha(3)\beta(4)-\beta(3)\alpha(4)\}$$

$$\begin{aligned}\Theta_2=\frac{1}{\sqrt{3}}[&\alpha(1)\alpha(2)\beta(3)\beta(4)+\beta(1)\beta(2)\alpha(3)\alpha(4)\\&-\frac{1}{2}\{\alpha(1)\beta(2)+\beta(1)\alpha(2)\}\{\alpha(3)\beta(4)+\beta(3)\alpha(4)\}]\end{aligned}$$

a) See Eq. (10).

Here $\Theta_{S,M;k}$ $(1, 2, \cdots, N-2r)$'s are the spin functions of $(N-2r)$ electrons, and their explicit forms adopted in this paper are given in Table III. Then we can construct g antisymmetrized wave functions $\Phi^{A,k}_{\Omega,S,M}$ with quantum numbers Ω, S, and M from the primitive function Ψ^{A}_{Ω}. The explicit form of these functions is

$$\Phi^{A,k}_{\Omega,S,M}(1, 2, \cdots, N) = \frac{1}{(N!\,2^r)^{1/2}} \sum_{\mathrm{P}} \sum_{h} \overline{U}^{S}_{hk}(\mathrm{P})\mathrm{P}\Psi^{A}_{\Omega}\Theta_{S,M;h} \quad (1 \leqq k \leqq g) . \tag{11}$$

The factor in (11) appears on account of normalization. In general we have many primitive functions $\Psi^{A}_{\Omega}, \Psi^{B}_{\Omega}, \cdots$, for each of which the functions of the form (11) can be constructed. The best wave function in our approximation is therefore a suitable linear combination of them, namely

$$\Phi_{\Omega,S,M}(1, 2, \cdots, N) = \sum_{A,k} c_{A,k}\Phi^{A,k}_{\Omega,S,M}(1, 2, \cdots, N) . \tag{12}$$

As is well known, the coefficients $c_{A,k}$ of (12) and the total energy E are determined from the following linear algebraic equations

$$\sum_{B,k} \{H_{(A,k),(B,h)} - E\Delta_{(A,k)(B,h)}\}c_{B,h} = 0 , \tag{13}$$

where $H_{(A,k),(B,h)}$ and $\Delta_{(A,k),(B,h)}$ are the matrix elements of the Hamiltonian (4) and the unity, respectively, referring to the functions (11). The evaluation of these matrix elements is performed according to the following formulae

$$H_{(A,k),(B,h)} = \sum_{\mathrm{P}_u} U_{hk}(\mathrm{P}_u)\int \mathrm{P}_u\Psi^{A*}_{\Omega}H\Psi^{B}_{\Omega}dv \tag{14}$$

$$\Delta_{(A,k),(B,h)} = \sum_{\mathrm{P}_u} U_{hk}(\mathrm{P}_u)\int \mathrm{P}_u\Psi^{A*}_{\Omega}\Psi^{B}_{\Omega}dv . \tag{15}$$

In the above equations $U_{hk}(\mathrm{P}_u)$ can be obtained according to the rules explained in KAIK⁶⁾.

As the primitive functions $\Psi^{A}_{\Omega}, \Psi^{B}_{\Omega}, \cdots$ are constructed simply from Schmidt-OMO's, the integrals in (14) and (15) can be reduced easily and are expressed in terms of one or two electron integrals involving Schmidt-OMO's. We notice here that this reduction can not be done so easily without the help of orthogonality of orbitals.

§ 4. Calculation of the Energy of the Ground State ${}^3\Sigma_g^-$

As can be shown by actual examination, we can construct thirty wave functions (11) havi ${}^3\Sigma_g^-$ symmetry from Schmidt-OMO's (3) a the spin functions given in Table III. T wave functions are denoted by A_1, B_1, $\cdots$ E_1, E_2, $\cdots$ and so on, where suffices 1, 2, · refer to the choice of spin functions Table III. Each of these functions correspon to a "configuration." In case for a giv primitive function the wave functions (1 with suffices other than 1 vanish, we om the suffix 1, for example, we write simply A instead A_1. Among thirty configuratio seventeen are shown explicitly in Table I where the product functions, contained the primitive functions Ψ^{A}, Ψ^{B}, $\cdots$ with pos tive coefficients are specified by the numbe and the orders of electrons accomodated i each Schmidt-OMO written on the first lin The whole primitive function can be co structed from this product function easily symmetry considerations. Configuration corresponds to the usual antisymmetrize orthogonalized-molecular-orbital wave functio (ASOMO) built from linear combinations atomic orbitals (LCAO). In nine configuration from A to F_3 in Table IV, Schmidt-OMO σ_{1g}, σ_{1u}, σ_{2g}, and σ_{2u} are fully occupied b eight electrons, while in the remaining twenty one configurations it is not the case.

Now, a lot of proposals have been put fo ward hitherto on the procedure of calculatin non-empirically the electronic ground state a molecule and we actually applied several these methods to the O_2 molecule. To explai our calculations it is convenient to divide the into sixteen cases.

Case 1. A (*single configuration*)

The total energy for single configuratio A, calculated by the formula (A.1), is foun to be -149.00734 a.u.

Case 2. A+C (π *electron configuratio* *interaction*

In the π electron theory, π electrons a considered to be loosely bound to the m lecular framework and play an importa role to the electronic structure of the groun state and lower excited states. In fact, almo all the calculations hitherto made on the molecule except perhaps Meckler's one⁵⁾, a based on the π electron theory. Since th π electron theory is widely accepted in i simplicity and usefulness, we have studie the configurational interaction within this a able IV. Configurations used in CI calculation and their coefficients in normalized wave function for ground state ${}^3\Sigma_g^-$.

	Configurations[a)]										Coefficients c_i [b)]

a) The product function contained with the positive coefficient in the primitive function of each configurational wave function is shown by specifying the numbers of electrons occupying each orbital. Further in this product function, it is assumed that the i-th unpaired orbital ($i=1, 2, \cdots, 2r$), if numbered from left to right, accomodates the i-th electron, and the j-th paired orbital ($j=1, 2, \cdots, 8-r$) accomodates the $(2j+2r-1)$th and the $(2j+2r)$th electrons.

b) See Eq. (12).

roximation. Then the configurations which iust be considered are only A and C. The ormalized wave function determined by the rinciple of minimun energy is

$$0.9629\mathrm{A}-0.2698\mathrm{C}\,, \tag{16}$$

nd the corresponding total energy is lower ian that of Case 1 by 1.403 e.v.

'ase 3. A+J_1 (*s-p hybridization*)

Contrary to Case 2, we consider in Case 3 ie configurations, whose primitive functions iffer from that of A only in the σ orbital art. B, H, J_i, $\cdots$ belong to such configu- itions. Since, however, the orbital energy f σ_{3u} is far above those of σ_{3g}, σ_{2u}, and σ_{2g}, ie contribution of B, H, $\cdots$ except J_i may e considered small. Among J_i's, it is shown y actual examination that the contribution f J_1 is most important. The wave function otained by taking into account only J_1 be- des A is

$$0.9704\mathrm{A}-0.2414\mathrm{J}_1\,, \tag{17}$$

id the total energy is lower than that of Case 1 by 2.1687 e.v. Since in J_1, σ_{2u} and σ_{3u} are coupled to a singlet, the mixing of J_1 may be taken in some sense as the *s-p* hybridization in the molecular orbital scheme, and is outside the scope of Meckler's approximation (cf. Case 8).

Case 4. $(u)^2$ *approximation*

In spite of the much higher orbital energy of σ_{3u} than σ_{2u}, the contribution of J_1 turns out to be so large that we are not always permitted to neglect J_1. While, we are allowed to use some other OMO's instead of Schmidt-OMO's (3) as the building block of our primitive functions. Then configuration A, if composed of suitable OMO's, may be accepted to give in general a better result than Case 1, and the corresponding best OMO's are nothing but the Roothaan's self-consistent field molecular orbitals (SCFMO)[9)]. Now the result does not depend upon the form of σ_g orbitals as they are fully occupied in A, while it depends of course upon the form of σ_u orbitals we employed. Here we shall limit ourselves to the case where 1*s* AO's are fully occupied, and the form of σ_{1u} orbital is fixed to Schmidt-OMO (3). Then among the OMO's included in A, only the form of σ_{2u} orbital is left undetermined. The best σ_{2u} orbital, determined by the principle of minimum energy with σ_{1u} held fixed to Schmidt-OMO (3), will be called here *u* orbital. The variational calculation shows that the form of *u* is

$$u=0.9855\sigma_{2u}-0.1698\sigma_{3u}\ , \qquad (18)$$

where σ_{2u} and σ_{3u} are Schmidt-OMO's defined by (3), and the total energy obtained is lower than that of Case 1 by 2.108 e.v. The wave function here obtained can be expressed in terms of the configurations in Table IV as follows

$$0.9712\mathrm{A}-0.2367\mathrm{J}_1+0.0288\mathrm{H}\ . \qquad (19)$$

By comparing this result with that of Case 3, we can confirm that the contribution of configuration J_1 can be much reduced, if we adopt a suitable *u* orbital instead of σ_{2u}.

Case 5. A+J$_1$+H (*u′u″ approximation*)

In Case 4, paired electrons are assigned to the same molecular orbital *u*, but we can generalize this treatment by introducing two different orbitals *u′* and *u″*. This generalization has in some sense a nature of the so-called in-out effect, although it must be mentioned that the same values of the orbital exponents δ_1 and δ_2 are taken for *u′* and *u″*. After the variation, we found

$$\left.\begin{aligned} u'&=0.9426\sigma_{2u}-0.3339\sigma_{3u}\ ,\\ u''&=1.0000\sigma_{2u}+0.0027\sigma_{3u}\ ,\end{aligned}\right\} \qquad (20)$$

and the corresponding total energy is lower than that of Case 1 by 2.1689 e.v. *u′* and *u″* can be shown to represent the outer and inner orbitals respectively. The wave functions here obtained can be written down also in terms of the configurations in Table IV as follows

$$0.9705\mathrm{A}-0.2412\mathrm{J}_1-0.0009\mathrm{H}\ . \qquad (21)$$

Case 6. *The* LCAO SCF *method*

As the O$_2$ molecule does not have a closed shell configuration of electrons, we have carried out a LCAO SCF calculation by modifying slightly Roothaan's method[9]. We have assumed the wave function as

$$\begin{aligned}\frac{1}{(16!)}&\sum_P(-1)^P\mathrm{P}(1\pi_g{}^+)(1\pi_g{}^-)(1\pi_u{}^+)^2(1\pi_u{}^-)^2\\ &\times(3\sigma_g)^2(2\sigma_u)^2(2\sigma_g)^2(1\sigma_u)^2(1\sigma_g)^2\\ &\times\alpha(1)\alpha(2)\alpha(3)\beta(4)\cdots\alpha(15)\beta(16)\ , \qquad (22)\end{aligned}$$

where $\alpha(i)$ and $\beta(i)$ are the spin functions electron *i* corresponding to the spin parall and antiparallel to a fixed direction, respe tively. Further we assumed that $1\sigma_g$, $1\sigma_u$, · are the molecular orbitals whose symmetri are σ_g, σ_u, ··· respectively, and can be e pressed in terms of Schmidt-OMO's (3) as

$$\left.\begin{aligned} 1\sigma_g&=c_{11}\sigma_{1g}+c_{12}\sigma_{2g}+c_{13}\sigma_{3g}\ ,\\ &\cdots\cdots\\ 1\sigma_u&=c_{41}\sigma_{1u}+c_{42}\sigma_{2u}+c_{43}\sigma_{3u}\ ,\end{aligned}\right\} \qquad (2$$

and so on. By the help of Eq. (A.1) and t principle of minimum energy, we can set the equations, by which the coefficients in (2 are determined. Adopting Roothaan's no tions, we can write the quations as

$$\left.\begin{aligned} &\{h+\sum_k(2J_k-K_k)+\tfrac{1}{2}\sum_a(2J_a-K_a)\}\varphi_j\\ &\qquad\qquad-\mathcal{E}_j\varphi_j=0\ ,\\ &\{h+\sum_k(2J_k-K_k)+(J_b-K_b)\}\varphi_a\\ &\qquad\qquad-\mathcal{E}_a\varphi_a=0\ .\end{aligned}\right\} \qquad (2$$

In the above equations, φ_k's denote the ful occupied orbitals in (22) and φ_a's are $1\pi_g{}^+$ ar $1\pi_g{}^-$. φ_k's and φ_a's are often abbreviate simply as *k*'s and *a*'s respectively. *h*, J and K$_k$ are the one electron, Coulomb, an exchange operators respectively. $\mathcal{E}_j$ and $\mathcal{E}_a$ a the orbital energies. Inserting (23) into (24 we can obtain the equations involving coe ficients c_{ij}. These can be determined follov ing Roothaann's self-consistent method. Th values of orbital energies $\mathcal{E}_j$'s, and the coe ficients c_{ij}'s are shown in Table V. Tot energies thus obtained is lower than in Case by 2.167 e.v.

The wave function for Case 5 is superio to that for Case 4 in so far as the former more flexible than the latter on account adopting different *u* orbitals and the wav function for Case 6 is superior to that for Cas 4 in so far as it takes into account the co figurations in which 1*s* electrons do not for a closed shell. The amount of the improve ment in the total energy is 0.061 e.v. for th former and 0.059 e.v. for the latter.

Case 7. A+F$_1$ (*σ-π interaction*)

In the *π* electron approximation, on whic our calculation till now has been based, th primitive functions can be written, even configurational mixing is taken into conside ation, in the form of the product of a *π* pa and a *σ* part, and so the correlation betwee able V. Expansion coefficients[a] of SCF MO's of ground state $^3\Sigma_g^-$ with respect to Schmidt-OMO's[b] and unnormalized symmetry orbitals[c], and orbital energies (R=2.3 a.u.).

SCF MO	Schmidt-OMO[a]				Unnormalized symmetry orbital[c]				Orbital energy (in a. u.)
	$\sigma_{1g,u}$	$\sigma_{2g,u}$	$\sigma_{3g,u}$	$\pi^{\pm}_{g,u}$	$(\sigma 1s)_{g,u}$	$(\sigma 2\bar{s})^{d)}_{g,u}$	$(\sigma 2p)_{g,u}$	$(\pi^{\pm}2p)_{g,u}$

a) See Eq. (23).
b) See Eq. (3).
c) See Eq. (2).
d) See Eq. (30).

electrons and π electrons, usually called the -π interaction, is not taken into account.

We have attempted here to improve this oint by mixing to A configuration F_1, which s derived from A by replacing one σ_{3g} by σ_{3u} nd one $\pi_u{}^{\pm}$ by $\pi_g{}^{\pm}$. The wave function obained by the variational method is

$$0.9739A+0.2269F_1\,, \tag{25}$$

nd the corresponding total energy is lower han that of Case 1 by 2.339 e.v.

ase 8. *p electron configurational interaction (Meckler's case)*

In this case, we considered the nine configuations from A to F_3 in Table IV, which are quivalent as a whole to those considered by leckler[5] in studying the O_2 molecule. If 1*s* nd 2*s* AO's can be considered fully occupied ctually, a wave function derived by the varition from a linear combination of these nine onfigurations will be a good approximation. he wave function obtained is shown in Table V, where the coefficients (cf. Eq. (12)) in our vave function are listed in column 3, and for omparison the coefficients obtained by interolating Meckler's ones to R=2.3 a.u. are iven in column 4. It is interesting to notice hat the coefficients here obtained agree well vith the corresponding Meckler's ones, though his seems rather fortuitous as the latter were alculated with the use of the AO's of Gausian type. The depression of the total energy rom Case 1 is 3.424 e.v. in our calculation, ompared with 2.29 e.v. in Meckler's one.

Case 9. Five dimensional configurational interaction

Judging from the coefficients of Case 8 in Table IV, we can expect that configurations A, F_1, C, and B contribute dominantly to the result. Further from the result of Case 3 we know that configuration J_1 is also very important. Thus it is likely that a rather simple but comparatively good wave function can be constructed from configurations A, B, C, F_1, and J_1. Here we examined this approximation. The resulting wave function after the variational calculation turned out to be

$$0.9526A-0.0774B-0.1541C \\ +0.1481F_1-0.2023J_1\,, \tag{26}$$

and the corresponding total energy is lower than that of Case 1 by 4.781 e.v.

Case 10. Fifteen dimensional configurational interaction

In order to obtain the best wave function within our framework, we must take into account all the thirty configurations. As this requires, however, a considerably laborious work, we selected only those fifteen configurations which have non-vanishing matrix elements between the main configuration A and themselves. From the standpoint of the second order perturbation theory, this selection seems to be reasonable. The configurations given in Table IV, except D and E_1, correspond to these fifteen ones. The wave function obtained by the variational calculation is given in Table IV. The corresponding total energy is lower than that in Case 1 by 5.000 e.v. The difference between the total energies of Case 9 and Case 10 is 0.219 e.v., whereas the number of configurations involved is only five for the former in contrast with fifteen for the latter.

Case 11. *Pure* HL *approximation*

The wave function for the Heitler-London (HL) approximation can be obtained by the following primitive function

$$\left.\begin{aligned}&\Psi=(\text{normalization constant})\times\{\Psi_{a,b}+\Psi_{b,a}\}\ ,\\&\Psi_{a,b}=\{\pi_a{}^+\pi_b{}^-(\pi_a{}^-)^2(\pi_b{}^+)^2-\pi_a{}^-\pi_b{}^+(\pi_a{}^+)^2(\pi_b{}^-)^2\}\\&\qquad\times\sigma_a\sigma_b(2s_a)^2(2s_b)^2(1s_a)^2(1s_b)^2\ .\end{aligned}\right\}\tag{27}$$

This wave function is shown to be expressed with the configurations of Table IV as

$$0.7265\text{A}-0.3328\text{B}-0.5466\text{C}+0.2504\text{D}\ .\tag{28}$$

By using this relation we have calculated the energy and this is found to be 4.160 e.v. higher than that in Case 1. Thus, unexpectedly, in the case of the O_2 molecule ground state, the straightforward application of the HL method proves to be not superior to that of the MO method. In part III of this series we shall explain the reason for this result.

Case 12. σ-HL, π-MO *approximation*

We have found that the pure HL method is a much poorer approximation compared with the pure MO method mentioned in Case 1. So we here examined an intermediate approximation shown by the following primitive function,

$$\left.\begin{aligned}&\Psi=(\text{normalization constant})\\&\times\{(\Psi_{a,b}+\Psi_{b,a})-\text{complex conjugate}\}\ .\\&\Psi_{a,b}=\pi_g{}^+\pi_g{}^-(\pi_u{}^+)^2(\pi_u{}^-)^2\\&\qquad\times\sigma_a\sigma_b(2\overset{\circ}{s}_a)^2(2\overset{\circ}{s}_b)^2(1s_a)^2(1s_b)^2\ .\end{aligned}\right\}\tag{29}$$

In the above, $2\overset{\circ}{s}_a$ is the orthonormalized $2s$ function of the following form

$$2\overset{\circ}{s}_a(1)=c_1 1s_a(1)+c_2 2s_a(1)\ ,\tag{30}$$

where c_1 and c_2 are the constants to be determined by the conditions of orthogonality of $2\overset{\circ}{s}_a$ and $1s_a$ and of normalization. In our case c_1 and c_2 are $-0.24051\ 76$ and $1.02851\ 77$, respectively. In Eq. (29), atomic orbitals are used for $1s$, $2\overset{\circ}{s}$, and $2p\sigma$, but for $2p\pi$, molecular orbitals are used. Accordingly we may call this treatment σ-HL, π-MO approximation. The total energy obtained turns out to be still 3.033 e.v. higher than that of Case 1. The wave function in this case is expresse in terms of the configurations of Table IV a

$$\Phi_{\sigma\text{-HL},\pi\text{-MO}}=0.9091\text{A}-0.4165\text{B}\ .\qquad(3$$

Case 13. π-HL, σ-MO *approximation*

Contrary to the previous case, we shall trea here the σ electrons by the MO scheme an the π electrons by the HL scheme. Then ou primitive function is

$$\begin{aligned}&\Psi=(\text{normalization constant})\times\{\Psi_{a,b}+\Psi_{b,a}\},\\&\Psi_{a,b}=\{\pi_a{}^+\pi_b{}^-(\pi_a{}^-)^2(\pi_b{}^+)^2-\pi_a{}^-\pi_b{}^+(\pi_a{}^+)^2(\pi_b{}^-)^2\}\\&\qquad\times(\sigma_{3g})^2(\sigma_{2u})^2(\sigma_{2g})^2(\sigma_{1u})^2(\sigma_{1g})^2\ .\end{aligned}\qquad(3$$

The energy value obtained by (32) is highe than that of Case 1 by 1.141 e.v. The wav function obtained can be written as

$$\Phi_{\pi\text{-HL},\sigma\text{-MO}}=0.7991\text{A}-0.6012\text{C}\ .\qquad(3$$

Summarizing the results of Cases 11, 12 and 13, we can conclude that (i) the MO method is superior to the HL method for th σ electrons as well as for the π electrons, an (ii) the MO method is more appropriate fo the σ electrons than for the π electrons.

Case 14. σ (*s-p hybridized*)-HL, π-MO *ap proximation*

We here attempted to improve Case 12 b taking into consideration the *s-p* hybridization that is, by using the primitive function

$$\begin{aligned}&\Psi=(\text{normalization constant})\\&\times\{(\Psi_{a,b}+\Psi_{b,a})-\text{complex conjugate}\},\\&\Psi_{a,b}=\pi_g{}^+\pi_g{}^-(\pi_u{}^+)^2(\pi_u{}^-)^2(\sigma_a+\lambda 2\overset{\circ}{s}_a)\\&\times(\sigma_b+\lambda 2\overset{\circ}{s}_b)(2\overset{\circ}{s}_a-\lambda\sigma_a)^2(2\overset{\circ}{s}_b-\lambda\sigma_b)^2(1s_a)^2(1s_b)^2,\end{aligned}\qquad(34$$

where λ is the variational parameter showin the degree of *s-p* hybridization. The tota energy obtained is still higher than that o Case 1 by 0.061 e.v., and the correspondin value of λ is found to be 0.2557. The improvement due to this second order hybridization is 2.972 e.v. (cf. Cases 3, 4, and 6) The wave function here obtained is expresse in terms of configurations in Table IV as follows,

$$\begin{aligned}&0.9095\text{A}-0.2991\text{B}+0.0377\text{H}\\&\qquad-0.2619\text{J}_1-0.0214\text{L}+0.1133\text{O}_1\ .\end{aligned}\qquad(35$$

If the degree of *s-p* hybridization is define by $\lambda^2/(1+\lambda^2)$, it can be estimated from the above value of λ as 6.1%.

Case 15. σ-SO, π-MO *approximation*

In general, a better approximation than the

O method as well as than the HL method n be obtained by the semilocalized orbital ethod (SO). We here applied this method the σ electrons, by replacing the σ_a and e σ_b orbitals in (29) by the orbitals of the rm

$$\sigma_a^{sl}=\sigma_a+\mu\sigma_b\ , \qquad \sigma_b^{sl}=\sigma_b+\mu\sigma_a\ , \tag{36}$$

the above μ represents the degree of semicalization and is obtained by the variational inciple. The energy depression from Case was found to be 0.881 e.v., and the value μ to be 0.2912. The wave function thus tained is decomposed into the configurations Table IV as follows:

$$\Phi_{\sigma\text{-SO},\pi\text{-MO}}=0.9906\mathrm{A}-0.1367\mathrm{B}\ . \tag{37}$$

Further the ionic character of the σ-bond can be seen by reexpressing wave function (37) as

$$\Phi_{\sigma\text{-SO},\ \pi\text{-MO}}$$
$$=(1/d_\sigma)(\Phi_{\sigma\text{-HL},\ \pi\text{-MO}}+c_\sigma\Phi_{\sigma\text{-ion},\ \pi\text{-MO}})\ ,$$

where $\Phi_{\sigma\text{-ion},\ \pi\text{-MO}}$ is the normalized wave function having σ-ionic, π-MO character, and we have found $d_\sigma=1.4105$ and $c_\sigma=0.5369$.

Finally, it is worth while to notice that the π-SO, σ-MO method is identical with Case 2, and Eq. (16) can be constructed from the following primitive function

$$\Psi=(\text{normalization constant})\times\{\Psi_{a,b}+\Psi_{b,a}\}\ ,$$
$$\Psi_{a,b}=\{(\pi_a{}^{+}+\nu\pi_b{}^{+})(\pi_b{}^{-}+\nu\pi_a{}^{-})(\pi_a{}^{-}-\nu\pi_b{}^{-})^2(\pi_b{}^{+}-\nu\pi_a{}^{+})^2$$
$$-(\pi_a{}^{-}+\nu\pi_b{}^{-})(\pi_b{}^{+}+\nu\pi_a{}^{+})(\pi_a{}^{+}-\nu\pi_b{}^{+})^2(\pi_b{}^{-}-\nu\pi_a{}^{-})^2\}(\sigma_{3g})^2(\sigma_{2u})^2(\sigma_{2g})^2(\sigma_{1u})^2(\sigma_{1g})^2\ , \tag{38}$$

ith $\nu=0.2420$.

Further the ionic character of the π-bond can be seen by reexpressing wave function (16) btained in Case 2 as

$$\Phi_{\sigma\text{-MO},\ \pi\text{-SO}}=(1/d_\pi)(\Phi_{\sigma\text{-MO},\ \pi\text{-HL}}+c_\pi\Phi_{\sigma\text{-MO},\ \pi\text{-ion}})\ ,$$

here $\Phi_{\sigma\text{-MO},\ \pi\text{-ion}}$ is the normalized wave inction having σ-MO, π-ionic character, and e have found $d_\pi=1.2093$ and $c_\pi=0.4573$.

ase 16 A′(*assuming* $S(2s, 2p\sigma)=S(2s, 1s)=0$)

Here we have calculated the energy using e wave function obtained by replacing σ_{3g} y the normalized symmetry orbital $(\sigma 2p)_g$ in onfiguration A and assuming the overlap tegrals, of $2p\sigma$ with $1s$ and $2s$ to be zero. his treatment is similar to that assumed by reenhow and Smith[10] in calculating the Q alues of the O_2 molecule and to that by Rosen d Ikehara[11] in treating the Li_2 molecule. he total energy obtained is -149.3898 a.u., d this is lower than that of Case 1 by .406 e.v.

The energies obtained by the various appromations are illustrated in Fig. 2. Matrix ements of Hamiltonian for the configurations nsidered in this section will be published sewhere[12].

5. Calculation of the Energies of the Excited States

As shown in Table II, we have eight excited ates by distributing six electrons into four MO's. The primitive function of the most

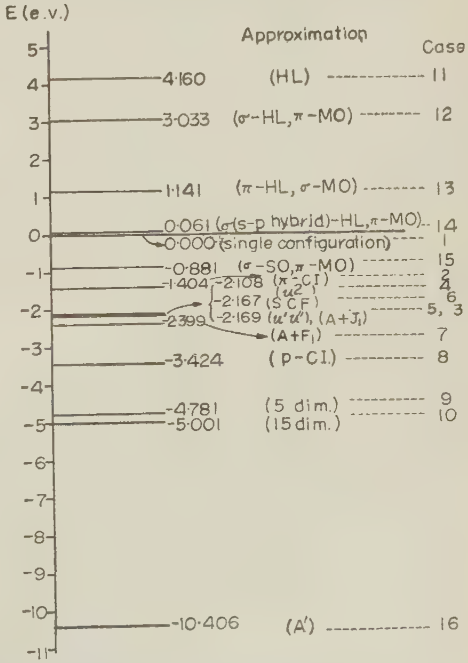

Fig. 2. Comparison of energy values of ground state.

important configuration for each excited state can be written down from Table II as

$$\begin{array}{lll}
{}^1\Delta_g & (\pi_g{}^+)^2(\pi_u{}^+)^2(\pi_u{}^-)^2 & \times(\sigma_{3g})^2(\sigma_{2u})^2(\sigma_{2g})^2(\sigma_{1u})^2(\sigma_{1g})^2 \\
{}^1\Sigma_g{}^+ & \frac{1}{2}\{\pi_g{}^+\pi_g{}^-(\pi_u{}^+)^2(\pi_u{}^-)^2 & \\
 & \quad +\text{complex conjugate}\} & \cdots \\
{}^1\Sigma_u{}^- & \frac{1}{\sqrt{2}}\{\pi_g{}^+\pi_u{}^-(\pi_g{}^-)^2(\pi_u{}^+)^2 & \\
 & \quad -\text{complex conjugate}\} & \cdots \\
{}^3\Delta_u & \pi_g{}^+\pi_u{}^+(\pi_g{}^-)^2(\pi_u{}^-)^2 & \cdots \\
\left.\begin{array}{l}{}^3\Sigma_u{}^+\\ {}^3\Sigma_u{}^-\end{array}\right\} & \frac{1}{\sqrt{2}}[\pi_g{}^+\pi_u{}^-(\pi_g{}^-)^2(\pi_u{}^+)^2 & \\
 & \quad \pm\text{complex conjugate}\} & \cdots \\
{}^1\Delta_u & \pi_g{}^+\pi_u{}^+(\pi_g{}^-)^2(\pi_u{}^-)^2 & \cdots \\
{}^1\Sigma_u{}^+ & \frac{1}{\sqrt{2}}\{\pi_g{}^+\pi_u{}^-(\pi_u{}^+)^2(\pi_g{}^-)^2 & \\
 & \quad +\text{complex conjugate}\} & \cdots\,.
\end{array} \qquad (39$$

For the $O_2{}^+$ molecular ion, the ground state, ${}^2\Pi_g$, and the three lower excited states, ${}^4\Pi_u$, ${}^2\Pi_u$, and ${}^4\Sigma_g{}^-$, are found by the spectroscopic measurements. For these states, the primitiv functions of the main configurations may be the following

$$\begin{array}{lll}
{}^2\Pi_g & \pi_g{}^+(\pi_u{}^-)^2(\pi_u{}^+)^2(\sigma_{3g})^2 & \times(\sigma_{2u})^2(\sigma_{2g})^2(\sigma_{1u})^2(\sigma_{1g})^2 \\
\left.\begin{array}{l}{}^4\Pi_u\\ {}^2\Pi_u\end{array}\right\} & \pi_g{}^+\pi_g{}^-\pi_u{}^-(\pi_u{}^+)^2(\sigma_{3g})^2 & \cdots \\
{}^4\Sigma_g{}^- & 1/2\{\pi_g{}^+\pi_g{}^-\sigma_{3g}(\pi_u{}^+)^2(\pi_u{}^-)^2 & \\
 & \quad -\text{complex conjugate}\} & \cdots
\end{array} \qquad (40$$

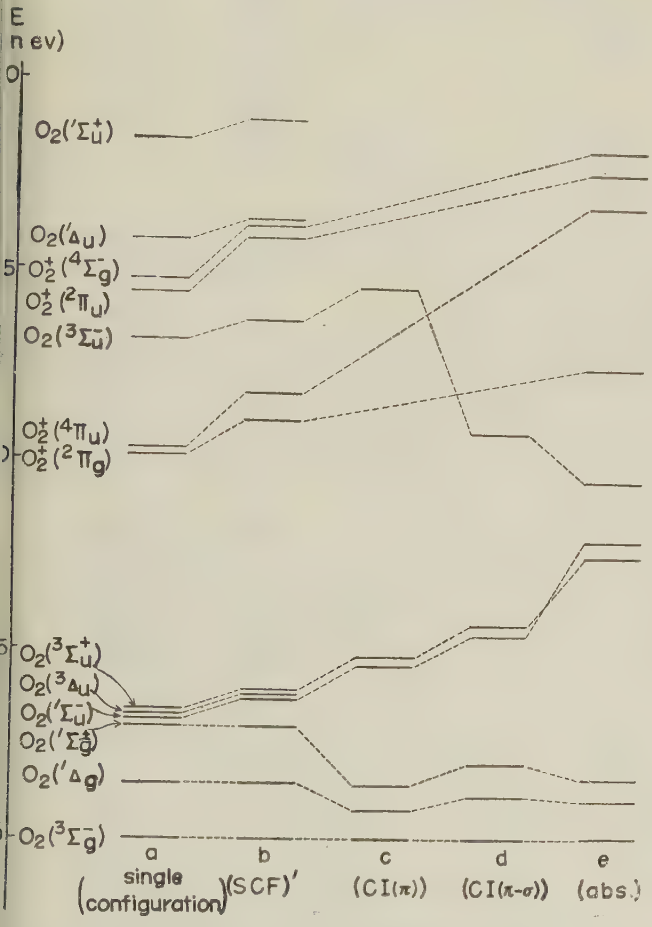
or each primitive function (39) or (40), we n determine the spin function Θ $(1, 2, \cdots,$ $-2r)$ uniquely, except the case of $^2\Pi_u(O_2^+)$. the latter case, we have adopted, as the in function of the main configuration, the ne in which the spins of two electrons in $_g^-$, and π_u^- couple to a triplet, because this nction is simple and its contribution to the est one was found to amount even to 99.96 %. This fact can be expected from the beginning, if we notice that the exchange integral volving π_g^- and π_u^- is considerably large mpared with the other exchange integrals volving π orbitals.



ig. 3. Comparison of energy levels calculated by various approximations with experiment.

Then we can construct the wave function om (39) and (40). Since these functions rrespond to that considered in Case 1 of the evious section, we shall denote them by A d give the formulae of H_{AA}'s in Appendix . 1). The values of H_{AA}'s are calculated at the fixed internuclear distance 2.30 a. u., using the same orbital exponents as used in the previous section. Numerical values of H_{AA} relative to the H_{AA} of the ground state of the O_2 molecule are given in column 2 in Table VI and also in Fig. 3a.

If, in the above calculation, we use SCF MO's obtained for the ground state instead of Schmidt-OMO's, we shall have a different approximation for the excited and ionized states. These calculations were actually performed and the results are shown in the column indicated by (SCF)′ in Table VI, and Fig. 3b.

As to the five excited states $^3\Sigma_u^-$, $^3\Sigma_u^+$, $^1\Sigma_u^-$, $^1\Sigma_g^+$, and $^1\Delta_g$ of the O_2 molecule, the spectroscopic data are available and various methods have hitherto been examined of calculating the respective excitation energies. Since these calculations assumed usually the π electron approximation, we also have, for the sake of comparison, carried out a similar calculation to Case 2 of the previous section for each state. The results are shown in the column indicated by CI(π) in Tables VI–X. In Tables VII–X, the coefficients of the linear combination and the total energy, relative to that of configuration A, for each state are given. In Table VI and in Fig. 3c. the excitation energies obtained by this π electron approximation are given.

Finally for the above five excited states we have performed the calculations which, as Case 9 for the ground state, are simple but may probably give the total energies in quite satisfactory agreement with fuller calculations. Configurations which are expected to play an important role can be easily selected from the experience in the previous section and are listed in column 1 in Tables VII–X. The rough meaning of the approximations of considering each configuration besides configuration A can be understood by seeing the last columns of the same tables. The matrix elements of the Hamiltonian operator for these configurations are to be published elsewhere[12].

c) and d) See the caption in Table VII. For this state, $E_0 = -148.8909$ a.u.

The coefficients of configurations and the total energy relative to that of configuration A, obtained for each state, are given in the column indicated by CI (π-σ) in the same tables. The excitation energies are also listed in the column indicated by CI (π-σ) in Table VI, and in Fig. 3d. The observed values of the excitation energies are written in column 6 in Table VI, and in Fig. 3e. They have been derived by fitting the spectroscopic data to Morse curves. We notice here that the real potential curves cannot be reproduced very closely by the Morse curves, so that some ambiguity is left for these experimental values.

6. Molecular Quantities

The wave functions obtained by the above alculations will serve to calculate the physial quantities of the O_2 molecule. Further by omparing these results with the experiments, e can study the validity, usefulness, and eatures of our approximations. Among the onstants of the O_2 molecule, we have conidered here the dissociation energy D_e, moleular quadrupole moment Q, magnetic yperfine structure parameters, $\langle\psi^2(0)\rangle$ and $P_2/r^3\rangle$, oscillator strengths f_{lk}, and diamagnec second order Zeeman term χ_{dia}16). Also r the polarizability α we have tried a rough stimation. The necessary matrix elements, eferring to the configurational wave functions efined earlier, can be calculated easily and eir numerical values are given elsewhere12).

1) *Dissociation Energy D_e*

In principle, the dissociation energy D_e can e obtained by

$$D_e=E(R_\infty)-E(R_e)\ , \tag{41}$$

here $E(R_\infty)$ is the energy of a pair of nonteracting atoms in the ground state, and (R_e) is the total energy of the molecule at e equiliblium internuclear distance. In aplying (41), we must remark that very accurate alues of $E(R_\infty)$ and $E(R_e)$ are required, since ese quantities are of comparable magnitude d both are very large compared with D_e. However, the calculated value of $E(R_e)$ has usually an error much larger than the magnitude of D_e. Therefore, to obtain a reasonable value of D_e, it is inevitably necessary to find a suitable value of $E(R_\infty)$ that is calculated in the same degree of approximation as $E(R_e)$.

Now we shall here adopt for $E(R_e)$, the values calculated at $R=2.30$ a.u. by using the various approximations in Section 4, though the observed equilibrium internuclear distance is slightly smaller than 2.3 a.u. Then it seems appropriate, for our purpose, to use the value of $E(R_\infty)$ calculated by the same atomic orbitals (1) as were used for the calculation of $E(R_e)$. The values of D_e obtained in such a manner are listed in Table XI. D_e obtained by our best wave function (Case 10) is 3.629 e.v. compared with the observed value of 5.08 e.v. Further Table XI shows that all the calculated values of D_e, exept that of Case 16, do not exceed the observed value. This means that the approximation for the calculation of $E(R_\infty)$ is, in our case, better than that of $E(R_e)$. In the exceptional Case 16, D_e calculated is very large compared with the observed one, since in this case the exchange repulsion between the valence electrons and the closed shell electrons is neglected.

(2) *Molecular Quadrupole Moment of the O_2 Molecule Q*

Though the O_2 molecule is non-polar, it can possess the quadrupole moment

$$\begin{aligned} Q&=\int r^2(3\cos^2\theta-1)\rho dv \\ &=8R^2-2\langle z^2\rangle+\langle x^2+y^2\rangle\ , \\ \rho&=\rho_n+\rho_{el}\ . \end{aligned} \tag{42}$$

Here ρ_n and ρ_{el} are the charge densities of the nuclei and the electrons respectively, r is the distance to the charge from the center of the molecule, θ is the angle between the symmetry axis and r, and the meaning of x, y, and z is explained in Fig. 1. Further, $\langle z^2\rangle=\int z^2\rho_{el}dv$ and $\langle x^2+y^2\rangle=\int(x^2+y^2)\rho_{el}\,dv$. We shall here study this quantity.

In Table XI, the values $\langle x^2+y^2\rangle/R^2$, $\langle z^2\rangle/R^2$, and Q obtained with the use of the various approximations explained earlier are given. From this table we can see that the values of Q calculated, except the one of Case (16), can be classified into two groups, namely, one group consisting of values around 0.1 and the other one around −1.5, and that the latter values are obtained only by the use of the wave functions taking into account s-p hydridization. Table XI shows, moreover, that the value of $\langle x^2+y^2\rangle/R^2$ does not vary appreciably from one approximation to another. So the said difference of the values of Q is chiefly ascribed to that of $\langle z^2\rangle/R^2$. This difference of $\langle z^2\rangle/R^2$ can be easily understood on the valence bond theory as follows. As two O atoms approach each other, two $2p\sigma$ electrons suffer a positive hybridization but four $2s$ ones suffer correspondingly a negative hybridization, and so the net charge density in the outer region becomes larger than that obtained without s-p hybridization.

Next we shall consider the value of Q in Case 16, which is much the largest of all. From Table XI, we can see that this situation comes mainly from the fact that $\langle z^2\rangle/R^2$ is by far the smallest of all. This implies that the charge density of the symmetry orbital $(\sigma 2p)_g$ is inside of that of Schmidt-OMO σ_{3g}. Greenhow and Smith[10] have also performed a similar calculation by neglecting $1s$ electrons, and have obtained $Q=3.1103$ a.u. for the case of no s-p hydridization and this value agrees well with our result. On this occasion, we shall point out a strange property of Schmidt-OMO. By comparing the Q value of Case 12 or Case 15 with that of Case 1, it can be found that the former are larger than that of the latter. This means that the charge density of the σ_{3u} orbital is larger than that of σ_{3g} in the region between two nuclei.

Now the value of Q obtained by our best wave function (Case 10) is −1.533. On the her hand the observed value is reported by ownes and Schawlow,17), and Gordy, Smith, nd Trambarulo18) as $|Q|<0.82$ a.u. Accord- ngly the agreement of the theory with the bservation seems not to be so satisfactory. his does not, however, necessarily lead to the onclusion that our calculation should be criti- ized. As a matter of fact, the observed value bove quoted is open to some questions, be- ause this value has been derived from the ne width measurement of the microwave pectrum, which is accompanied with the dif- culty of the experimental technique and of he analysis of the measurement. Therefore, nore refined observations and their analysis re desirable.

3) *Magnetic Hyperfine Structure Parameters* $\langle P_2/r^3\rangle$ *and* $\langle\psi^2(0)\rangle$

From the microwave absorption measure- nents on $O^{16}O^{17}$ gas, Miller and Townes19) letermined the values of the following quan- ities

$$\left\langle\frac{P_2}{r^3}\right\rangle=\int\left(\frac{3\cos^2\theta_a-1}{2r_a{}^3}\sigma\right)\rho(\boldsymbol{r}_a,\sigma)d\tau\ , \tag{43}$$

nd

$$\langle\psi^2(0)\rangle=\int\{\delta(\boldsymbol{r}_a)\sigma\}\rho(\boldsymbol{r}_a,\sigma)\,d\tau\ , \tag{44}$$

vhere $\boldsymbol{r}_a$ is the position vector with its origin aken at the nucleus A, θ_a is the angle bet- veen $\boldsymbol{r}_a$ and the symmetry axis, and σ is the pin variable. Further $\rho(\boldsymbol{r}_a,\sigma)$ is the total umber density of electrons at $(\boldsymbol{r}_a,\sigma)$ which is ummarized as τ. In this subsection these uantities will be investigated.

As can be seen from (43) and (44), only the npaired orbitals contribute to the values of $P_2/r^3\rangle$ and $\langle\psi^2(0)\rangle$. Moreover, π electrons o not contribute to $\langle\psi^2(0)\rangle$. Therefore $\langle\psi^2(0)\rangle$ anishes in the simple valence bond theory or he single configuration of MO (Case 1) and as a finite value only after introducing con- gurations which have unpaired σ-orbitals. 'hus $\langle\psi^2(0)\rangle$ depends on a very "fine-struc- ure" of the electronic wave function and rovides an important clue for the study of he configurational mixing.

In the paper succeeding to that of Miller nd Townes, they and one of us, Kotani20), ave already estimated the value of $\langle P_2/r^3\rangle$ rom the standpoint of the simple valence bond heory. They considered that the experimental value of this quantity could be explained approximately by taking into account the contribution from the unpaired electron, which is accomodated in a π AO of the nucleus considered˙ Then it was shown that

$$\left\langle\frac{P_2}{r^3}\right\rangle=-\frac{1}{5}\int\pi_a{}^*(1)\frac{1}{r_a{}^3}\pi_a(1)dv$$
$$=-\frac{1}{5}\left\langle\frac{1}{r^3}\right\rangle_{av}, \tag{45}$$

and it amounts to 71 and 78 percent of the observed value by the use of the Hartree-Fock atomic orbital21) and Yamanouchi-Horie's data22) based on the atomic fine structure analysis, respectively. If we now use the Slater-type π orbital employed in our paper instead of the Hartree's one, we have 60 percent of the observed value. According to Miller, Townes, and Kotani20), the agreement with the experiment may be improved by a few percent, if the overlapping of atomic orbitals is taken into account.

Kleiner23) also calculated $\langle P_2/r^3\rangle$ and $\langle\psi^2(0)\rangle$ by the use of Meckler's wave function5). He found that the calculated value of $\langle P_2/r^3\rangle$ is almost determined by configuration A of Table IV, which, however, afforded only 27 percent of the observed value. Kleiner showed, however, that if the Hartree-Fock AO's were adopted instead of the Gaussian-type AO's in calculating the integral $\int\pi_a{}^*\frac{1}{r_a{}^3}\pi_a dv$, this result could be improved to 85–90 percent of the observed value. The inclusion of the remaining eight configurations did not alter the matter seriously and rather made the agreement worse. The value of $\langle\psi^2(0)\rangle$ found by Kleiner using Meckler's wave function was too small to explain the experiment. If the Hartree-Fock AO's were used instead of the Gaussian-type orbitals, the result was improved appreciably, but still accounted only for at most one percent of the observed value ($\langle\psi^2(0)\rangle<0.001$).

Since the previous calculations are only a rough estimation or based on the Gaussian-type AO's we have tried to study these quantities again with the use of the wave functions described in Section 4. The results of calculations are summarized in Table XI.

The differences between the values of $\langle P_2/r^3\rangle$ calculated by various approximations are rather small and indeed most of the contribution to this quantity comes from configuration A. More precisely speaking, the values of $\langle P_2/r^3\rangle$, in Cases, 1, 3, 4, 5, 6, 12, 14, 15, and 16, come solely from unpaired $\pi_g{}^+$ and $\pi_g{}^-$ electrons and coincide with one another. This situation does not change appreciably for the other cases, in which the mixing of the configurations with the unpaired orbitals different from those of configuration A is taken into account. The value of $\langle P_2/r^3\rangle$ obtained is about 65 percent of the observed one and the difference from 60 percent estimated by the single atom approximation (45) is due to the overlapping of orbitals. If we assume that the overlapping effect can be taken into account by multiplying the factor 65/60 to the results of the single atom approximation, Miller, Townes, and Kotani's values are improved to 77 and 85 percent from 71 and 78 percent, respectively. These values are a little smaller than that estimated by Kleiner. The remaining discrepancy of about 15% might be expected to result from contraction of π orbitals in a molecule due to the molecular formation. Then it requires the change of the orbital exponent δ_2 from 2.283 to 2.410, and it seems difficult energetically to explain the change of δ_2 of this magnitude. We might well expect another possiblity of eliminating this discrepancy on the fact that the ground state of O_2 is half-ionic in character and the orbitals in the positive ion O^+ will probably contract compared with those in neutral atom O, even if embedded in the molecule. A rough estimation of this effect shows that the discrepancy can be reduced to 5%.

The situation is quite different for the case of $\langle\psi^2(0)\rangle$. We can see in Table XI that $\langle\psi^2(0)\rangle=0$ except Cases 8 and 10. This is because there is no unpaired σ orbital in all the configurations except F_2, F_3, J_3, M_2, and M_3 of Table IV. The value obtained by the p electron configurational wave function (Case 8) which includes only F_2 and F_3 among the above five configurations, is far smaller than that observed and agrees in its order of magnitude with the Kleiner's estimation. On the other hand the fifteen configurational wave function (Case 10) gives a quite satisfactory result. In Table XII, the contributions of each configuration and of their cross terms are shown. From this table we can see that the cross terms with the main configuration A give an important contribution. A similar fact found also by Abragam, Horowitz, and Price in connection with a similar problem concer ing a paramagnetic ion. Further we can s that the contribution of configurations F_2 ar F_3 is small compared with that of J_3 and M in spite of the fact that the coefficients them in the fifteen configurational wave fun tion are almost comparable. However this ca be explained as follows. Since the values the nodeless Slater-type $2s$ and $2p$ orbita vanish at the nucleus, the values of Schmid OMO's at the nucleus are mainly due to th $1s$ orbital involved in them. Then from th coefficients of Schmidt-OMO's (3), we can ex pect that $|\sigma_{2u}(0)|$ and $|\sigma_{2g}(0)|$ are much large than $|\sigma_{3g}(0)|$ and $|\sigma_{3u}(0)|$. Since, however, un paired σ orbitals considered are σ_{3g} and σ_{3u} i F_2 and F_3, while they are σ_{2u} and σ_{3u} in J and σ_{2g} and σ_{3u} in M_3, the above situation i what should be so. Thus we can see that fo $\langle\psi^2(0)\rangle$, the configurations not so importan for the energy, make remarkable contributions Hence a satisfactory agreement of our resul with the observed value seems a little for tuitous.

Table XII. Numerical details of calculation o $\langle\psi^2(0)\rangle$ (values of $c_i{}^2\langle\psi^2(0)\rangle_{ii}$ and $2c_ic_j\langle\psi^2(0)\rangle$ $(i>j)$).[a]

a) c_i's are the expansion coefficients given i Table IV.

b) From reference (21).

In this respect it is interesting to calculat

$\psi^2(0)\rangle$ by using some other suitable AO's an the Slater's ones. We adopt here the artree-Fock (H-F) AO's[21] which are likely to ve a more reliable result of $\langle\psi^2(0)\rangle$ than the ater's ones. It is difficult, however, to construct the wave function built from the H-F AO's including the CI, by carring out a variational calculation. Accordingly a simplified calculation is attempted here. Namely, the expressions for $\langle\psi^2(0)\rangle$ associated with the p

Fig. 4. Comparison of normalized Slater type radial functions $R(2\mathring{s})$ and $R(2p\pi)$ used in this paper with the corresponding Hartree-Fock functions. A: $R(2\mathring{s})$ of Hartree-Fock, B: $R(2\mathring{s})$ of Slater, C: $R(2p)$ of Hartree-Fock, D: $R(2p)$ of Slater. r is measured in a.u.

lectron configurational and fifteen configu- ational wave functions are at first written ı terms of the values of the orthogonalized later's AO's, 1s, 2$\mathring{s}$, and 2$p\sigma$ at the nucleus onsidered, which are then replaced by those of he corresponding H-F AO's. This procedure may be justified, provided that coefficients of the configurational wave functions and the values of the overlapping integrals between the AO's do not change appreciably for the case of the H-F AO's from the case of the Slater's AO's. The values of $\langle\psi^2(0)\rangle$ calculated by the method just explained are 0.0022 and 0.1732 for the p electron configurational and fifteen configurational wave functions, respectively, while the corresponding values obtained previously are 0.0025 and 0.1948. The reason for this good agreement of the values obtained by the different methods is that the values of the Slater's $2\mathring{s}$ AO and the H-F $2s$ AO are not so different even in the neighbourhood of the nucleus. This situation can be seen from Fig. 4, where the radial parts of the H-F and Slater's AO's are shown. The contribution to the value of $\langle\psi^2(0)\rangle$ of each configuration and their cross parts is shown in Table XII.

(4) *Oscillator Strengths f_{lk}*

The oscillator strength f_{lk} with respect to the transition from a state k to an energetically higher level l is expressed, in atomic units, as

$$f_{lk}=2/3\cdot|(\sum_i \boldsymbol{r}_i)_{lk}|^2(\Delta E)_{lk}\ , \qquad (46)$$

where $(\Delta E)_{lk}=E_k-E_l$. Eq. (46) can also b expressed as

$$f_{lk}=2/3\cdot|(\sum_i \nabla_i)_{lk}|^2/(\Delta E)_{lk}\ . \qquad (47)$$

Accordingly, in calculating f_{lk} we may use an of these equations. When approximate wave functions are used these two equations give in general, different results. The method o calculation by (46) is called the dipole length method and that by (47) is called the dipol velocity method.

Concerning the nine states of O_2 considere in this paper, neither x nor y components o the dipole length and velocity introduce an transition, but their z components give rise to the transitions ${}^3\Sigma_g{}^- - {}^3\Sigma_u{}^-, {}^1\Delta_g - {}^1\Delta_u$, an ${}^1\Sigma_g{}^+ - {}^1\Sigma_u{}^+$, all of which correspond to th one electron jump $\pi_u{}^\pm - \pi_g{}^\pm$. We have calculated the f-values concerning these transition by using four kinds of approximations, single configuration, (SCF)′, CI(π), and CI($\pi-\sigma$), explained in the calculation of the excitation energies. These values are listed in Table XIII. Column 4 shows the values of $(\Delta E)_{lk}$, found by the calculation of the previous section. $1/R\langle z\rangle_{lk}$ and $R\langle d/dz\rangle_{lk}$ are given in columns 5 and 6. f_{lk} obtained by the dipole length method (46) and the dipole velocity method (47) are shown in the next two columns In the last column of Table XIII are shown the values of $\langle\Delta E\rangle_{lk}$ which have been obtained

om the following formula

$$\langle \Delta E\rangle_{lk}=\left|\left(\sum_i \nabla_i\right)_{lk}/r_{lk}\right|\ . \tag{48}$$

rom this table, we can see that the configu- tional interaction reduces the values of $\langle z\rangle$ nd the corresponding f_{lk}, and that for the tter quantity this reduction is very remark- ble. The observed value of f_{lk} for ${}^3\Sigma_g^-$ -${}^3\Sigma_u^-$ (Schuman-Runge bands) was reported s 0.19[25] and this agrees well with that cal- ulated by the use of the dipole length method nd CI(π-σ). It is known that the similar tuation occurs in the ${}^1A_{1g}-{}^1E_{1u}$ transition of e C_6H_6[26] molecule and the ${}^1A_{1g}-{}^1B_u$ transi- on of the C_4H_6[27] molecule. Concerning the ipole velocity method, we mention here that, ough we obtained f values of reasonable agnitude by the single configuration, (SCF)′, nd CI(π), CI(π-σ) makes the result, unfortu- ately, very wrong. The effect of the con- gurational interaction to ΔE obtained by (48) also not so satisfactory. Further we can e that f-values from the dipole length ethod are much larger than those from the elocity method. The studies on other mole- ules by several authors[1b)28)], however, show at this is not always the case.

) *Diamagnetic Second Order Zeeman Term* $\chi_{\rm dia}$

The temperature independent part of the usceptibility is given as the sum of two rms, the paramagnetic high-frequency term $_{\rm H\text{-}F}$ and the diagmagnetic second order eeman term $\chi_{\rm dia}$. Tinkham and Strandberg[16] stimated the value of $\chi_{\rm H\text{-}F}$ with the use of e data on the rotational magnetic moment f the the O_2 molecule and obtained (24.6 ± 1.7) $\times10^{-6}$ cm³/mol for it. $\chi_{\rm dia}$, on the other hand, given by the following formula

$$\chi_{\rm dia}=-0.7922\times\langle r^2\rangle\times10^{-6}\ {\rm cm^3/mol}\ , \tag{49}$$

here $\langle r^2\rangle$ is measured in atomic units.

With the use of Meckler's wave function[5] nd (49), Tinkham and Strandberg obtained -29.5×10^{-6} cm³/mol as the value of $\chi_{\rm dia}$, so e temperature independent part of the usceptibility estimated by them becomes $-4.9\pm1.7)\times10^{-6}$ cm³/mol.

Now we have calculated $\chi_{\rm dia}$ by using the arious approximate wave functions considered Section 4 and the results are given in Table I. $\chi_{\rm dia}$ calculated by our fifteen configura- onal wave function together with $\chi_{\rm H\text{-}F}$ estimated by Tinkham and Strandberg, yields the temperature independent part of the susceptibility of -7.3×10^{-6} cm³/mol. This value is of the same order as that of Tinkham and Strandberg, and seems to support their interpretation that the departure of the observed total susceptibility from Curie's law, found by Woltjer, Coppoolse, and Wiersma[29], would be due to the experimental error.

(6) *Polarizabilities $\alpha_{//}$ and $\alpha_\perp$*

The Hamiltonian of a molecule in the presence of a static field $\boldsymbol{F}$ is written down as follows

$$H=H_0+F\left(\frac{\boldsymbol{F}}{F}\cdot\sum_i \boldsymbol{r}_i\right), \tag{50}$$

where H_0 is the field free Hamiltonian of the molecule (4). Following the second order perturbation theory, the total energy E is expressed to the second order of F as follows

$$E=E_0-F^2\sum_n\frac{1}{E_n-E_0}\left|\left(\frac{\boldsymbol{F}}{F}\cdot\sum_i\boldsymbol{r}_i\right)_{n0}\right|^2. \tag{51}$$

Therefore the polarizability parallel to the molecular axis, $\alpha_{//}$, and that perpendicular to it, $\alpha_\perp$, become

$$\alpha_{//}=2\sum_n\frac{|(\sum_i z_i)_{n0}|^2}{E_n-E_0}\ , \tag{52.1}$$

$$\alpha_\perp=2\sum_n\frac{|(\sum_i x_i)_{n0}|^2}{E_n-E_0}\ . \tag{52.2}$$

In order to calculate α by means of Eq. (52), we have to know, in advance, the exact energy values and the corresponding wave functions of all the eigenstates of H_0. Therefore, the straightforward application of Eq. (52) is practically impossible. Hence we have here tried an approximate calculation by taking into account only the nine states of O_2 considered in Section 5 and using the eigenvalues and the eigen-functions obtained there by the various approximations. The values of the polarizabilities calculated by this procedure are listed in the column indicated by "perturbation" in Table XIV. The observed values are also added in the same table.[30] From this table we see that $\alpha_{//}$ decreases appreciably by introducing the CI. Further from the fact that $\alpha_{//}$ of CI(π–σ) is very small compared with the observed value and all the calculated values of $\alpha_\perp$ vanish, it seems necessary to take into account other states besides the above mentioned nine states. In

	Obs.						8.2

a) See Eqs. (51), (52), and (53).
b) See Eqs. (54) and (55).
c) From reference (30).

order to investigate this situation, we estimated the values of $(\Delta E)_{//}$ and $(\Delta E)_{\perp}$ defined by the relations

$$\alpha_{//}=2\,\frac{1}{(\Delta E)_{//}}|\{(\sum_i z_i)^2\}_{00}|\,, \tag{53.1}$$

$$\alpha_{\perp}=2\,\frac{1}{(\Delta E)_{\perp}}|\{(\sum_i x_i)^2\}_{00}|\,, \tag{53.2}$$

using the observed values of $\alpha_{//}$ and $\alpha_{\perp}$, and the calculated values of $|\{(\sum_i z_i)^2\}_{00}|$ and $|\{(\sum_i x_i)^2\}_{00}|$. These values of (ΔE)'s represent some average values of the energy denominators (E_n-E_0) of Eq. (52), and suggest that we must take into account excited levels higher than the ground state at least by these amounts. In Table XIV are listed these calculated values.

The polarizabilities can be derived also by variational treatment. In fact, the simplest method along this line was given by Kirkwood[31)]. The perturbed wave function adopted is

$$\Phi=\left\{1+aF\left(\frac{F}{F}\cdot\sum_i r_i\right)\right\}\Phi_0\,, \tag{54}$$

where a is a parameter to be determined by the energy minimum condition, and Φ_0 is the eigenfunction of the unperturbed Hamiltonian H_0. By picking up the coefficients of F^2 in the total energy expression, we obtain the following formulae for the polarizabilities, $\alpha_{//}$ and $\alpha_{\perp}$,

$$\alpha_{//}=\frac{4}{N}[\{(\sum_i z_i)^2\}_{00}]^2\,, \tag{55.1}$$

$$\alpha_{\perp}=\frac{4}{N}[\{(\sum_i x_i)^2\}_{00}]^2\,, \qquad (55.$$

where N is the number of the electrons co sidered. Thus in Kirkwood's approximatio we can calculate the polarizabilities from on the knowledge of the wave function of th ground state. Using the wave functions single configuration, (SCF)′ CI(π), and CI(π– for the ground state, we have calculated α and $\alpha_{\perp}$, and the results are listed in th column indicated by $N=16$ in Table XIV. Fro these values we can see that

(i) the effect of the CI on $\alpha_{//}$ is appreciab also here, while that on $\alpha_{\perp}$ is not so importan and

(ii) $\alpha_{//}$ and $\alpha_{\perp}$ obtained for our best wa function, CI(π–σ), are very small compare with the observed values. However, this di crepancy may be ascribed to some extent the fcat that, in Kirkwood's approximatio each orbital involved is assumed to suffe a similar change governed by the same facto ar due to the perturbation caused by the applie electric field. Hence we may improve Kir wood's approximation by allowing to multipl each orbital φ_i by a different modulation fa tor $a_i r_i$. It is, however, laborious to carry ou this procedure strictly, and so we have aime to take into account this effect by omittin the inner shell electrons, which would be ver difficult to suffer any polarization. Namel we have applied Kirkwood's approximation (i) the twelve electrons except $\sigma_{1g}{}^2$ and σ_1

ectrons, and (ii) the six π electrons. The sults are shown in the column indicated by $=12$ and 6 respectively in Table XIV. As has ready been expected, the value of $\alpha_{//}$ in- eases from $N=16$ to 12, and also that of $\alpha_{\perp}$ creases from $N=16$ to 12 and to 6. Con- dering that Kirkwood's approximation is ther crude, we may say that the agreement ith the experiment of the value of $\alpha_{//}$ for I(π-σ), $N=12$) and that of $\alpha_{\perp}$ for (CI(π-σ), $=6$) is satisfactory.

7. Population Analysis

In order to obtain a useful insight for the ave function of the molecule, Mulliken[32),33)] eveloped a population analysis method, and is method was already applied to N_2[1c)], O[32),34)], BH[35)], and H_2O[32),1b)]. We also at- mpted the similar analysis for the O_2 wave nctions obtained in Case 1 (single configura- on), Case 7 (SCF MO), and Case 4 (u^2 appro- imation) of Section 4. For the sake of onvenience we introduced specific overlap opulations and specific AO populations in rthonormalized MO

$$\varphi_i=\sum_{rk} c_{i,rk}\chi_{rk} \qquad (r=a,b;\ k=1s, \overset{\circ}{2s}, 2p\sigma, 2p\pi^{\pm}) \quad (56)$$

s follows

$$n'(i;\ k,\ l)=\sum_{rs} 2c_{i,rk}c_{i,sl}S_{rk,sl} \qquad (57.1)$$

$$n'(i)=\sum_{k\geqq l} n'(i;\ k,\ l) \qquad (57.2)$$

$$N'(i;\ k)=\sum_{r} \{c_{i,rk}(c_{i,rk}+\sum_{l\neq k} c_{i,sl}S_{rk,sl})\}\ , \qquad (57.3)$$

where $S_{rk,sl}=\int \chi_{rk}\chi_{sl}dv$. Then the overlap population $n(i)$ and the gross AO population $N(i;\ k)$ in each orbital and the total overlap population n are given by

The amounts of s–p promotion obtained by the population analysis method for the wave functions of single configuration, SCF, and u^2 approximations, together with the total overlap populations n are listed in Table XIX. The corresponding values of the N_2, CO, and BH molecules are also shown in the same table. From this table we can see that

(i) the charge distribution is nearly the same for SCF and u^2 wave functions,

(ii) the values of n for SCF and u^2 wave functions are much larger than that for the single configurational wave function, which manifests well that the bonding power increases due to s–p promotion, and

(iii) the amount of s–p promotion for O_2 is smaller than that for N_2, as is usually s posed.

Next we have examined the relation s gested by Mulliken[32)]

$$\frac{n_k-n_0}{n_0}=2\frac{R_k-R_0}{R_0}\ .$$

Here n_0 and R_0 are respectively the total ov lap population and the equiliblium internucl distance in the O_2 ground state, and n_k a R_k are those in the excited or ionized stat Here it is worth while to note that the re tion (59) tells us the equiliblium internucl

O_2 $(^1\Sigma_u^-)$	0.55475	0.645	one electron in $^3\Sigma_g^-$ (O_2) being excited from $\pi_u^\pm$ to $\pi_g^\pm$.
O_2 $(^1\Sigma_g^+)$	0	0.026	same orbital assignment.
O_2 $(^1\Delta_g)$	0	0.013	same orbital assignment.

a) See Eq. (59).

Finally we wish to investigate the electron distribution in the wave function obtained in Case 9 of Section 4 (CI(π–σ)). For this purpose, we have applied the population analysis method to the natural orbitals φ_i'[36], which are constructed by diagonalizing the one electron density materix in the following way,

$$\rho(1)=\int \Phi^*\Phi d\sigma_1 d\tau_2\cdots d\tau_N=\sum_{i,j}\varphi_i^*(1)\mu_{ij}\varphi_j(1)$$
$$=\sum_i \varphi_i'^*(1)N(i)\varphi_i'(1)\ , \tag{60}$$

where μ_{ij} is the matrix element of $\rho(1)$ for Schmidt-OMO's $\varphi_i(1)$, and $\varphi_i'(1)$ and $N(i)$ are respectively the eigenfunction and the eigenvalue. From Eq. (60), $N(i)$ may be taken as the effective number of electron occupying natural orbital $\varphi_i'(1)$. The natural orbitals for the wave function of CI(π–σ) are the same as Schmidt-OMO (3) except the higher two σ_u orbitals which are here designated as σ_{2u}' and σ_{3u}'. The coefficients $c_{i,rk}$ in σ_{2u}' and σ_{3u}' are listed in Table XV. The various populations in these orbitals are given in Tables XVI, XVII, and XXI. The amount of s–p promotion and the total overlap population n in CI(π–σ) wave function were calculated by using the natural orbitals and the results are shown in Table XIX. From his table, we can see that the value of n is maller in this case than in SCF case. Thus e find that electron correlation decreases the onding power. It is interesting to notice ere that we can expect the similar situation lso in the H_2 molecule by comparing the equiliblium internuclear distance calculated by ASMO wave function, 0.850Å (0.732Å)[37], with that by ASMO CI wave function, 0.884Å (0.750Å)[38]; the values within parenthesis being those found by taking into account the screening effect.

Table XXI. Occupation numbers $N(i)$, gross AO populations $N(i;\ k)$,[a] and overlap populations $n(i)$[b] in each orbital, for the case of five dimensional configurational interaction CI(π-σ) (Case 9).

i	$N(i)$	$N(i;\ 1s)$	$N(i,\ 2s)$	$N(i;\ 2p\sigma)$	$n(i)$

b) See Eqs. (58.1) and (57.2).

§ 8. Summary

The results of our calculations hitherto made are compared with the observations in Table XXII by taking the ratio of the computed to observed values. From this table, it is seen that all the results of the single configuration theory, except the f value calculated by the dipole velocity method, are improved as well though not fully, taking into acco the mixing of a relatively small numbe configurations. Especially satisfactory res are obtained for $\langle\psi^2(0)\rangle$ and for f va calculated by the dipole length method.

By examining the CI(π–σ) wave functio

Table XXII. Ratio of computed to observed value of each molecular quantity.
A). Total energy E, D_e, Q, $\langle P_2/r^3\rangle$, and $\langle\psi^2(0)\rangle$ of ground state.[a]

Case	E	D_e	Q[b]	$\langle P_2/r^3\rangle$	$\langle\psi^2(0)\rangle$
1 (A)	0.9907	−0.27	−0.19	0.644	0
2 π-CI	0.9910	0.01	−0.06	0.633	0
3 (A+J_1)	0.9912	0.16	2.10	0.644	0
4 u^2	0.9912	0.14	2.13	0.644	0
5 $u'u''$	0.9912	0.16	2.10	0.644	0
6 SCF	0.9912	0.16	2.14	0.644	0
7 (A+F_1)	0.9913	0.20	−0.16	0.640	0
8 p-CI	0.9915	0.40	−0.26	0.632	0.013 (0.012)[c]
9 5 dim.	0.9919	0.67	1.75	0.639	0
10 15 dim.	0.9919	0.71	1.87	0.651	1.042 (0.926)[c]

13 (π-HL, σ-MO)	0.9904	−0.49	0.46	0.590	0
14 (σ(s-p hybrid.)-HL, π-MO)	0.9907	−0.28	2.55	0.644	0
15 (σ-SO, π-MO)	0.9909	−0.10	−0.20	0.644	0
16 (A′)	0.9932	1.78	−3.72	0.644	0

a) See Table XI.
b) In this column are listed the values found by taking $Q_{\text{obs.}} = -0.82$.
c) The values within parenthesis are those obtained by using the H-F orbital. See also subsection (3) of § 6.

Table XXII. (continued)

B). Excitation energies from the ground state of O_2, $^3\Sigma_g^-$.

	$O_2^+(^4\Sigma_g^-)$	$O_2^+(^2\Pi_u)$	$O_2^+(^4\Pi_u)$	$O_2^+(^2\Pi_g)$	$O_2(^3\Sigma_u^-)$
Single configuration	0.807	0.812	0.614	0.806	1.387
(SCF)′	0.884	0.894	0.700	0.880	1.441
CI(π)					1.535
CI(π-σ)					1.131
	$O_2(^3\Sigma_u^+)$	$O_2(^1\Sigma_u^-)$	$O_2(^1\Sigma_g^+)$	$O_2(^1\Delta_g)$	$O_2(^3\Sigma_u^-)$[a]
Single configuration	0.455	0.402	1.817	1.515	0.483
(SCF)′	0.524	0.468	1.817	1.515	0.483
CI(π)	0.642	0.581	0.871	0.780	0.860
CI(π-σ)	0.755	0.683	1.216	1.144	0.296

a) From Eq. (48)

C). f_{lk}[a] of transition from $^3\Sigma_g^-$ to $^3\Sigma_u^-$, $\alpha_{//}$, and $\alpha_{\perp}$.[b]

	f_{lk} (length)	f_{lk} (velocity)	$\alpha_{//}$ Perturb.	$\alpha_{//}$ Kirkwood ($N=12$)
Single configuration	4.59	0.558	0.701	1.292
(SCF)′	4.77	0.537	0.674	1.029
CI(π)	2.44	0.763	0.304	0.883
CI(π-σ)	0.80	0.053	0.184	0.567
	$\alpha_{//}$ Kirkwood ($N=6$)	$\alpha_{\perp}$ Perturb.	$\alpha_{\perp}$ Kirkwood ($N=12$)	$\alpha_{\perp}$ Kirkwoord ($N=6$)
Single configuration	0.704	0	0.526	0.995
(SCF)′	0.704	0	0.536	0.995
CI(π)	0.314	0	0.524	0.988
CI(π-σ)	0.480	0	0.531	0.992

a) See Table XIII.
b) See Table XIV.

one can see that the interatomic correlation among valence electrons, above all among π and σ electrons, plays an important role in the present ASMO CI treatment.

Further from this table, one can see that the MO approach yields better results than the HL one in so far as the total energy is concerned (compare Case I with Cases 11, 12, and 13).

These interesting results, will be discussed* in Part III of this series of papers, for various diatomic molecules in a summarized form.

Acknowledgements

The authors would like to express their gratitudes to Dr. T. Nakamura for informing us his similar calculation on the N_2 molecule before publication, and to Drs. K. Ohno and T. Itoh for their helpful discussions. They further appreciate the valuable and kind assistance, in our numerical work, of Misses. N. Mizushima, N. Sugawara, K. Matsuoka, S. Noguchi, S. Maniwa, J. Matsuoka, K. Murata, and H. Komuro, and moreover the secretary assistance of Mrs. Y. Yuminami.

---

* A brief account of the last topic was already given in the Progress Report No. 6 of our research group.

They are also indebted to the Ministry of Education and to the members of Kota Laboratory for their financial aids.

Appendix 1. Some Matrix Elements H_{ij} (i=A, j=A,B,$\cdots$)

We shall list for each state the formulae for the diagonal elements of the Hamiltonia matrix for the main configurational wave function, relative to that of the ground state of O_2.

$$H_{AA}({}^3\Sigma_g^-)=\sum_l(\mathcal{E}_l+h_l)+\frac{64}{R}=\sum_l(2h_l)+\Big[\sum_k\sum_j\{2J(k,j)-K(k,j)\}$$

$$+\sum_k\sum_a\{2J(k,a)-K(k,a)\}+\{J(\pi_g^+\pi_g^-)-K(\pi_g^+\pi_g^-)\}\Big]+\frac{64}{R}.$$

$$(l=\sigma_{1g},\ \sigma_{1u},\ \sigma_{2g},\ \sigma_{2u},\ \sigma_{3g},\ \pi_u^\pm,\text{ and }\pi_g^+\text{ or }\pi_g^-)$$

$$(j,\ k\neq\pi_g^\pm;\ a=\pi_g^\pm)$$

$$\left.\begin{array}{ll}
\text{State} & H_{AA}\\
O_2({}^3\Sigma_g^-) & 0\\

Hartree-Fock Values of Diamagnetic Susceptibilities of Neon-like Ions*

By Shigehiro KOBAYASHI

Department of Physics, Kagawa University, Takamatsu

(Received March 25, 1957)

On the basis of the Thomas-Fermi-Dirac (TFD) model Thomas and Umeda[1)] have recently investigated the dependence on degree of ionization of the molar diamagnetic susceptibilities χ_{TFD} by calculating these for the neutral atom as well as positive ions up to quadruply ionized, all homologous to inert gases.

It may be of some interest to compare this result with that based on the Hartree-Fock (HF) method. We have done it for neon-homologue for which alone the HF fields are known at present up to quadruple ionization, by calculating anew the values of χ_{HF} for F^-, Al^{3+} and Si^{4+}. For completeness the values for Ne, Na^+ and Mg^{2+} were also recalculated more accurately than hitherto. The results are given in Table I.

Since neon-homologue has not sufficient number of electrons to make the statistical treatment valid, there are some deviations between χ_{HF} and χ_{TFD} which decrease, however, with the increasing degree of ionization, as seen from Fig. 1. This can be reasoned from the fact that the higher ionization causes the larger electron density due to stronger contraction of the electron cloud.

Table I. Molar diamagnetic susceptibility χ in unit of 10^{-6} cm³.

Ion	Ionization degree	$-\chi_{HF}$				$-\chi_{TFD}$
		1s	2s	2p	Total	
F^-	−1/9	0.066	2.21_1	14.80_3	17.08	
Ne	0	0.053	1.75_6	6.24_3	8.06^a	14.33
Na^+	1/11	0.044	1.15_9	3.88_2	5.08^b	7.83
Mg^{2+}	1/6	0.036	0.908	2.79_9	3.74^c	5.24
Al^{3+}	3/13	0.031	0.724	2.12_1	2.88	3.81
Si^{4+}	2/7	0.026	0.594	1.67_2	2.29	2.92

a: previously 8.8 by P. Gombás[3)]

b: previously 5.7 by P. Gombás[3)] and 4.9 by D. R. Hartree and W. Hartree[2)]

c: previously the same value by W. J. Yost[2)]

Note: These three values of a and b are not in favor to the smooth dependence of χ on the degree of ionization.

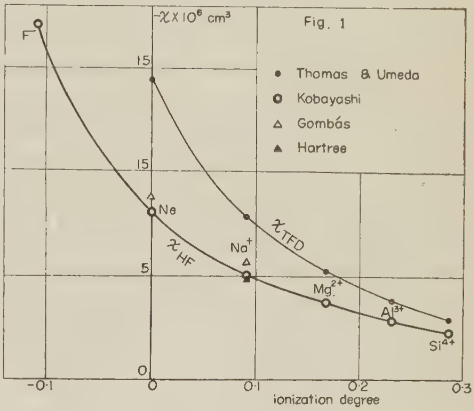

Fig. 1

The author wishes to express his sincere thanks to Professor K. Umeda of Okayama University for his suggestion of this calculation and his kind guidance.

Beta Interaction in the Decay of Cs^{137}

By Toshio KATOH, Masao NOZAWA,
Yasukazu YOSHIZAWA

Department of Physics, Faculty of Science, Osaka University, Osaka

and Yujiro KOH

Faculty of Science-Engineering, Osaka City University, Osaka

(Received April 5, 1957)

Recently it has been said that the ratio of $|G_S/G_T|$ in beta interaction is close to one.[1] Its sign, however, has not been determined, though some attempts have been done.[2],[3] The present paper concerns a trial for this problem, investigating the spectrum of the higher component of beta rays from Cs^{137}.

A two directional focusing beta ray spectrometer of mushroom type with the mean radius of 40 cm was used. Theresolution of the spectrometer was 0.17~0.5%. It could be concluded from the measurements of P^{32} and Y^{90} spectra that the distortion due to the spectrometer was negligible. The thickness of the source was about 0.2 mg/cm².

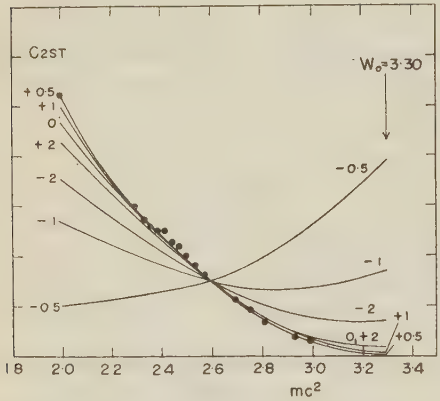

Fig. 1. The experimental and theoretical correction factors of the higher component of beta rays. Points show experimental values, $N/(B\rho f q^2)$ in arbitrary ordinate axis. The values in Figure indicate Y. Curves are theoretical ones normalized at 2.6 mc², and for each Y, parameters except Y were selected to fit them to experimental points.

The experimental results and the calculated correction factors of the higher component of beta rays are shown in Fig. 1. This spectrum was analysed in the following ways. First, measured spins and estimated parities of the ground states of Cs^{137} and Ba^{137} were to be reliable, i.e., the higher component was analysed on the basis of the second forbidden transition $\Delta I=2$, no parity change. Second, the linear combination of the scalar and tensor interactions was used. Third, the maximum energy of the higher component, 1176±2 kev, was taken to be the sum of precisely measured gamma ray energy, 662 kev, and the maximum energy of the lower component, 514±2 kev, which was observed in our experiment

It was the important feature that this spectrum became a straight line in the Kurie plot using the correction factor $C=q^2$ within the experimental error, where q was the momentum of neutrino.

When the lower component was analysed, this correction factor was used to subtract the higher component from the total spectrum and was obtained the straight corrected Kurie plot of the lower component using unique first forbidden correction factor. The branching ratio of the lower and the higher component was 92.4/7.6 which agreed with the result of Langer and Moffat.[4]

We tried to determine the value of $Y=(iG_S R_{ij})/(G_T T_{ij})$ in the approximate formula for the correction factor of Konopinski and Uhlenbeck.[5] The experimental correction factor was found to agree with the theoretical one in the region $2 \gtrsim Y > 0$, but was not in the region $Y < 0$. Assuming the time reversal property and the single particle model approximation, $R_{ij}/T_{ij}=i/2$[3] in the case of Cs^{137}. Then $Y=-G_S/2G_T$, and $Y=+0.5$ was rather good as shown in Fig. 1, whereby $|G_S/G_T|\simeq 1$. It was concluded that the negative sign of G_S/G_T was better than another, as Morita, Fujita and Yamada[3] had pointed out. Details of experiments and discussions will be published in near future.

Intermolecular Free Length in Liquids in Relation to Sound Velocity

By Otohiko NOMOTO

Kobayasi Institute of Physical Research, Kokubunzi, Tokyo

(Received March 29, 1957)

Jacobson[1] has found an empirical relation

$$\beta = kL^p \qquad (1)$$

(k and p=constants, slightly dependent on temperature) between the compressibility (adiabatic or isothermal) β and the intermolecular free length L of the organic liquids, defined by

$$L = 2v_a/Y = 2(v-v_0)/Y\,, \qquad (2)$$

where v_a means the available volume, v the molar volume and v_0 the actual volume of the molecules in one mole, and Y is the total surface area of the molecules in one mole of the liquid, given by

$$Y = (36\pi N_L v_0^2)^{1/3}\,, \qquad (3)$$

where N_L denotes the Loschmidt number. In case β is the adiabatic compressibility, p and k in (1) becomes as $p=2.083$ and $\log k=7.097$ at 20°C, when the value of L is determined by adopting as v_a the difference of the molar volumes at 20°C and 0°K. The approximation $p=2$ leads to the relation

$$VL\rho^{1/2} = \text{const.} = K \qquad (4)$$

by (1).

Explanation for this relation has been put forward by Wada[2] by employing the hole-theory of Eyring et al.[3] and giving the expression of the constant K as

$$K_W = (6/\pi N^L)^{1/3}(\gamma_g RT)^{1/2}v^{-1/6}\,, \qquad (5)$$

where γ_g means the ratio of the specific heats of the gas or vapour of the corresponding liquid, R the universal gas constant and T the absolute temperature. The factor $\gamma_g^{1/2}v^{-1/6}$ being only slightly dependent on the various kinds of the liquids, K is expected to be nearly independent of the kinds of liquids and proportional to $T^{1/2}$, as has been pointed out and ascertained by Wada by employing Jacobson's data.

The numerical value of the constant K calculated by Wada, however, is about twice the experimental value. The reason for this discrepancy seems to be involved in the use of Eyring's liquid model for the calculation. So we performed a similar calculation by employing Toncks' equation of state[4], which becomes

$$pv_a = 3RT \qquad (6)$$

for liquids, where p means the pressure. The corresponding sound velocity is given by Kittel[5] as

$$V_K = (v/v_a)\gamma_l^{1/2}(3RT/M)^{1/2}\,, \qquad (7)$$

where M is the molecular weight and γ_l the ratio of the specific heats of the liquid, being equal to $(C_v+3R)/C_v$ in this case, where C_v is th molar specific heat at constant volume. The constant K in (4) becomes in this case as

$$K_K = \frac{2v^{1/2}}{(36\pi N_L v_0)^{1/3}}\gamma_l^{1/2}(3RT)^{1/2}\,. \qquad (8)$$

Comparing this constant with that of Wada, we have

$$K_K/K_W = (1/\sqrt{3})(\gamma_l/\gamma_g)^{1/2}(v/v_0)^{2/3}\,. \qquad (9)$$

Jacobson's empirical value is $K=618$ at 20°C, and we have $K/\sqrt{T}=36.1$, while Wada's value of K affords $K_W/\sqrt{T}=69$, when it is assumed that $v=90\,\text{cm}^3$ and $\gamma_g=1.2$. The relation (9) gives, on the other hand, $K_K/\sqrt{T}=46$, if it is assumed that $\gamma_l=\gamma_g$ and $v/v_0=1.25$.

Collins and Navidi[6] has obtained the expression of the sound velocity also by employing Toncks' equation of state, but without employing the geometrical assumption of the sound propagation model and directly from the thermodynamical equation of the sound velocity. Expanding their expression in terms of (v_a/v) and conserving the first order terms, we have as the sound velocity

$$V_c = \{1-(1/3)(v_a/v)(\gamma_l-1)\}V_K\,, \qquad (10)$$

where V_K means Kittel's sound velocity given by (7). This gives the value of K given by

$$K_C/K_W = (1/\sqrt{3})(\gamma_l/\gamma_g)^{1/2}\left\{1-\frac{1}{3}(v_a/v)(\gamma_l-1)\right\}\,, \qquad (11)$$

the corresponding value of $K/\sqrt{T}$ becoming

$$K_C/\sqrt{T} = 45\,, \qquad (12)$$

nearly in agreement with the empirical value.

On the Conducting Mechanism of Oxide Coated Cathode

By Hiroyuki MIZUNO

Matsushita Electronics Corporation Takatsuki

(Received March 15, 1957)

We have pointed out that the theory of Loosjes-Vink can be applied on the rectification theory at the interface of oxide cathode[1]. Referring to this consideration we have studied some rectification properties between sleeve and coated oxide. Experimental cathodes consist of nickel circular sleeve*) coated with oxide, and double probes embedded in it. Direct voltage was applied through the contact between sleeve and first probe, first probe and second probe were used to measure the currents**) and temperature was measured simultaneously by using thermo-couple and micropyrometer. The difference between these two measured currents was taken as the conducting current through blocking layer. Fig. 1 shows the logarithm of current as a function of $(1/T)$ for forward direction. The curves consist of two regions. The one is the low temperature region (below 700° K) and the other is the high temperature region (beyond 700° K). There are some fluctuations according to different tubes but these tendencies are similar. In Fig. 2 we ploted $\log I/T^2$ as a function of $1/T$ in the high temperature region. Fig 3 and 4 show the logarithms of the currents in reverse direction in low temperature region ($<700°$ K) and of current divided by T^2 in high temperature region ($>700°$ K) respectively. Contrary to the case of forward flow, the gradients change with applied voltages in high temperature region and do not change in low temperature region. From these results, it can be assured that the low temperture conduction is attributed to the electrons moving through a granule to a granule, while high temperature conduction is attributed to electron gas emitted from granules. However the critical temperature is about 700° K, not 800° K as pointed by Loosjes and Vink.

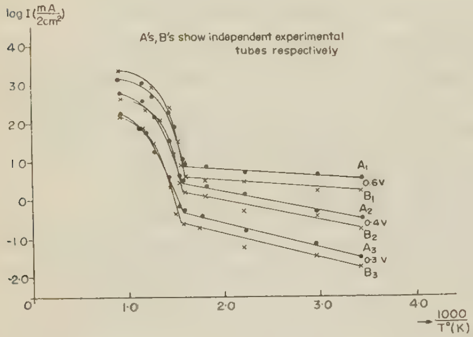

Fig. 1. Log I-$1/T$ curves for forward direction flow.

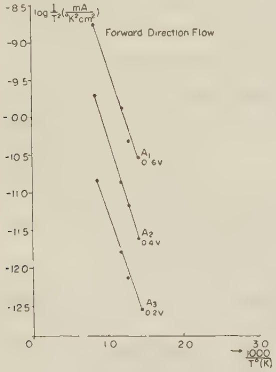

Fig. 2. Log $I/T^2-1/T$ curves for high temperatures.

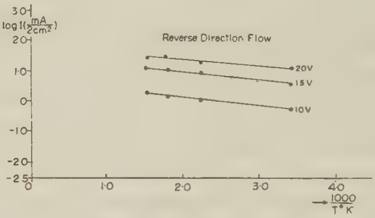

Fig. 3. Log. $I-1/T$ curves for low temperatures.

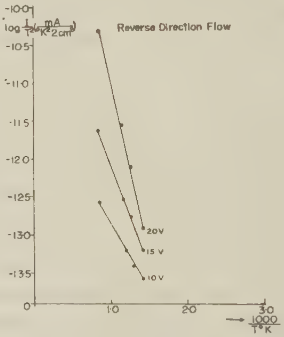

Fig. 4. Log. $I/T^{\frac{1}{2}}-1/T$ curves for high temperatures.

---

* It is to be noted that the sleeve must be cleaned completely. If there should be oxide films on the surface, the rectification property was something curious.

** Note: The rectifying area between sleeve and coating is computed by substraction of the contact area between probe and coating from the total contact area between sleeve and coating.

On the Carrier Recombination through Nickel Impurities in Germanium

By Jun'ichi Okada

Matsuda Research Laboratory, Tokyo-Shibaura Electric Co., Kawasaki-city, Japan

(Received April 2, 1957)

Several recent experiments indicate that there exist impurities which act as both recombination and trapping centers in germanium: examples are Cu, Au, Fe and Ni[1]. These results have been explained by assuming that such impurities each introduce at least two acceptor levels whose charge distribution affects capture cross-sections for free carriers. A proposal will be presented here that there is a temperature range where carrier recombination through these impurities can be interpreted without above assumption.

The samples used in this study were prepared by diffusing nickel into originally n-type germanium. This method permits us to control the concentration of nickel and the position of Fermi level in germanium.

Figure 1 shows experimental results characteristic of high-resistivity p-type samples. Intrinsic photoconductivity $\Delta\sigma$ and resistivity ρ are plotted as a function of temperature T. Results indicate that $\Delta\sigma$ increases with decreasing temperature but saturates gradually. This fact cannot be interpreted by simple recombination theory[2], but we can explain it by assuming that each nickel atom introduces two acceptor levels, and applying the theory of recombination through multiple levels of constant capture cross-sections.[3] Rather simple explanations proposed here are as follows.

Assume that, for high-resistivity nickel-doped germanium, there exist two independent levels, one (upper level) 0.3eV below the bottom of the conduction band, the other (lower level) 0.22eV above the top of the valence band[4]. In the case of high-resistivity p-type samples, upper level captures excess electrons which recombine with free holes through this level. Therefore, in steady state, $p_0\gamma_{p1}\Delta N_1^- \simeq \Delta n\gamma_{n1}N_t$, where γ_{n1} is the rate of filling an empty site of upper level per unit electron concentration, γ_{p1} is the rate of emptying an occupied site per unit hole concentration, p_0 is the equilibrium free hole concentration, ΔN_1^- is the change of the density of electron captured in this level and N_t is the concentration of nickel. On the other hand, lower level acts as hole trapping centers. Thus, $p_2\gamma_{p2}\Delta N_2^+ \simeq \Delta p\gamma_{p2}N_t$, where γ_{p2} is the capture constant for holes, p_2 is the free hole concentration when the Fermi level equals to the lower level and ΔN_2^+ is the change of the density of empty sites in this level. In this case, we have two carrier lifetimes principally determined by the recombination rate U at upper level which is given by $\Delta n\gamma_{n1}N_t$ and neutrality condition requires $\Delta n+\Delta N_1^- = \Delta p+\Delta N_2^+$. Then, if we define an effective lifetime τ^* by the equation

$$\tau^*(\mu_n+\mu_p) = \tau_{n1}[\mu_n+\mu_p\{1+(\gamma_{n1}/\gamma_{p1})N_t/p_0\}/(1+N_t/p_2)], \quad (1)$$

photoconductivity $\Delta\sigma$ is given by

$$\Delta\sigma = \Delta n\mu_n+\Delta p\mu_p = L\tau^*(\mu_n+\mu_p), \quad (2)$$

where $\tau_{n1}=1/\gamma_{n1}N_t$ and L is the rate of excitation. In this expression, N_t and p_0 are obtained from resistivity data and p_2 can be calculated by assuming the position of lower level. γ_{n1} and γ_{p1} are determined by comparing the effective lifetimes. At room temperature, we have obtained, using two p-type samples of different concentrations of nickel, $\gamma_{n1}=0.9\times10^{-9}$ cm³/sec and $\gamma_{p1}=1.8\times10^{-9}$ cm³/sec. Figure 1 also shows the $\Delta\sigma$ curve calculated from Eq. (2) with $N_t=7\times10^{14}$/cm³. This is in good agreement with the experiment. Moreover, from Hall coefficient measurements, we have obtained $\Delta p/\Delta n \simeq 3$ for above sample at room temperature, while calculated value is 2.9.

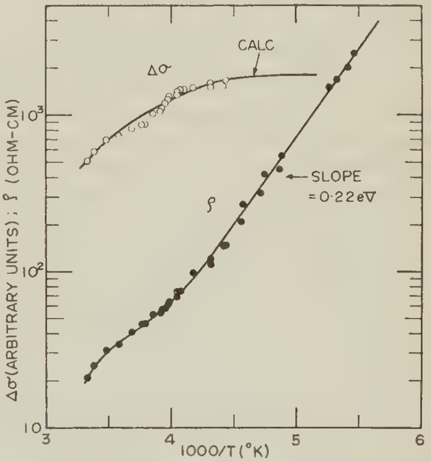

Fig. 1. Photoconductivity and resistivity *vs* temperature for high-resistivity p-type Ni-doped sample.

The author thanks Mr. M. Takabayashi for his kindness of preparing the samples.

Magnetic Annealing Effect in Iron-Nickel Ferrites

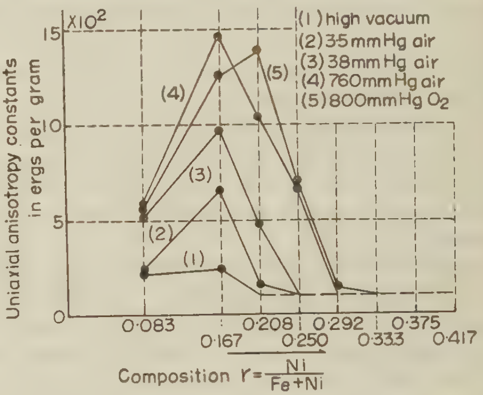
By Yoshimichi AIYAMA, Hisashi SEKIZAWA
and Shûichi IIDA
Department of Physics, Faculty of Science, Tokyo University, Tokyo, Japan

(Received April 15, 1957)

It has been shown by us[1,2] that the magnetic annealing effect in iron-cobalt ferrites can well be accounted for by the mechanism of the directional short range order, which is analogous to the case of metallic solid solution,[3] among Co^{2+} ions and cation vacancies on 16d sites of the spinel structure. The details will be published soon.[2] One of the experimental facts which lead us to this conclusion is that the magnetic annealing effect disappears after the specimens have been heat-treated in a high vacuum and recovers again by oxidizing the specimens, and the magnitude of the uniaxial anisotropy depends strongly on the degree of oxidation of the specimens. According to the phase diagram established by one of the authors[4], it is certain that the specimens after the vacuum heat-treatment are almost stoichiometric and the oxidation of the specimens means the oxidation of iron ions from Fe^{2+} to Fe^{3+}, accompanied by the increase of cation vacancies in the spinel matrixes. It is presumed that the orbital of Co^{2+} ion neighbouring a vacancy of a cation suffers the axial crystalline field and hence, combined with the spin-orbit coupling, the electronic energy of the Co^{2+} ion depends considerably on the direction of magnetization. According to this mechanism, every kind of mixed ferrites of magnetite and other ferrites are expected to show the magnetic annealing effect to some extent after appropriate oxidation heat-treatment, although the magnitude of the induced uniaxial anisotropy is to depend on both the manner of splitting of the orbital energy levels under the influence of the crystalline field and the strength of the spin-orbit coupling of the metal ions concerned.

Our preliminary experiments have shown that the magnetic annealing is effective in Fe-Ni ferrites, and also in Fe–Mn and Fe–Cu ferrites to some extent. It seems probable that the uniaxial anisotropy of these ferrites is also induced by the above mechanism. In order to confirm this presumption in the case of Fe–Ni ferrites, the dependence of the magnitude of the uniaxial anisotropy on the concentration of vacancies, i.e. the degree of oxidation of specimens, has been studied with the same method as in the case of Fe–Co ferrites[1].

Eight disk-shaped polycrystalline specimens, ranging in composition from Ni/(Fe+Ni)=0,083 to 0,417, were prepared by using cobalt-free carbonyl nickel and electrolytic iron. After prepared by sintering at 1400°C under an appropriate pressure of oxygen, they were heated up to 1000°C in a high vacuum, kept for one hour and then cooled slowly to room temperature. The cation-anion ratio of the specimens at this stage is thought to be almost stoichiometric. Then they were heated up to 400° in a high vacuum, kept ten minutes and cooled with an applied magnetic field of about 5000 Oe. The uniaxial anisotropy constants measured after this treatment are shown by curve (I) in figure. Similar magnetic annealing treatments from 400°C were repeated four times in various atmospheres. The anisotropy constants measured after each heat-treatment are shown in figure by curves (2), (3), (4) and (5), respectively. The atmospheres used are also indicated in the figure.



These results show that the magnitude of the uniaxial anisotropy of iron-nickel ferrites also depends essentially on the degree of oxidation of the specimens and the mechanism of this magnetic anneling effect will be the same as in the case of iron-cobalt ferrites. Contrary to the case of iron-cobalt ferrites, the magnetic annealing is ineffective in nickel rich specimens. It is perhaps due to the insufficiency of the vacancy concentration, for the ionization potential of Ni^{2+} ion is higher than that of Co^{2+} ion and the specimens were not so much oxidized as to have sufficient vacancies in our heat-treatments.

The authors wish to express their hearty thanks to Prof. S. Kaya for his constant encouragement. The authors are also indebted to Mr. H. Yamato who helped them in some parts of this work.

Magnetic and Electrical Anisotropies of the Iron Sulfide Single Crystal

Tadamiki HIHARA
Department of Physics, Faculty of Science, Hiroshima University, Hiroshima,
Miyuki MURAKAMI and Eiji HIRAHARA
Department of Applied Physics, Faculty of Engineering, Hiroshima University, Hiroshima

(Received March 6, 1957)

We have reported on the behavior of the magnetic[1] and electrical[2] anisotropies of iron sulfide single crystal at the α-transformation temperature ($T\alpha$), and are now studying it in the temperature range over the Néel point (T_N, about 330°C).

The thermal variation of susceptibility is shown in Fig. 1, in which curve 1 and 2 are results when an applied magnetic field H, is perpendicular and parallel to the c-axis of the single crystal respectively. At temperatures above the Néel point there still remains a small but obvious anisotropy of susceptibility. Oxidation of the specimen was carefully avoided, because even very small quantities of oxide would disturb the measurements. The results shown in Fig. 1 may be explained qualitatively in the following way.

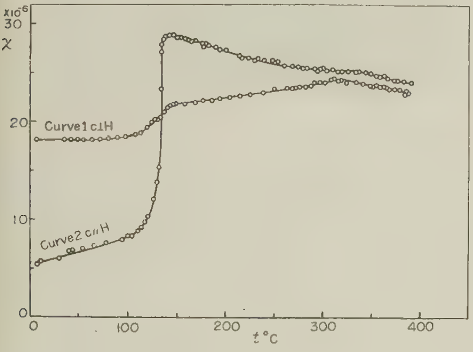

Fig. 1. Anisotropy of magnetic susceptibility.

As mentioned in [1] (the reference 1 will be denoted as [1]), the direction of antiferromagnetism is parallel to the c-axis at temperatures below T_α and is perpendicular to the c-axis at temeratures above T_α. On the basis of the fact that the crystal contracts along the c-axis as temperature rises through the α-transformation point, we may suppose that a super-exchange interaction between antiparallel spin pairs decreases and hence it causes an abrupt increase of susceptibility.

After the transformation the super-exchange energy would again increase on account of the usual lattice expansion and the gradual decrease of susceptibility follows in the temperature range between T_α and T_N, as seen in curve 2 in Fig. 1. In the same range of temperature curve 1 gradually increases, and hence we suppose that spins in the c-plane take two or more different directions in two or more sublattices (or domains) in the c-plane and their components parallel to the field contribute to the increment of susceptibility in this temperature range.

We now remark that the presence of two or more sublattices (or domains) is prerequisite in order to expain the constant susceptibility for the rotating measurements of [I] (curve B′ of Fig. 2), though in [I] we concluded incorrectly that spins in the c-plane turn easily keeping themselves perpendicularly to the external field H.

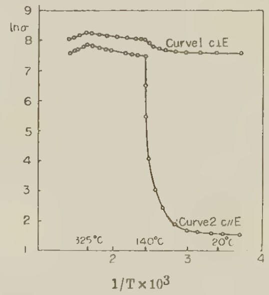

Fig. 2. Anisotropy of electrical conductivity.

The thermal variation of electrical conductivity is shown in Fig. 2, in which curves 1 and 2 are the results when an applied electric field is perpendicular and parallel to the c-axis respectively. The explanation for the anisotropy of conduction may be as follows.

In the range of temperature below T_α an easy flow of current will take place along a direction perpendicular to the c-axis because the spins in this direction are arrayed in parallel with each other, and a hard flow will be expected along the c-axis because the spins in this direction are arrayed in antiparallel with each other. In the range of temperature between T_α and T_N, the spins are disposed in the c-plane as mentioned above, and hence a flow of current along the c-axis increases to the same amount as a flow along a direction perpendicular to the c-axis. Above the Néel point the electrons released from antiferromagnetic interaction behave as ones in the conduction band and contribute to the metallic conduction as seen in Fig. 2. This work was partially supported by the Scientific Research Expenditure of the Ministry of Education.

A Density Filter Improving Aberrant Optical Image

By Jumpei TSUJIUCHI
Government Mechanical Laboratory, Tokyo, Japan

(Received April 12, 1957)

In the image-forming optical system, the complex amplitude of the image of an axial point source can be calculated, apart from constant factors, as follows:

$$U(\rho)=2\int_0^1 T(r)\exp[ikW(r)]\,J_0(\rho r)\,rdr\,, \qquad (1)$$

where r and ρ are the normalized radial coordinates in the pupil and image plane respectively, $T(r)$ the amplitude transmittivity, $W(r)$ the wave aberration, and $k=2\pi/\lambda$, then the intensity is

$$I(\rho)=U(\rho)\,U^*(\rho)\,. \qquad (2)$$

In case of the density filter attached to the ordinary optical system with $T(r)=1$, it is not introduced but the variation of absorption, so it is said that $T(r)$ is real and positive. Taking

$$T(r)=\frac{1}{2}\{1+\cos[kW(r)+\delta]\}\,, \qquad (3)$$

$T(r)\exp[ikW(r)]$ in (1) can be changed into the summation of two terms, of which one contains $W(r)$ and δ, and another contains δ only, so it is expected that the effect of $W(r)$ on the image can be reduced by the suitable choice of δ value.

We took (3) as the filter which improved the image formed by the aberrant system and was specified by the parameter δ, and studied the effect of this filter about the defocused system with

$$W(r)=ar^2\,. \qquad (4)$$

As to the evaluation of the optical image, Strehl's *definition*[1] has been used, and the *definition* in this case is obtained by setting $\rho=0$ in (2), which is calculated by (3), (4) and (1), and finally we have, with $\operatorname{sinc} t=\sin t/t$,

$$D(\delta)=I(0)=\frac{1}{4}\Big[\operatorname{sinc}^2\frac{ka}{2}+\frac{1}{4}\operatorname{sinc}^2 ka+\frac{1}{4}+\operatorname{sinc}\frac{ka}{2}(1+\operatorname{sinc}ka)\cos\Big(\frac{ka}{2}+\delta\Big)+\frac{1}{2}\operatorname{sinc}ka\cos 2\Big(\frac{ka}{2}+\delta\Big)\Big]\,. \qquad (5)$$

Taking $dD/d\delta=0$, the following values of δ are obtained corresponding to the extremums of $D(\delta)$;

$$\delta_1=2n\pi-\frac{ka}{2}\,,\quad \delta_2=\delta_1+\pi\,. \qquad (6)$$

On the other hand, the transmitted flux of the system with this filter can be calculated, using that without filter as unit;

$$E(\delta)=2\int_0^1\frac{1}{4}\{1+\cos[kar^2+\delta]\}^2\,rdr$$
$$=\frac{1}{4}\Big[\frac{3}{2}+2\operatorname{sinc}\frac{ka}{2}\cos\Big(\frac{ka}{2}+\delta\Big)+\frac{1}{2}\operatorname{sinc}ka\cos 2\Big(\frac{ka}{2}+\delta\Big)\Big]\,.$$

Here we take

$$D_0(\delta)=\frac{D(\delta)}{E(\delta)}$$

as the normalized *definition*, and the relations b tween a and D_0 for the filters of δ_1 and δ_2 a shown in Fig. 1, where we find that the *definiti* with the suitable filter is larger than that withou filter, or in other words, such a filter can improv the aberrant image. For $2n\lambda<a<(2n+1)\lambda$ the filte of δ_1 makes the *definition* maximum and that o δ_2 makes it mimium, whereas for $(2n+1)\lambda<a<2n$ the relations become contrary.

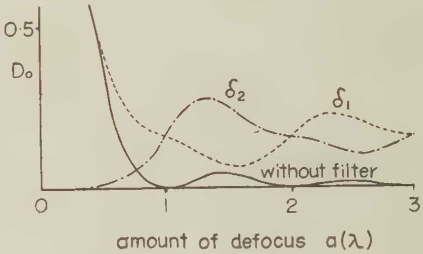

Fig. 1. Strehl's *definition* of defocused optica system with filter of δ_1, δ_2 and without filter.

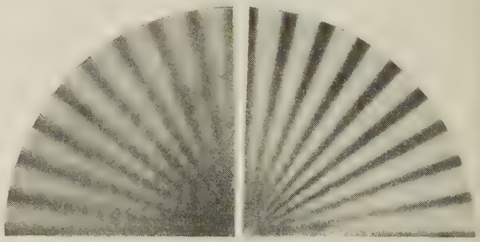

(A) without filter (B) with δ_1-filter

Fig. 2. Images of $3/4\,\lambda$ defocused system.

In order to ascertain the effect of this filter, w used as an appoximate filter the developed phot graphic plate of interferogram taken by Twyman lens interferometer, in which the objective to b tested was arranged to show the half amount o aberration due to defocusing, and the value of was adjusted by slight variation of the optical pat difference between two beams.

Thus, Fig. 2 (A) shows the nearly axial imag formed by $3\lambda/4$-defocused objective without filte and (B) with the filter of $\delta_1=5\pi/4$. The effect o improving the image is well recognized.

Angular Distribution of Proton Groups from the Reaction F^{19} (*d,p*) F^{20}

Kazuo ÔNO, Junji SHIMADA, Keiichi KURODA
and Shigeya TANAKA

Institute of Science & Technology,
University of Tokyo

Bromley et al(1) at Rochester University measured the angular distribution of the protons from the reaction F^{19} (*d,p*) F^{20} using 3.6 Mev. deuterons. From the results they concluded that the proton group from the reaction in the ground state of F^{20} was interpreted with a mixture of $1_n=0$ and $1_n=2$ stripping. After that, the same reaction was also investigated by Takemoto et al(2) with 0.75–1.45 Mev. deuterons and by Black(3) with 14.3 Mev. deuterons. These two results can not be available to determine whether F^{20} in the ground state is formed by capturing *s*-neutron or not, because in Takemoto's experiment the proton angular distribution is nearly isotropic, and in the other one's the angular distribution has been measured from 20 to 100 degrees, which indicates only the existence of captured *d*-neutrons.

Our experiments were begun in order to probe the angular distribution characterized by two 1_n values, which were obtained by Bromley et al. So we measured the proton angular distribution near angles of zero degree with great precautions.

Deuterons of energy 1.92 and 2.03 Mev. from the 16-inch variable energy cyclotron were used to bombard a thin PbF_2 target. The out-going protons were detected from −10° to 160° with 100 micron Sakura nuclear plate. The proton group of P_0 corresponding to the F^{20} in the ground state, and that of P_1 corresponding to the 0.65 Mev. level were clearly resolved. The proton angular distributions of our experiments are shown in Fig 1. The group P_1 shows a large peak at about 60°(c.m. angle) and it seems to be caused by the stripping process of *d*-neutrons in good agreement with the results obtained hitherto.

On the contrary, the angular distribution of P_0 shows no peak at 0° and a large peak in the backward direction. These results at our bombarding energies indicate that the reaction proceeds mostly by compound nucleus formation. Recently, Rochester group(4) has repeated the previous experiment with the deuteron energy in the range 3.5–4.0 Mev. and they have obtained the same results with ours.

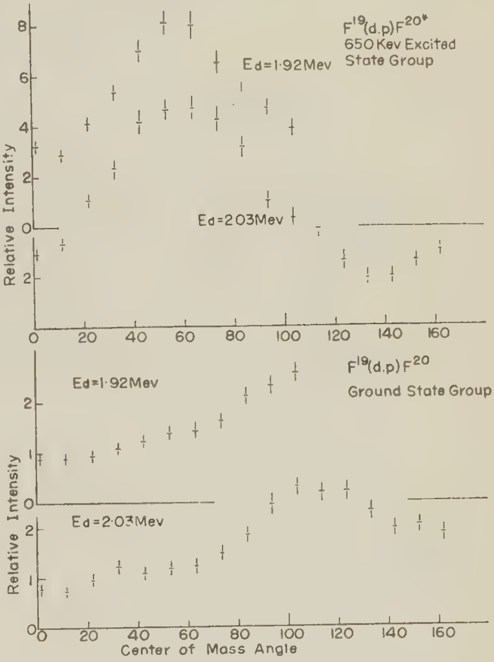

Fig. 1. Angular distribution of protons leaving F^{20} from F^{19} (*d,p*) F^{20}.

We are indepted to Professor T. Muto and Professor H. Kumagai for valuable discussions and contineous encouragements. We also thank to Mr. Y. Wakabayashi of Konishiroku Photo Manufacturing Co. for supplying nuclear plates for us.

On the Analysis of the Slow Particles Emitted from Cosmic-Ray Stars (II)

By Shigeo NAKAGAWA, Eiji TAMAI, Humiaki HUZITA and Kiyoaki OKUDAIRA

Department of Physics, Rikkyo (St. Paul's) University, Ikebukuro, Tokyo, Japan

(Received February 21, 1957)

Observations have been made on the heavy fragments from stars produced by cosmic-rays and 6.2 BeV protons from the Bevatrons. The charges of the heavy fragments were determined by measuring the width of tracks.[1] The charge distribution of the heavy fragments emitted from silver or bromine nuclei seems approximately to decrease exponentially. The energy distributions of lithium and beryllium nearly agreed with the curves deduced from the evaporation model, assuming the appropriate nuclear temperatures and Coulomb barrier heights. The angular distributions of them were nearly isotropic. According to these results, the process of slow fragment emission seems to be interpreted as that of evaporation.

§ 1. Introduction

Studies of heavy fragments associated with cosmic ray stars have been made by several investigators.[2] Perkins[3] analysed the heavy fragments, both stable and unstable, emitted from heavy nuclei contained in C2 and G5 emulsions exposed at high altitude. He found that fragment emission might be interpreted in terms of an asymmetric fission process. Recently, Munir[4] reported[8] Li fragments from proton induced stars at 950 MeV, and found that they were ejected as part of the cascade process in the heavy nuclei. In the present paper we have also examined the fragments emitted from heavy nuclei (Ag or Br) of G5 emulsions exposed to cosmic rays in the high altitude and 6.2 BeV proton beam of Bevatron. 155 heavy fragments have been analysed from 1450 cosmic ray stars of more than 8 prongs. In the plates exposed to the Bevatron beam, 62 measurable heavy fragments have been observed in 680 stars. Distributions of charges, energies, and emission angles of the heavy fragments obtained from these two exposures were examined and in this paper the analysis of the relatively slow fragments were discussed.

§ 2. Experimental Procedure

G5 emulsions 600 microns thick were exposed for 3.5 hours to cosmic rays at 27,000 m in England* and to 6.2 BeV proton beam of the Berkeley Bevatron.** As the emulsion contains several elements and the determination of the light target nuclei is rather difficult in the analysis of stars, we only measured the stars produced by Ag and Br in selecting those which had more than 8 prongs (grey tracks +black tracks). Moreover, as written in the previous paper,[1] the analysis of star prongs were made by selecting those which fitted to the following restrictions:

i) the tracks terminated in the emulsions,
ii) location of tracks were more than 20 microns apart from the surface and bottom of the emulsions,
iii) the dip angles of the tracks were less than 12.5° before processing of emulsion.

The mean width over 6 microns lengths of the track was measured step by step along the track from its end point using an eyepiece with secrew micrometer. Since it was found in the previous analysis[1] that the width of track was approximately proportional to $\sqrt{Z}$ (Z: atomic number), in this experiment also the charge of the stable fragments was determined by the track width. Fig. 1 shows one example of the distribution of the track width and from this figure, we can see that the separation of each group is good enough to identify the charge of the fragment. The identification of the unstable fragments was also made according to the method given by Perkins.3) In the analysis we observed only

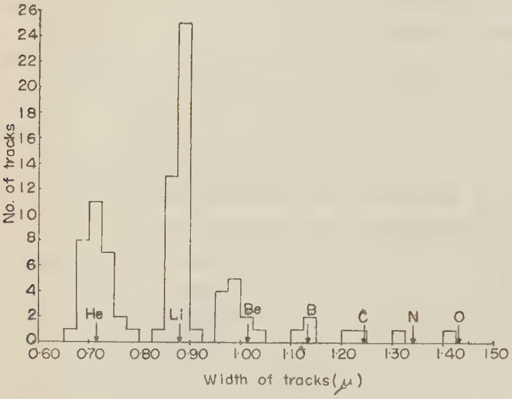

Fig. 1. Distribution of track width. The arrows show the estimated width of the each group by assuming the proportionality of the width to $\sqrt{Z}$. In the case of He we analysed the tracks from Radio Thorium stars in the emulsion.

the simpler cases such as

i) ^{8}Be→2^{4}He disintegration,

ii) ^{9}B →2^{4}He+H^1 disintegration,

and in the more complex cases we could not obtain any clear event. Besides these, we have of course observed the "hammer tracks" due to ^{8}Li and ^{8}B. However, as the "recoil fragments" always have ranges of less than 10 microns,5) our observations were restricted to the fragments of ranges in excess of 25 microns.

§3. Experimental Results

3·1. *Charge distribution of heavy fragments*

In this experiments we analysed the fragments which have charge $Z \geqq 3$. The number of fragments, are given in Table I (A) and I (B). In these Tables, (A) represents the charge distribution of heavy fragments emitted from cosmic ray stars and (B) shows that from the stars produced by the Bevatron proton beam. Total number of observed fragments of (A) and (B) are 155 and 62, respectively.

Table I. (A) Cosmic ray

Z	3	4	5	6	7	8	—	13	total
Observed	95	38	16	2	2	1	—	1	155
Corrected	468±47	179±29	73±18	11±8	7±5	4±4	—	4±4	750
Frequency/star	0.32	0.12	0.05	—	—	—	—	—	—

(B) Accelerator (Bevatron) beam

Z	3	4	5	6	7	total
Observed	37	14	5	4	2	62
Corrected	168±27	63±17	22±10	18±9	9±6	280
Frequency/star	0.25	0.09	0.03	—	—	—

These frequencies were corrected for

(i) geometrical loss of long tracks out of the emulsion layer, (ii) restriction in dip angle ($\theta \leqq 12.5°$), (iii) location of star in the emulsion, on the assumption that the distribution of tracks is isotropic. The assumption of isotropic distribution seems to be correct in the case of the slow fragments as will be seen in section 3·3.

The corrected frequencies of heavy fragments ($Z \geqq 3$) in both (A) and (B) case are equally about 0.5 per star and it seems to show that the emission probability does not depend on the incident proton energy above 6.2 BeV.

Fig. 2 shows the charge distributions of the fragments which have the energies greater than the Coulomb potential barrier heights experimentally deduced, as indicated in Fig. 3 and 4, and the three plots were done according to the star sizes (1) 9–14 prongs, (2) 15–28 prongs, (3) 9–28 prongs in the case of cosmic ray stars. In the Bevatron case we obtained the curve (4). It is seen that the four curves are similar in shape and show a exponential decrease when the charge Z increases, although the statistical error is yet large at the region of higher charges. This decrease can be represented approximately by the following formula:

$$F \propto \exp(-Z)\,,$$

where F is the frequency of the heavy fragment of the charge Z.

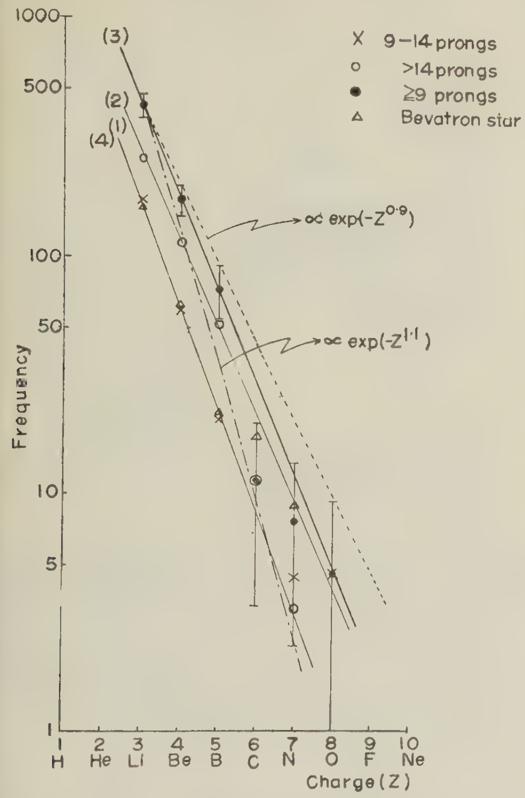

Fig. 2. Charge distribution of heavy fragments from cosmic ray stars with (1) 9 to 14 prongs; (2) >14 prongs; (3) ≥9 prongs. The plot of (4) was obtained from 6.2 BeV proton induced stars.

3·2. *Energy distribution of fragments*

The energies of the heavy fragments were obtained by measuring their ranges. Although the range-energy relation is not well established for slow heavy particles, some uncertainty of energies of the slower particles does not appreciably change the energy distribution. The energy distribution of Li fragments emitted from cosmic ray stars in the center of mass system is shown in Fig. 3. The full curve shows the theoretical evaporation distribution and is plotted after the following formula[6]:

$$N(E)dE = \frac{(E-V)}{T^2}\cdot\exp\left(-\frac{E-V}{T}\right)dE \qquad \text{for } E>V,$$

in which V means the average Coulomb barrier height during the evaporation process and T is the nuclear temperature. The value of V was calculated as 15 MeV (corresponding to $Z=34$, $A=79$) and that of T was given as 10 MeV to fit to the experimental histogram. Fig. 4 shows the energy distribution histogram of Be fragments in the center of mass system. In this case since the data of Be fragments from the cosmic ray induced stars were not sufficient in number, those from 6.2 BeV proton stars were added. In this figure, also the full curve was obtained from the evaporation theory, using the values $T=10$ MeV, $V=19$ MeV. It is found that the both experimental distributions are in good agreement with the calculated ones, except the lower energy region.

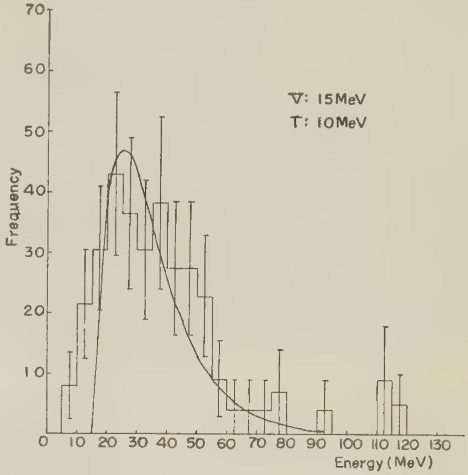

Fig. 3. Energy distribution of Li fragments in the center of mass system.

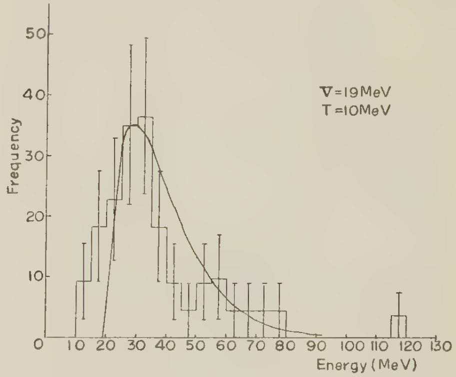

Fig. 4. Energy distribution of Be fragments in the center of mass system.

This excess of slow particles was discussed by several authors[7] on the case of α-particle.

They suggested that these slow particles may be due to expansion of nuclear volume or to secondary emission from the fragment emitted by the fission of mother nuclei. On the case of Li and Be, also slow particle excess was shown but we are not sure whether this is due to the above suggestion or to the emission at the near end of successive evaporation process.

We observed about ten more energetic fragments emitted from the stars and whether these fragments form a tail of the main distribution or are generated by a knock-on process is not certain. This point will be further studied. Fig. 5 and 6 show the energy distributions of protons and α-particles. There were plotted in the center of mass system from that in the laboratory of the previous paper.[1] The temperatures deduced from this figures are 3 and 5 MeV in proton and α-particle cases respectively. It seems to be interesting that the mean temperature is lower in emitting lighter particles than heavier ones.

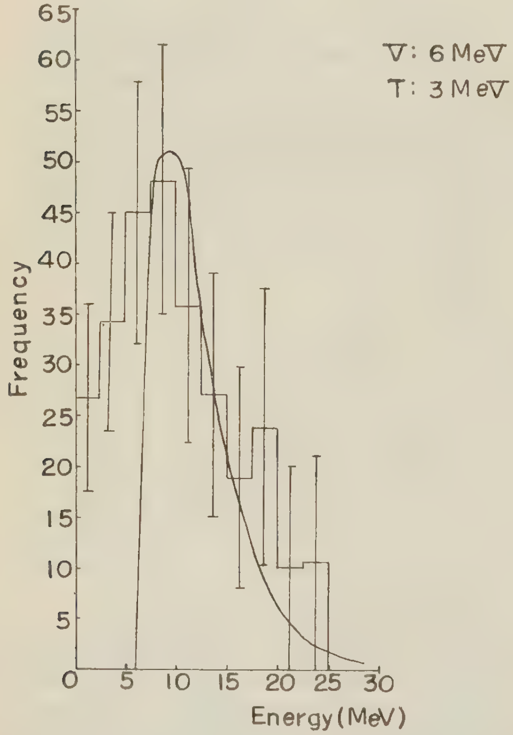

Fig. 5. Energy distribution of protons in the center of mass system.

For the fragments with charge $Z \geqq 5$ the statistics are now poor for describing the energy distribution.

3·3. *Angular distribution of fragments*

For obtaining the angular distribution, the analysis of the nuclear plates exposed to the Bevatron beam is available. In this case the incident protons lay nearly in the plane paral- lel to the emulsion surface and the dip angles of the heavy fragments in our measurement are less than 12.5°, so that measured angular distribution may approximately indicate the true distribution. Fig. 7 shows the angular distribution of the fragments $Z \geqq 3$ emitted from 6.2 BeV proton induced stars. The histogram seems to indicate nearly the isotropic angular distribution. In Fig. 8 the data is replotted in the center of mass system by correcting the forward motion of target nucleus. Considering the slower particles emitted backwards lost in the measurement by the forward motion of target nucleus, these two figures

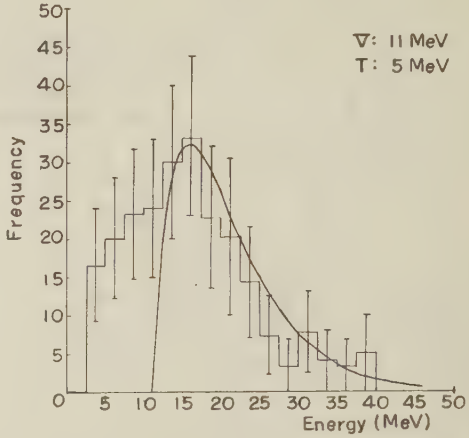

Fig. 6. Energy distribution of α-particles in the center of mass system.

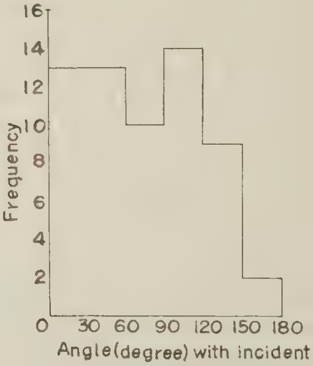

Fig. 7. Angular distribution of the fragments ($Z \geqq 3$) emitted from 6.2 BeV proton induced stars.

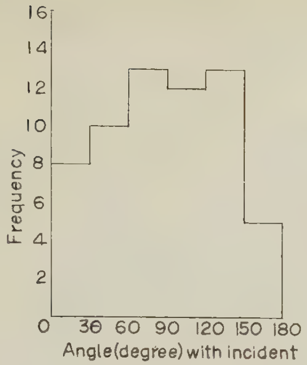

Fig. 8. Corrected angular distribution for the distribution of Fig. 7.

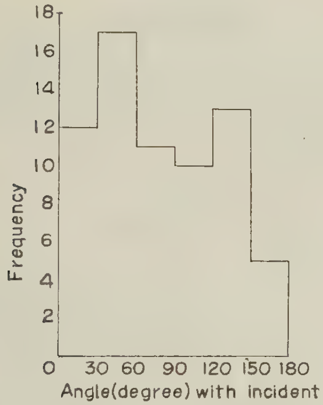

Fig. 9. Angular distribution of Li fragments (slow) emitted from the cosmic ray stars.

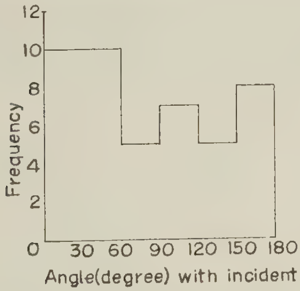

Fig. 10. Angular distribution of the higher charged fragments ($Z\geq 4$) emitted from the cosmic ray stars.

fairly represent the isotropic distributions of the emitted fragments. In Fig. 9 and 10, the distributions of fragments from the cosmic ray stars are shown. These figures also shows the nearly same distributions as in the case of the Bevatron exposure. So it seems to be that the angular distribution of the slow fragments emitted from the stars is isotropic and according to this conclusion, we corrected the frequency and energy distributions as was described in 3·1 and 3·2. In Fig. 11, the angular distribution of the more energetic fragments of $Z\geq 3$ is shown, although the data are poor. This distribution shows strongly collimated in the direction of the star-producing particle.

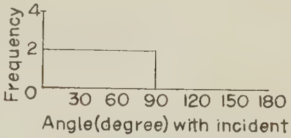

Fig. 11. Angular distribution of the more energetic fragments ($Z\geq 3$) from cosmic ray stars.

§ 4. Interpretation

The results of the measurements may be summarized as follows:

(a) At high excitation energies (the number of star prong is more than 8), a heavy fragment is emitted from a silver or bromine nucleus, with a probability of 0.5.

(b) The charge distribution of these emitted at high excitation energy ($U\sim 800$ MeV) seems nearly to decrease exponentially.

(c) The both energy spectra of the lithium and the beryllium fragments (slow) approximately agree with the calculated spectra assuming the appropriate nuclear temperature and Coulomb potential.

(d) The angular distribution of the Li fragments and that of the fragments of $Z\geq 4$ are nearly isotropic, except the more energetic fragments.

On the basis of the above results described in (c) and (d), the most suitable model to explain the emission of the slow fragments, at least Li and Be fragments, from the nuclei Ag or Br seems to be due to the evaporation process. The most suitable value of nuclear temperature T is 10 MeV in both cases of Li and Be, although, on account of poor statistics, the nuclear temperature could not be analysed more precisely by classifying the star size. We can estimate the excitation energy U of the parent nucleus (Ag or Br) using the following relation,8)

$$U=aT^2\lesssim 800\text{ MeV}, \quad a=\text{const},$$

assuming the Fermi gas model. And this value is comparable to the total nuclear binding energy of Ag or Br nucleus. In the cases of proton and α-particle emissions, the nuclear temperatures were evaluated as 3 and 5 MeV (Fig. 5 and Fig. 6), respectively, so the excitation energy of nucleus becomes higher for emission of heavy fragments. We are not assured that in both Li and Be cases the 10 MeV temperature indicates the true one, however, it seems to be probable that the emission of heavy fragments takes place at higher excitation energy state than proton and α-particle. As the temperature of nucleus is roughly same for Li and Be and it amounts nearly to the highest excitation state of nucleus, we can consider that the more heavier particles may probably be emitted at nearly same condition of nucleus. On discussion more detail, the data of heavier fragments $Z \geqq 5$ are not yet sufficient and we are now accumulating more data on these.

However, it is very interesting to examine the emission probability of various particles from the definite excited state of nuclei and to obtain some informations, especially on the existence or formation probabilities of heavy fragments in the nucleus. From this point of view the exponential decrease of Z dependence of emitted fragments may give us some clue, provided that more precise knowledge may be obtained. Above obtained results indicate only the mean value of emission probability, and so it is necessary to obtain more precise knowledge, that is, by classifying the star size. And also the investigation of more energetic particles emitted from the nuclei may give us important data.

Acknowledgement

We should like to express our sincere thanks to Professor C. F. Powell of the University of Bristol for kindly sending us the nuclear plates exposed to cosmic rays at high altitude, and we are much indebted to the Berkeley Bevatron group to give the chance to analyse the plates exposed to the Bevatron beam. Also the assistance of Mr. S. Nomoto is highly appreciated. This work was partially financed by the Scientific Research Fund from the Ministry of Education.

Cluster Variation Method of Cooperative Phenomena and its Generalization I

By Tohru MORITA

Physics Department, Tokyo Institute of Technology

(Received March 6, 1957)

The cluster variation method of approximation for the cooperative phenomena in the lattice system is generalized so as to be applicable to the cases where the range of the interaction is long compared to the distance of neighboring (lattice) points.

The cluster variation method*) was originally proposed by Kikuchi[1)] and Kurata, Kikuchi and Watari[2)] and applied to lattice systems with the nearest neighbor interaction[1)2)], and then extended by Kikuchi[3)] to those with the 2nd and 3rd neighbor interactions. However, it is difficult to apply this method in its original form to cases where the interaction is of much longer range. In this paper a formulation of the method will be proposed which is valid independently of the kind of lattice structure and is applicable to cases where the range of interaction is long compared to the distance of neighboring (lattice) points.

The system to be considered in this paper is one which is characterized by the following three conditions: 1) The configuration of the system is described by the configurations of L fixed points in it. 2) The possible configurations x_i for the i-th point $(i=1, 2, \cdots, L)$ are denoted by $\alpha_i, \beta_i \cdots, \nu_i$. 3) The potential energy of the system is given by

$$\Phi(x_1, x_2, \cdots, x_L) = \sum_{i=1}^{L} V^{(1)}(x_i) + \frac{1}{2} \sum_{\substack{i=1 \\ (i \neq j)}}^{L} \sum_{j=1}^{L} V^{(2)}(x_i, x_j) + \frac{1}{3!} \sum \sum \sum V^{(3)} + \cdots \tag{1}$$

for the configuration $(x_1, x_2, \cdots, x_L)$.

Our problem is to calculate the free energy of the system. The free energy is given by the minimum value of

$$F = \sum_{x_1=\alpha_1}^{\nu_1} \sum_{x_2=\alpha_2}^{\nu_2} \cdots \sum_{x_L=\alpha_L}^{\nu_L} \rho^{(L)}(x_1, x_2, \cdots, x_L) \times \Phi(x_1, x_2, \cdots, x_L) + kT \sum_{x_1=\alpha_1}^{\nu_1} \sum_{x_2=\alpha_2}^{\nu_2} \cdots \sum_{x_L=\alpha_L}^{\nu_L} \rho^{(L)}(x_1, x_2, \cdots, x_L) \times \ln \rho^{(L)}(x_1, x_2, \cdots, x_L) \tag{2}$$

for the variation of the probability distribution function $\rho^{(L)}(x_1, \cdots, x_L)$, the variation being restricted by the normalization condition

$$\sum_{x_1=\alpha_1}^{\nu_1} \sum_{x_2=\alpha_2}^{\nu_2} \cdots \sum_{x_L=\alpha_L}^{\nu_L} \rho^{(L)}(x_1, x_2, \cdots, x_L) = 1 . \tag{3}$$

Some approximate procedures will be necessary to find the minimum value of F.

For this purpose we introduce clusters of points, a cluster meaning any set of points from L fixed points. Then we introduce several functions connected with a cluster $(i_1, \cdots, i_n)$, $(1 \leq i_1 < i_2 < \cdots < i_n \leq L;\ n=1, 2, \cdots, L)$: The probability distribution function $\rho^{(n)}(x_{i_1}, \cdots, x_{i_n})$ defined by

$$\rho^{(n)}(x_{i_1}, \cdots, x_{i_n}) = \sum_{x_1'=\alpha_1}^{\nu_1} \cdots \sum_{x_L'=\alpha_L}^{\nu_L} \prod_{s=1}^{n} \delta_{x_{i_s}, x_{i_s}'} \rho^{(L)}(x_1', \cdots, x_L'), \tag{4}$$

the correlation function $g^{(n)}(x_{i_1}, \cdots, x_{i_n})$ defined by

$$\rho^{(2)}(x_i, x_j) = \rho^{(1)}(x_i) \rho^{(1)}(x_j) g^{(2)}(x_i, x_j) \tag{5''}$$

$$\rho^{(3)}(x_i, x_j, x_k) = \rho^{(1)}(x_i) \rho^{(1)}(x_j) \rho^{(1)}(x_k) g^{(2)}(x_i, x_j) \times g^{(2)}(x_j, x_k) g^{(2)}(x_i, x_k) g^{(3)}(x_i, x_j, x_k) \tag{5'''}$$

$$\cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot$$

$$\rho^{(L)}(x_1, \cdots, x_L) = \prod_{i=1}^{L} \rho^{(1)}(x_i) \prod_{i>j} g^{(2)}(x_i, x_j) \times \Pi\, g^{(3)} \cdots g^{(L)}(x_1, \cdots, x_L) , \tag{5^L}$$

and the function $G^{(n)}(i_1, \cdots, i_n)$ defined by

$$\ln G^{(n)}(i_1, \cdots, i_n) = - \sum_{x_{i_1}=\alpha_{i_1}}^{\nu_{i_1}} \cdots \sum_{x_{i_n}=\alpha_{i_n}}^{\nu_{i_n}} \rho^{(n)}(x_{i_1}, \cdots, x_{i_n}) \times \ln \rho^{(n)}(x_{i_1}, \cdots, x_{i_n}) . \tag{6}$$

The last function $G^{(n)}(i_1, \cdots, i_n)$ has been introduced by the following considerations. When we consider an ensemble of M ($M\to\infty$) similar systems to ours, $[G^{(n)}(i_1,\cdots,i_n)]^M$ is equal to the number of ways in which each of the M systems can be in one of the configurations $(x_{i_1},\cdots,x_{i_n})$ in such a way that $M\rho^{(n)}(x_{i_1}\cdots,x_{i_n})$ systems among M systems are in configuration $(x_{i_1},\cdots,x_{i_n})$, so that $[G^{(n)}(i_1,\cdots,i_n)]^M$ is equal to

---

* Full references on this method are found in reference 2.

$$M!\Big/\prod_{x_{i_1}=\alpha_{i_1}}^{\nu_{i_1}}\cdots\prod_{x_{i_n}=\alpha_{i_n}}^{\nu_{i_n}}(\rho^{(n)}(x_{i_1},\cdots,x_{i_n})M)!$$

and (6) follows from this in the limit $M\to\infty$. It will be noticed that $\ln G^{(n)}(i_1,\cdots,i_n)$ is of a nature of entropy for cluster $(i_1,\cdots,i_n)$. Next, we introduce functions $F^{(n)}(i_1,\cdots,i_n)$ given by

$$G^{(2)}(i,j)=G^{(1)}(i)\,G^{(1)}(j)F^{(2)}(i,j) \qquad (7'')$$

$$G^{(3)}(i,j,k)=G^{(1)}(i)G^{(1)}(j)\,G^{(1)}(k)\,F^{(2)}(i,j)\times F^{(2)}(j,k)F^{(3)}(i,k)F^{(3)}(i,j,k)$$

$$\cdots\cdots \qquad (7''')$$

$$G^{(L)}(1,\cdots,L)=\prod_{i=1}^{L}G^{(1)}(i)\prod_{i>j}F^{(2)}(i,j)\times\prod F^{(3)}\cdots F^{(L)}(1,\cdots,L)\,, \qquad (7^L)$$

and note that from these difinitions we have

$$\ln F^{(n)}(i_1,\cdots,i_n)=-\sum_{x_{i_1}=\alpha_{i_1}}^{\nu_{i_1}}\cdots\sum_{x_{i_n}=\alpha_{i_n}}^{\nu_{i_n}}\rho^{(n)}(x_{i_1},\cdots,x_{i_n})\times\ln g^{(n)}(x_{i_1},\cdots,x_{i_n})\,. \qquad (8)$$

In the following we will adopt the approximations that $F^{(n)}=1$ for most of the clusters, so that it is desired to get some knowledges about the plausibility of the assumption $F^{(n)}=1$. First, from the definitions of $G^{(n)}$ and $F^{(n)}$ and the meaning of $G^{(n)}$, $F^{(n)}$ for a cluster composed of groups of points far apart from each other can be taken to be nearly equal to unity. Secondly, some plausible discussions are found in Takagi's[4)] and Kikuchi's[1)2)] papers that $F^{(n)}$ for a large n may be approximated to 1.

By means of these functions, we rewrite (2) as

$$F=\sum_{i=1}^{L}\sum_{x_i=\alpha_i}^{\nu_i}\rho^{(1)}(x_i)V^{(1)}(x_i)+\frac{1}{2}\sum_{i=1}^{L}\sum_{\substack{j=1\\(i\neq j)}}^{L}\sum_{x_i=\alpha_i}^{\nu_i}\sum_{x_j=\alpha_j}^{\nu_j}\rho^{(2)}(x_i,x_j)V^{(2)}(x_i,x_j)+\frac{1}{3!}\sum\cdots\sum\rho^{(3)}V^{(3)}$$
$$+\cdots+kT\left[\sum_{i=1}^{L}\ln G^{(1)}(i)+\sum_{i>j}\ln F^{(2)}(i,j)+\sum\sum\sum\ln F^{(3)}+\cdots+\ln F^{(L)}(1,\cdots,L)\right]. \qquad (9)$$

The minimum value of this cannot be calculated if no approximate procedures are adopted.

The cluster variation method is as follows: We divide 2^L-1 clusters into two groups, "preserved clusters" and "not-preserved clusters". In the following, if the cluster of points $(i_1,\cdots,i_n)$ belongs to the group of preserved clusters, $F^{(n)}(i_1,\cdots,i_n)$, $G^{(n)}(i_1,\cdots,i_n)$, $\rho^{(n)}(x_{i_1},\cdots,x_{i_n})$ and $g^{(n)}(x_{i_1},\cdots,x_{i_n})$ will be called functions for a preserved cluster or briefly the preserved $F^{(n)}$, $G^{(n)}$, $\rho^{(n)}$ and $g^{(n)}$, and if otherwise they will be called not-preserved functions. Using (5) and (7) we rewrite the right-hand side of (9) so as to express the first row in terms of the preserved $\rho^{(n)}$ and the not-preserved $g^{(n)}$ with no not-preserved $\rho^{(n)}$ or preserved $g^{(n)}$ and the second row in terms of the preserved $G^{(n)}$ and the not-preserved $F^{(n)}$ with no not-preserved $G^{(n)}$ or preserved $F^{(n)}$. In the expression for F thus obtained, we equate $F^{(n)}$ and $g^{(n)}$ to 1**), and make use of (6) for the preserved $G^{(n)}$. Then function F can be expressed in terms of the preserved $\rho^{(n)}$'s only. Now we let this approximate expression for F take the minimum value with respect to the preserved $\rho^{(n)}$'s, where we notice that there exist the recurrence relations

$$\rho^{(s-1)}(x_{i_1},\cdots,x_{i_{s-1}})=\sum_{x_{i_s}=\alpha_{i_s}}^{\nu_{i_s}}\cdots\sum_{x_{i_n}=\alpha_{i_n}}^{\nu_{i_n}}\rho^{(n)}(x_{i_1},\cdots,x_{i_{s-1}},x_{i_s},\cdots,x_{i_n}) \qquad (10)$$

between two preserved $\rho^{(s-1)}$ and $\rho^{(n)}$ and the normalization conditions

$$\sum_{x_{i_1}=\alpha_{i_1}}^{\nu_{i_1}}\cdots\sum_{x_{i_n}=\alpha_{i_n}}^{\nu_{i_n}}\rho^{(n)}(x_{i_1},\cdots,x_{i_n})=1 \qquad (11)$$

for preserved $\rho^{(n)}$'s; Eqs. (10) and (11) follow from the definition of $\rho^{(n)}$, Eq. (4), and the normalization condition for $\rho^{(L)}$, Eq. (3). The minimum value obtained can be considered to be an approximate value to the exact free energy.

Which clusters are to be the "preserved" ones is to be decided from the physical considerations. The approximation will generally become better if we have more preserved clusters in our theory*).

---

* To equate $g^{(n)}$ for any configuration for not-preserved clusters constitutes an extension of the superposition approximation introduced by Kirkwood.

In the development by Kikuchi et al., the preserved clusters are lattice points, bonds of nearest neighbor lattice points and also polygons and polyhedrons which are composed of the bonds; the approximation has been shown to be generally improved as larger clusters are preserved*). It is easily shown that for nearest neighbor interacting systems, their bond approximation is equivalent to our pair approximation where the preserved clusters are all pairs of L points.

As to the degree of approximation of our method, nothing can be said from our formulation, but if the method is applied to a case where our approximations $F^{(n)}=1$ for not-preserved clusters are justified for $\rho^{(L)}=\exp[(F-\Phi)/kT]$, our variation gives an underestimated value for the free energy.

We have considered a system which satisfies 1), 2) and 3). However, we can easily generalize the method to apply to cases where the possible configurations x_i are continuous.

Our scheme of formulation to introduce $G^{(n)}$ is due to Kikuchi. An equivalent formulation is obtained as follows: We substitute from (5^L) into $\ln\rho^{(L)}$ in Eq. (2) so as to obtain

$$\begin{aligned}F=&\sum_{i=1}^{L}\sum_{x_i=\alpha_i}^{\nu_i}\rho^{(1)}(x_i)V^{(1)}(x_i)+\sum_{i>j}\sum_{x_i=\alpha_i}^{\nu_i}\sum_{x_j=\alpha_j}^{\nu_j}\rho^{(2)}(x_i,x_j)V^{(2)}(x_i,x_j)+\sum\cdots\sum\rho^{(3)}V^{(3)}+\cdots\\&+kT\Bigg[\sum_{i=1}^{L}\sum_{x_i=\alpha_i}^{\nu_i}\rho^{(1)}(x_i)\ln\rho^{(1)}(x_i)+\sum_{i>j}\sum_{x_i=\alpha_i}^{\nu_i}\sum_{x_j=\alpha_j}^{\nu_j}\rho^{(2)}(x_i,x_j)\ln g^{(2)}(x_i,x_j)+\sum\cdots\sum\rho^{(3)}\ln g^{(3)}\\&+\cdots+\sum\cdots\sum\rho^{(L)}\ln g^{(L)}\Bigg],\end{aligned}\tag{9'}$$

and express the right-hand side in terms of the preserved $\rho^{(n)}$ and the not-preserved $g^{(n)}$ with no not-preserved $\rho^{(n)}$ or preserved $g^{(n)}$, and finally equate $g^{(n)}$ to 1 in the expression for F**): it should be noted that to equate $g^{(n)}(x_{i_1},\cdots,x_{i_n})$ for any of configurations $(x_{i_s}=\alpha_{i_s},\cdots,\nu_{i_s};\ s=1,\cdots,n)$ to unity is to assume much more than to equate $F^{(n)}$ to unity for the same cluster**).

We have assumed in the above considerations that any configuration x_i is not degenerate. In case configuration x_i is $n(x_i)$-fold degenerate so that point i represents configuration x_i in $n(x_i)$ ways, $\rho^{(L)}\ln\rho^{(L)}$ in the second term in the right-hand side of (2) should be replaced by $\rho^{(L)}\ln\left[\rho^{(L)}(x_1,\cdots,x_L)/\prod_{i=1}^{L}n(x_i)\right]$ and so in the right-hand side of (9) and (9′) the term

$$-kT\sum_{i=1}^{L}\sum_{x_i=\alpha_i}^{\nu_i}\rho^{(1)}(x_i)\ln n(x_i)\tag{12}$$

should be added. (This is obtained if we consider that allowed configurations of point i are $\alpha_{i1},\alpha_{i2},\cdots,\alpha_{in(\alpha_i)},\cdots,\nu_{i1},\cdots,\nu_{in(\nu_i)}$, which are all simple, and x_{ij} and x_{ik} $(j,k\leq n(x_i))$ are equally probable.)

In conclusion, it should be emphasized again that this scheme of approximation is applicable to the cases where the range of interaction is long compared to the distance of neighboring points. Applications of this method will be published in the near future for lattice gases composed of molecules with hard core and for liquids. The latter constitutes an example of the case of continuous configuration for points.

The author wishes to express his cordial thanks to Prof. A. Harasima and Dr. K. Hiroike for the former's continual guidance and the latter's suggestive discussions and also for their kind inspection of the manuscript.

* This point is illustrated for nearest neighbor interacting cases in ref. 1 and 2. An exception is also given in ref. 1.

** Note that $g^{(n)}=1$ for any configuration is followed by $F^{(n)}=1$, while the converse is not true: see Eq. (8).

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 7, JULY, 1957

Some Experiments on the Surface Field Effects in Germanium Single Crystals

By Makoto KIKUCHI

Electrotechnical Laboratory, Tokyo, Japan

(Received March 19, 1957)

From the combined measurements of the field effect on the surface conductance G and on the surface recombination velocity s, it has been found that φ_s (i.e., the difference between the Fermi level and the middle of the energy gap at the surface) drifts towards a negative value when the surface is kept in room air after being submitted to CP-4 etching. This drift is accompanied by a gradual growth of oxide layer on the surface, which has been checked by the observation of the relaxation effect. It is suggested from the results that $s\sim\varphi_s$ curves calculated by Stevenson el al[16] must be shifted by 0.1–0.2 Volts towards right.

§ 1. Introduction

It has already been observed that the surface conductance of a germanium single crystal varies with the electric field applied perpendicular to the surface. The first experiment of this kind was performed by Pearson and Shockley[1], which gave strong evidence for the existence of the "surface states". The remarkable progress in the experiments and theories on the surface field effect, however, has been made in these three years.

By using suitable experimental apparatus, Montgomery[2] succeeded in seeing the variation of the surface conductance with applied transverse field directly on an oscilloscope. Thomas and others[3] performed the similar experiments on the variation of surface recombination velocity s using an alloyed junction diode, taking the saturation current as a measure of s. A number of experimental results on the field effect have been reported in these three years[4–17].

On the other hand, the models for the interpretation of surface phenomena have become quite clear. For instance, we can calculate the variation of the surface conductance G as a function of φ_s (the difference between the Fermi level and the middle of energy gap at the surface), using Schrieffer's calculation of the mobility[18]. As for the surface recombination velocity s, we have a work by Stevenson et al[19] on the basis of Shockley-Read model[20] for the recombination through deathnium centers.

The purposes of this paper are to find more evidences for the models accepted at present, and to find informations for clarifying the mechanisms underlying "relaxation effects." The experiment was at first planned

1. to find variation of surface recambination velocity s with applied field,
2. to measure the accompanying chang of s and G,
3. to observe the relaxation effects in G and s.

On the course of the study, however, it has been found out that it is possible to see the variation of φ_s qualitatively from the experimental results. It has also been intended, therefore, to observe the change of φ_s in the room air after CP-4 etching.

On the other hand, the experimental results on the relaxation effect has shown that the oxide layer gradually grows up in the room air after the etching.

The experimental apparatus and the results are mentioned in the following sections, and the discussions will be given in the last section in some detail.

§ 2. Experimental Procedures

The experimental apparatus is shown in Fig. 1 with schematic diagrams of the measuring circuits. A light beam of about 50 microns in width which is chopped at 200 c.p.s. is focused on the upper surface of the specimen. A thin mica plate is sandwiched between the specimen and a fine metal mesh, as a spacer. A voltage V_p of either plus or minus 1,000 volts are applied to this mesh plate from the d.c. voltage source to cause the field effect. A constant d.c. current I is supplied to the specimen and the variation of the surface conductance G is measured as the variation of the voltage across the specimen by means of a d.c. V.T.V.M. The voltage signal of 200 c.p.s. across the resistor R_0 is measured as a measure of surface recombination velocity. Of course, leakage current through the mica spacer and undesirable disturbances of 50 c.p.s. are checked by inserting high sensitivity ampere-meters in proper places in the circuits.

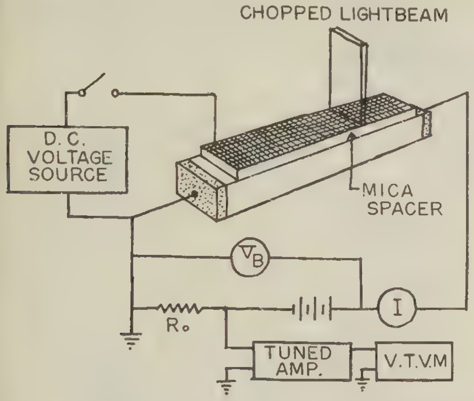

Fig. 1. Experimental apparatus and the measuring circuits.

For the p-n junction experiments, the rod specimen in Fig. 1 is replaced by a germanium grown p-n junction bar.

The specimens used in this work are a grown p-n junction bar and a single crystal rod. The junction was prepared by zone leveling, whose n-side is Sb-doped 2Ω cm, and p-side is In-doped 40Ω cm. The rod specimen is n-type 25Ω cm, which was cut from an Sb-doped pulled single crystal. When the photoresponse is measured as a function of distance, the specimen is moved by the micromanipulator on which it is mounted.

§ 3. Experimental Results

A. *p-n junction experiments*

The photoresponse was measured as a function of distance along the reverse biased p-n junction. When the voltage V_p of +1000 volts is suddenly applied, the photoresponse R_p decreases nearly instantaneously[21] on the n-side and the magnitude of this decrease is greater for larger distances from the junction. On the p-side, however, almost no change is observed in the photoresponse. The results are shown in Fig. 2. (Similar result was observed when the open-circuited photovoltage across the junction was measured instead of the photocurrent.)

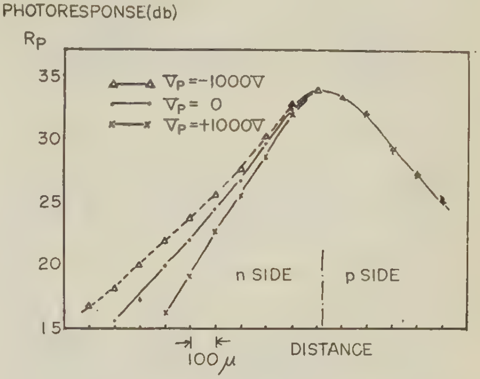

Fig. 2. The local photoresponse as a function of distance along the junction bar with and without the applied voltage V_p.

When V_p of either +1000 or −1000 volts is applied, also the voltage across the junction (V_B) varies instantaneously. It has been observed that these instantaneous change in V_B and R_p is followed by slow decay as shown Fig. 3.

These relaxation effects in V_B and R_p occur in a sense that they tend to recover the values before applying voltage V_p. In the

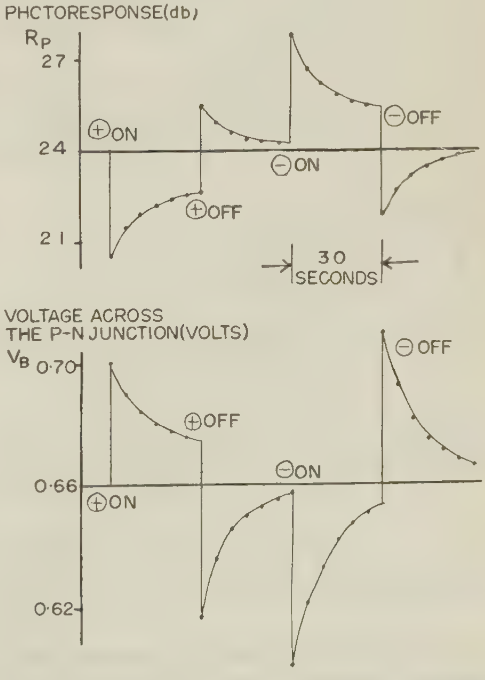

Fig. 3. Accompanying variation of R_p and V_B and the relaxation effect on the p–n junction.

case of Fig. 3, they reach the equilibrium values in 40–50 seconds, but the decay curves can not in general be expressed in a simple exponential function. An example of the time dependence of the photoresponse after "on" and "off" of −1000 volts is shown in Fig. 4.

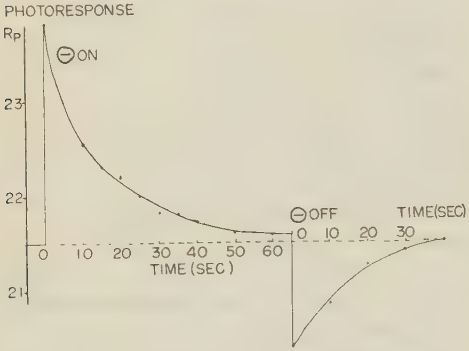

Fig. 4. Example of the relaxation effect.

The time constant, although it can not be defined well, has been found to change under certain surface treatments. For instance, when the surface is etched by CP-4 for 15 minutes, the decay occurs in a very short time. Sometimes, it is very difficult to observe the first "instantaneous" change by applied field just after the CP-4 etching, since the recovery time constant becomes much less than the time constant of the indicator of the V.T.V.M.

If the surface is exposed to the room air, however, the time constant gradually increases as shown in Fig. 5. The decay time increases with the time of exposure in the room air after CP-4 etching. When the surface is exposed to O_3 just after CP-4 etching, the decay curve becomes as shown in th figure by a broken line (*e*).

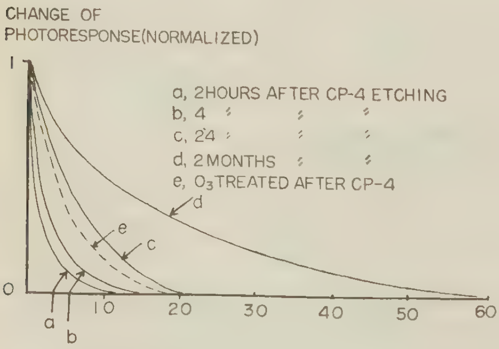

Fig. 5. Time dependence of the relaxation effect for different exposure time to the room air after CP-4 etching.

B. *Single crystal rod experiments*

Fig. 6 shows the results of the photoresponse as a function of distance along the single crystal rod for five different times after HF surface treatment. As is shown, the photoconductance increases after HF treatment, which shows that the surface recombination velocity *s* decreases also monotonically.

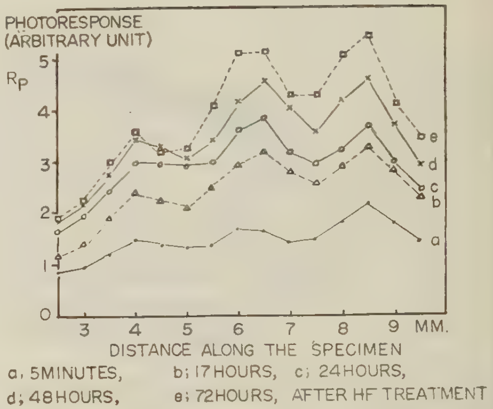

Fig. 6. Local photoresponse along the single crystal rod for different times after HF surface treatment.

When the d.c. voltage V_p is applied to the mesh plate, the photoresponse R_p and the surface conductance *G* vary with time as shown in Fig. 7.

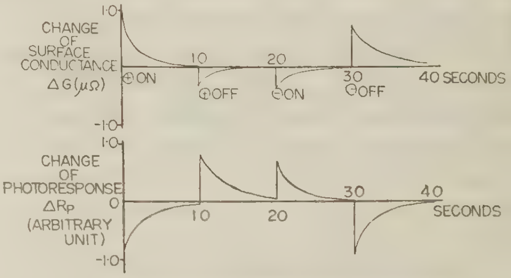

Fig. 7. Accompanying variation of surface conductance *G* and the surface recombination velocity *s* with the voltage V_p, and the "relaxation effect" on the single crystal rod.

It should be noticed that the result shown in Fig. 7 is the case of (b) in Fig. 6, i.e. 17 hours after HF treatment. In this case the relaxation effect occurs in about 10 seconds.

It has been observed that the instantaneou variations of the surface conductance and th photoresponse depend on the polarity of th applied voltage V_p both in sign and magnitude. The results are shown in Fig. 8 for the cases of a, b, c, d in Fig. 6, respectively.

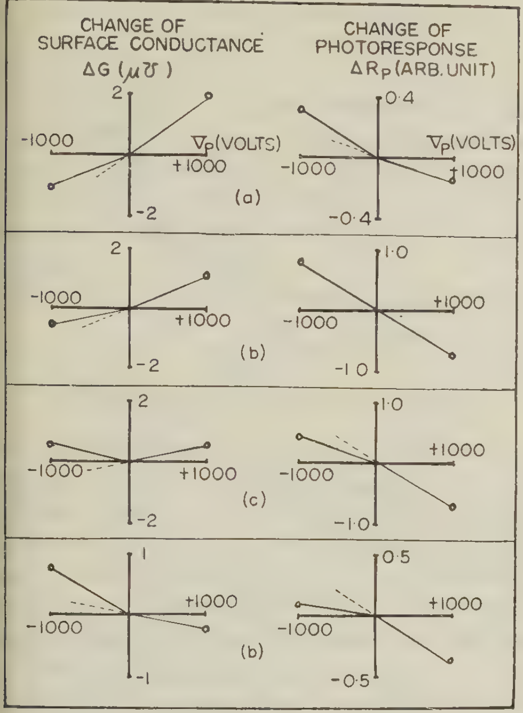

Fig. 8. The field effect on G and R_p of the single crystal rod. (a), (b), (c), (d) corresponding to (a), (b), (c), (d) in Fig. 6.

As is shown, the surface conductance increases with +1000 volts of V_p in the case of (a), while it decreases in (d). In the case of (c), it increases either with +1000 volts or −1000 volts in nearly the same magnitude. On the other hand, the magnitude of the variation of photoresponse R_p is greater for −1000 volts than +1000 volts of V_p in (a), while it becomes opposite in the case of (d). Since the accuracy of the measurements is high enough, above mentioned analysis is quite meaningful.

Fig. 9 shows the results of the same kind of measurements. Fig. 9 (a) is the result when the specimen is kept in high humidity ambient (~95% RH). When it is taken out from the high humidity ambient to the room air, it returns to the state shown in (c) within few minutes, passing through (b). It should be noted that the variation of G is larger in this case than in Fig. 8.

The time dependence of the relaxation effects is shown in Fig. 10 for the single crystal rod. These are the relaxation of the photoresponse (normalized), when +1000 volts of V_p is abruptly applied, for the cases of a, b, c, d and e in Fig. 6, respectively. The general trend is quite similar to the result observed on *p-n* junction.

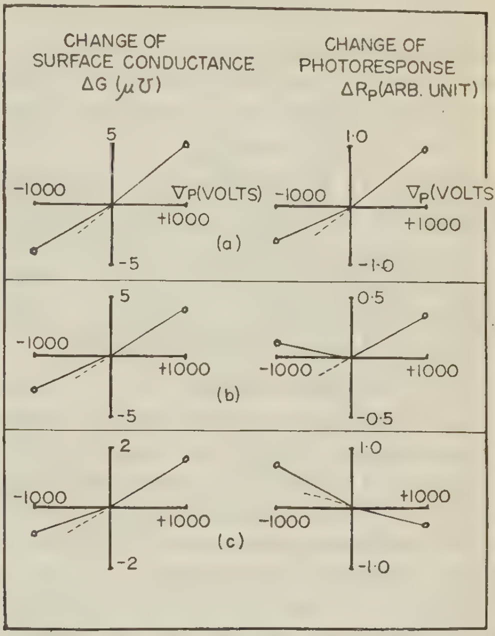

Fig. 9. The field effect on G and R_p of the single crystal rod. (a); in high humidity, (b), (c); when returned into the room air.

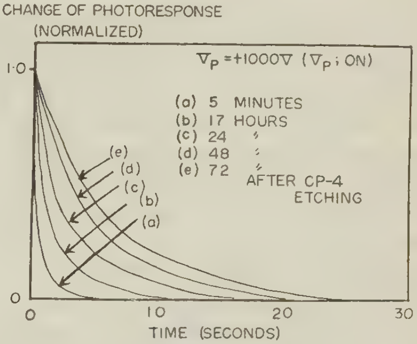

Fig. 10. Time dependence of the relaxation effect. (a), (b), (c), (d), (e) correspond to (a), (b), (c), (d), (e) in Fig. 6.

§ 4. Discussion

A. *Field effect on the surface recombination velocity s*

From the experimental results shown in Fig. 2 on *p-n* junction bar, we can conclude directly that the surface recombination velocity s on the n-side varies with the applied voltage V_p. The photoresponse R_p may be roughly written as a function of distance

$$R_p(x)=Ae^{-\frac{|x|}{L_p}}\,, \qquad (1)$$

where x is the distance from the junction, A is a constant, and L_p is the effective diffusion length, which in turn may be written;

$$L_p=\sqrt{D_m\tau_m} \qquad (2)$$

D_m, τ_m are the diffusion constant and effective lifetime of the minority carriers, respectively. As has been calculated by Shockley[23)], τ_m depends on the bulk lifetime τ_b, the surface recombination velocity s and also on some geometrical factors. Hence, in general,

$$\tau_m=F(\tau_b,\ s,\ \text{geometry})\,. \qquad (3)$$

It may well be expected that τ_m is a monotonic function of s, which decreases with increasing s. Since D_m, τ_b, and geometrical factors are kept constant during the field effect experiment, the result shown in Fig. 2, i.e., the variation of the slope of $\log R_p\sim x$ curve with V_p, may serve as a direct evidence for the field effect on the surface recombination velocity.

In Fig. 2, no field effect on s can be seen on the p-side, which will be discussed later.

B. *Accompanying variation of conductance G and surface recombination velocity s*

As are shown in Fig. 3, 4, for p-n junction and in Fig. 7 for single crystal rod, surface conductance G and surface recombination velocity s show accompanying variation in the field effect. These experimental results are qualitatively in good agreement with the work of Harrik et al[13)].

These results give also strong evidence for the fact that both the surface conductance and the surface recombination velocity are determined by common factors, one of which is the quantity φ_s as discussed later. The experimental fact, that the time dependence of the relaxation effect is almost same for G and s, shows that the relaxation occurs also through that common factor φ_s. The details are discussed in the following paragraph.

C. *The "drift" of φ_s in the room air*

Discussions on the results of Fig. 6, 8 and 9 will be given here. First, the quantity φ_s is defined as the energy difference between the Fermi level and the middle of the energy gap at the surface (Fig. 11). Roughly speaking, the sign of φ_s is plus for n-type surfac and minus for p-type surface.

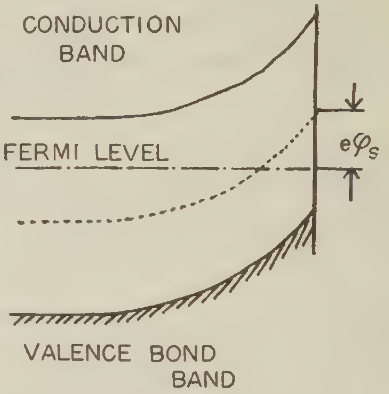

Fig. 11. Schematic energy diagram.

For simplicity, only the experimental result on single crystal rod are discussed. In thi case, the photoresponse R_p is proportional t the usual photoconductance, which in turn i a function of effective lifetime τ_m, since th thickness of the rod is much smaller tha the diffusion length of minority carriers an the d.c. current flowing in the specimen i small enough that sweeping-out effect is negligible. Hence,

$$R_p=A\Delta\sigma_p \qquad \text{(4}$$

$$=B\int_0^\infty e^{-\frac{\xi}{L_p}}d\xi=c\sqrt{\tau_m}\,. \qquad \text{(5}$$

According to Shockley's estimation[24)], th effective lifetime τ_m of a rod specimen whos cross-sectional dimensions are $2X$ and $2Y$ ma be expressed by;

$$\frac{1}{\tau_m}=\frac{1}{\tau_b}+\nu_s\,, \qquad \text{(6}$$

where τ_b is the bulk lifetime, and ν_s is written in the form;

$$\nu_s=s\left(\frac{1}{X}+\frac{1}{Y}\right), \qquad s\to 0 \qquad \text{(7}$$

$$\nu_s=\frac{\pi^2D_m}{4}\left(\frac{1}{X^2}+\frac{1}{Y^2}\right), \qquad s\to\infty\,. \qquad \text{(8}$$

Therefore, τ_m can be expressed;

$$\tau_m=\frac{1}{\frac{1}{\tau_b}+\alpha s}\,, \qquad s\to 0 \qquad \text{(9}$$

$$\tau_m=\frac{1}{\frac{1}{\tau_b}+\beta}\,, \qquad s\to\infty \qquad \text{(10}$$

where α, β are constants which includes th factor that s is varied only on one surface of the rod. Taking Eqs. (9), (10) and (4), (5) into consideration, $R_p \sim s$ curve is plotted qualitatively in Fig. 12.

On the other hand, according to the result of Stevenson's calculation[19)], s varies with φ_s as shown in Fig. 13 by a broken line. Combining the curves of $R_p \sim s$ in Fig. 12 with $s \sim \varphi_s$ in Fig. 13, we can obtain the shape of $R_p \sim \varphi_s$ curve as shown in Fig. 14. The position of the minimum of R_p in Fig. 14 is shifted towards right, which will be discussed later.

As for the surface conductance G, we can calculate it using the Schrieffer's estimation of the mobility[18)]. The solid curve in Fig. 14 is the $\Delta G \sim \varphi_s$ curve for n-type 25Ω cm sample.

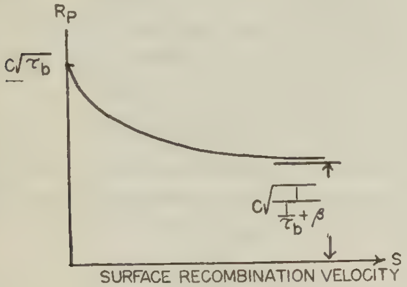

Fig. 12. Qualitative plotting of $R_p \sim s$ curve.

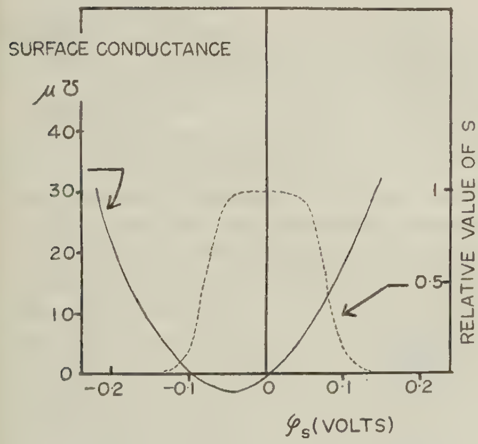

Fig. 13. $G \sim \varphi_s$, $s \sim \varphi_s$ curves.

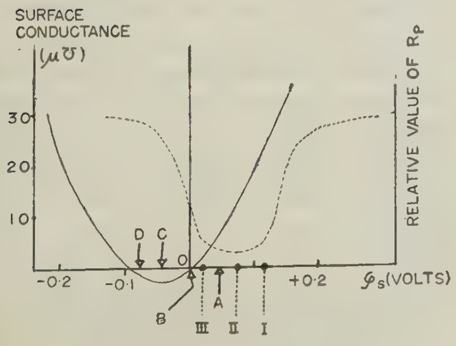

Fig. 14. $G \sim \varphi_s$, $R_p \sim \varphi_s$ curves.

Comparing the results of Fig. 8 with the curves in Fig. 14, it may be directly concluded, that the value of φ_s drifted from the point A to D on the φ_s axis in Fig. 14 when the etched surface was kept in the room air, since positive and negative values of V_p corresponds to the increase and decrease of φ_s, respectively. This conclusion is consistent with the result of Fig. 6.

If, in this process of estimation, the $R_p \sim \varphi_s$ curve were plotted without shifting towards right, it is impossible to obtain one unique point on the φ_s axis for one pair of the results of ΔG and ΔR_p. This means, therefore, that the curves obtained by Stevenson must be shifted towards right, which has been independently suggested by Harrik et al[13)].

The similar procedure applies to the result of Fig. 9, which shows that φ_s increases to the value of (I) in Fig. 14 in the high relative humidity ambient, and goes back to (III) passing through the point of R_p minimum when the specimen is again taken out to the room air.

From this standpoint, the result in Fig. 2, that no change of photoresponse occurs with V_p on the p-side of p-n junction bar, can be explained as that φ_s is just near the minimum point of $R_p \sim \varphi_s$ curve in Fig. 14.

This kind of procedure is quite reliable since it is qualitative rather than quantitative. For instance, the minimum of G or R_p can be directly checked by experiments.

D. *The relaxation effect*

The relaxation effects are already discussed by Kingston, Mcwhorter, and other workers on the model of two kinds of surface states. These surface states are usually called " fast " states and " slow " states. " Fast " states are localized between the germanium bulk and the germanium oxide layer and has the density of about 10^{11}/cm^2. They have time constant comparable to the lifetime of minority carriers, and they are believed to be responsible for the surface recombination. On the other hand, " slow " states exist in or on the outer surface of the oxide layer and have large density of about 10^{13}/cm^2.

When the external voltage V_p is applied, φ_s is changed in the time which is necessary for the readjustment of the carrier distribution through "fast" states. After that, gradual recovery of φ_s to the initial value occurs as the transport of electrons to the "slow" states goes on. This is the relaxation effect on the above mentioned model.

There are two standpoints in explaining the slow transport of electrons to the "slow" states. One is the jumping of electrons over the potential barrier of oxide layer with kinetic energy. The time constant τ of this process may be written in the form;

$$\tau=\tau_0 e^{-\frac{eH}{kT}}, \tag{11}$$

where H is the height of the potential barrier. Therefore, τ must be quite temperature dependent. Experimental results show, however, that τ is not temperature sensitive, so this may be not a predominant process.

The other standpoint is the transport by the tunnel effect. In this case, τ will have the form,

$$\tau=\tau_0 e^{\gamma W}, \tag{12}$$

where W is the thickness of the oxide layer.

According to the result in Fig. 5 and 10, the time constant is drastically decreased by CP–4 etching or *HF* treatment, both treatments are effective in removing the oxide layer on the surface. The time constant tends to increase when the etched surface is kept in the room air, which seems to show that W in Eq. (12) is increased. Brattain et al[25] have quoted the results of Heidenreich. Measuring the thickness of the oxide layer on germanium surface, he found it was 10 Å just after CP–4 etching, while it was increased to 20–50 Å after being aged in the air. Kingston[4] has reported that Green et al found 3 layers of the oxide 5 minutes after etching, and 6 layers after 3 days' exposure to the room air. These results are in agreement with our observations.

The experimental result in Fig. 5 that O_3 treatment increases the time constant of relaxation effect may be another evidence for the above mentioned model[26].

It might be concluded that the drift of φ_s in the air after *HF* treatment is either caused or accompanied by the gradual growing up of the oxide layer on the freshly etched surface.

As is well known, there are also two different theories for the explanation of non-exponential decay of relaxation effect. One is Mcwhorter's theory of multi-time-constants and the other is the theory of non-linea equation by Morrison. Both theories are clo sely related with the $1/f$ noise in semicon ductors. However, nothing has been checke on these problems in this work.

§ 5. Conclusion

By observing combined field effect on th surface conductance and surface recombinatio velocity, it has been found that φ_s drifts to wards some negative value when the surfac is kept in the room air after being submitte to CP–4 etching or *HF* treatment. This drif is accompanied by the gradual growth o oxide layer on the surface, which has bee verified by the observation of the relaxatio time constant of the field effect.

Electron Coupled Interaction in Solid Iodine

By Takashi ITOH*
Department of Physics, Faculty of Science,

By Kenjiro KAMBE
University of Electro-Communications, Tokyo

(Received March 25, 1957)

Hyperfine structure in the nuclear quadrupole resonance spectrum of solid iodine observed by Kojima, Ogawa, Hagiwara, Abe and Minematsu is analysed in terms of electron coupled interaction between nuclear spins. Theoretical expression for the Hamiltonian of the electron coupled interaction between two nuclei in an iodine molecule is derived, having the form of $JI_{Az}I_{Bz}+K(I_{Ax}I_{Bx}+I_{Ay}I_{By})$, where z is the bond axis. Electron coupled interactions between nuclei belonging to different molecules in the crystal are neglected. Values of the coupling constants J and K are determined to be both equal to 3.0 kc from the comparison with the experimental data.

Electronic structure of the chemical bond is discussed on the basis of the above coupling constants in combination with the previously known quadrupole coupling constants. It is concluded that the bond in an iodine molecule has 22% s character and 33% d character. It is also concluded that there are auxiliary bonds between neighboring molecules with a fractional importance of 10%.

§1. Introduction

Nuclear quadrupole resonance spectrum of solid iodine has been observed by Dehmelt,[1] Pound[2] and Kamei.[3] Two lines have been found, and their frequencies are 332 Mc and 644 Mc. Recently Kojima and Tsukada[4] found that the lower frequency line has a hyperfine structure with an overall spreading of about 80 kc. Tsukada[5] investigated the Zeeman effect on this line, and observed a very complicated pattern in the case of weak magnetic field where Zeeman energy is comparable with the hyperfine energy. This hyperfine structure has been studied more precisely by Kojima, Ogawa, Hagiwara, Abe and Minematsu.[6] The same pattern has also been observed independently by Watkins and Walker.[7]

Solid iodine is a molecular crystal of orthorhombic symmetry.[8] The lattice constants are $a=4.78$ Å, $b=7.25$ Å and $c=9.77$ Å. A unit cell contains four molecules, whose centers of gravity are located at $(0,0,0)$, $(\frac{1}{2}a, \frac{1}{2}b, 0)$, $(\frac{1}{2}a, 0, \frac{1}{2}c)$ and $(0, \frac{1}{2}b, \frac{1}{2}c)$. The direction of the bound axes of the molecule at $(0,0,0)$ and $(\frac{1}{2}a, \frac{1}{2}b, 0)$ is $(\sin\varphi, 0, \cos\varphi)$, and that of the molecules at $(\frac{1}{2}a, 0, \frac{1}{2}c)$ and $(0, \frac{1}{2}b, \frac{1}{2}c)$ is $(-\sin\varphi, 0, \cos\varphi)$, where $\varphi=32°4'$. All the nuclei are equivalent in the sense that they can be superimposed on each other by a symmetry operation of the crystal. Therefore, no multiplet structure would appear if there were no interaction between nuclear spins. Thus the hyperfine structure observed by Kojima and others must be due to some kind of interaction between nuclear spins.

There are various interactions between nuclear spins, which might give rise to a hyperfine structure such as observed by Kojima and others. Among them, the direct interaction between nuclear magnetic moments is of the order of 1 kc. This is too small to account for the observed spreading. Also the interaction between nuclear quadrupole moments is very small. However, there is another type of interaction between nuclear spins, which is called electron coupled interactions. This is the second order perturbation energy of the interaction between nuclei and electrons. This has been often invoked to explain the hyperfine structure in nuclear magnetic resonance spectra of liquids.[9][10] In the case of iodine crystal, the second order energy of the magnetic interaction between nuclei and electron proves to be of a reasonable order of magnitude to explain the observed spreading. The second order energy of quadrupole interactions and the crossed second order energy of magnetic and quadrupole interactions are so small as to be negligible.

§ 2. Electron Coupled Interation Between Nuclear Spins

Theory of the electron coupled interaction between nuclear spins has been developed by Ramsey[9] and Gutowsky, NcCall and Slichter.[10] The coupling constant for this interaction depends on the electronic structure of the chemical bond. In our paper, we consider an iodine molecule in which an electron pair bond between s-p hybridized orbitals of the constituent atoms is assumed. Since intermolecular bond is weak, the electron coupled interaction between nuclei of different molecules can be neglected.

The Hamiltonian for the magnetic interaction between nuclei and electrons is given by

$$H=\sum_N H_N\,, \tag{1}$$

$$H_N=\sum_j H_{Nj}\,, \tag{2}$$

$$H_{Nj}=2\beta\gamma\hbar\left\{\frac{\boldsymbol{I}_N\cdot\boldsymbol{l}_{jN}}{r_{jN}^3}-\frac{(\boldsymbol{I}_N\cdot\boldsymbol{s}_j)r_{jN}^2-3(\boldsymbol{I}_N\cdot\boldsymbol{r}_{jN})(\boldsymbol{s}_j\cdot\boldsymbol{r}_{jN})}{r_{jN}^5}+\frac{8\pi}{3}\delta(r_{jN})\boldsymbol{I}_N\cdot\boldsymbol{s}_j\right\}, \tag{3}$$

where β is the Bohr magneton, γ the magnetomechanical ratio of the nucleus, $\boldsymbol{I}_N$ the spin of the N th nucleus, $\boldsymbol{s}_j$ the spin of the j th electron, $\boldsymbol{l}_{jN}$ the angular momentum of the j th electron around the N th nucleus, and $\boldsymbol{r}_{jN}$ is the radius vector joining the N th nucleus and the j th electron. The electron coupled interaction between the nuclei A and B is given by

$$H_{AB}=-\sum_n\frac{(0|H_A|n)(n|H_B|0)+(0|H_B|n)(n|H_A|0)}{E_n-E_0} \tag{4}$$

where E_0 and E_n are the energies of the ground state and n th excited state of the molecule. To simplify the calculation, we replace the denominator E_n-E_0, as usual, by a certain average excitation energy ΔE, obtaining

$$H_{AB}=-\frac{(0|H_AH_B+H_BH_A|0)}{\Delta E} \tag{5}$$

The calculation of this demands essentially the knowledge about the ground state electronic wave function only. The ground state function is assumed to have the form

$$\Phi_0=\Psi_0\chi_0 \tag{6}$$

$$\Psi_0=(1/\sqrt{2})(\psi_A(1)\psi_B(2)+\psi_B(1)\psi_A(2)) \tag{7}$$

$$\chi_0=(1/\sqrt{2})(\alpha(1)\beta(2)-\beta(1)\alpha(2)) \tag{8}$$

where ψ_A and ψ_B are the s-p hybridized orbitals of the two iodine atoms:

$$\left.\begin{aligned}\psi_A&=\sqrt{s}\,\psi_{5sA}+\sqrt{1-s}\,\psi_{5p\sigma A}\\ \psi_B&=\sqrt{s}\,\psi_{5sB}+\sqrt{1-s}\,\psi_{5p\sigma B}\end{aligned}\right\} \tag{9}$$

s is the s character of ψ_A and ψ_B. α and β in Eq. (8) are spin functions. We neglect the overlapping between ψ_A and ψ_B, which ensures the normality of Ψ_0. The above wave function represents the electron pair bonded state. We do not consider inner core electrons, since their contribution to electron coupled interaction is not important.

Eq. (5) can further be rewritten as

$$H_{AB}=-\sum_{jk}\frac{(0|H_{Aj}H_{Bk}+H_{Bk}H_{Aj}|0)}{\Delta E}\,, \tag{10}$$

where j and k may be 1 and 2. H_{Aj} is appreciable only when the electron j is near the nucleus A, and similarly H_{Bk} is appreciable only when the electron k is near the nucleus B. Therefore, when $j=k$, $H_{Aj}H_{Bk}$ is small everywhere. We neglect this type of terms in (10). When $j\neq k$, H_{Aj} and H_{Bk} commute, so that the two terms $H_{Aj}H_{Bk}$ and $H_{Bk}H_{Aj}$ in (10) make equal contributions on account of the antisymmetry property of the wave function. Thus we obtain

$$H_{AB}=-\frac{4(0|H_{A1}H_{B2}|0)}{\Delta E}\,. \tag{11}$$

Now we consider the integral

$$\int\Psi_0H_{A1}H_{B2}\Psi_0dv_1dv_2\,, \tag{12}$$

where Ψ_0 is the spatial wave function given by (7). From the forms of (7) and (12) it is obvious that the second term of Ψ_0 can safely be omitted. Then we obtain

$$\int\Psi_0H_{A1}H_{B2}\Psi_0dv_1dv_2=\frac{1}{2}\int\psi_A(1)H_{A1}\psi_A(1)dv_1\int\psi_B(2)H_{B2}\psi_B(2)dv_2\,. \tag{13}$$

(3) and (9) give

$$\int \psi_A(1) H_{A1} \psi_A(1) dv_1 = P I_{Az} s_{1z} + Q(I_{Ax} s_{1x} + I_{Ay} s_{1y}) \,, \tag{14}$$

and a similar equation for $\int \psi_B(2) H_{B2} \psi_B(2) dv_2$, where

$$\left.\begin{aligned} P &= 2\beta\gamma\hbar\left\{\frac{8\pi}{3} s|\psi(0)|^2 + \frac{4}{5}(1-s)\left\langle\frac{1}{r^3}\right\rangle\right\} \,, \\ Q &= 2\beta\gamma\hbar\left\{\frac{8\pi}{3} s|\psi(0)|^2 - \frac{2}{5}(1-s)\left\langle\frac{1}{r^3}\right\rangle\right\} \,. \end{aligned}\right\} \tag{15}$$

$|\psi(0)|$ is the absolute value of the ψ_{5s} atomic orbital function at the position of the nucleus, and $\left\langle\frac{1}{r^3}\right\rangle$ is the average value of $\frac{1}{r^3}$ for the ψ_{5p} orbital. Z axis in (14) is taken in the direction of the chemical bond, and x axis is for convenience taken in the direction of the crystalline b axis.

Substituting (14) into (13) and averaging over the spin state (8), we have

$$(0|H_{A1} H_{B2}|0) = -\frac{1}{8} P^2 I_{Az} I_{Bz} - \frac{1}{8} Q^2 (I_{Ax} I_{Bx} + I_{Ay} I_{By}) \,. \tag{16}$$

Thus the final expression for the electron coupled interaction between A and B becomes

$$H_{AB} = J I_{Az} I_{Bz} + K(I_{Ax} I_{Bx} + I_{Ay} I_{By}) \,, \tag{17}$$

where

$$\left.\begin{aligned} J &= \frac{2}{\Delta E}(\beta\gamma\hbar)^2\left\{\frac{8\pi}{3} s|\psi(0)|^2 + \frac{4}{5}(1-s)\left\langle\frac{1}{r^3}\right\rangle\right\}^2 \,, \\ K &= \frac{2}{\Delta E}(\beta\gamma\hbar)^2\left\{\frac{8\pi}{3} s|\psi(0)|^2 - \frac{2}{5}(1-s)\left\langle\frac{1}{r^3}\right\rangle\right\}^2 \,, \end{aligned}\right\} \tag{18}$$

§ 3. Analysis of the Hamiltonian for the Electron Coupled Interaction and the Experimental Results

The Hamiltonian of the nuclear spin system is

$$\mathscr{H} = H_Q + H_{AB} \,. \tag{19}$$

Here H_Q is the Hamiltonian for the quadrupole coupling

$$H_Q = \sum_{N=A,\,B} eQq_{zz} \frac{3I_{Nz}^2 - I(I+1) + \eta(I_{Nx}^2 - I_{Ny}^2)}{4I(2I-1)} \tag{20}$$

with $\eta = (q_{xx} - q_{yy})/q_{zz}$, where q's are the principal values of the electric field gradient tensor, and H_{AB} is the Hamiltonian for the electron coupled interaction given by (17). Rigorously speaking, the x,y,z axes in (20) may be different from the x,y,z axes defined in the preceding section, that is, the former ones are the principal axes of the electric field gradient tensor, whereas the latter ones are the principal axes of the electron coupled interaction and these two sets of axes may not necessarily coincide with each other. However, according to the Zeeman effect study of Tsukada[5] the principal axes of the field gradient tensor coincide with the x,y,z axes defined in the preceding section within experimental error, so that we may use common axes in (17) and (20).

The Hamiltonian (19) has certain symmetry properties. It is not only symmetrical with respect to two nuclear spins, but also invariant under the reflection in the *ac* plane. The eigenvalue problem can be greatly simplified if we take into account these symmetries. The eigenfunctions must therefore be symmetrical or antisymmetrical with respect to these symmetry operations. Now, if we regard the term H_{AB} in (19) as a perturbation, the unperturbed eigenfunctions with the above symmetry properties are given by

$$\left.\begin{aligned} \Psi(m, m', A_1, \pm) &= C\{\psi_m(A)\psi_{m'}(B) + \psi_{m'}(A)\psi_m(B) \pm \psi_{-m}(A)\psi_{-m'}(B) \pm \psi_{-m'}(A)\psi_{-m}(B)\} \,, \\ \Psi(m, m', A_2, \pm) &= C\{\psi_m(A)\psi_{m'}(B) - \psi_{m'}(A)\psi_m(B) \pm \psi_{-m}(A)\psi_{-m'}(B) \mp \psi_{-m'}(A)\psi_{-m}(B)\} \,. \end{aligned}\right\} \tag{21}$$

where ψ_m are the eigenfunctions of the quadrupole coupling of individual nuclei, $m(=\pm 5/2, \pm 3/2, \pm 1/2)$ being the approximate quantum number corresponding to the z component of the nuclear spin angular momentum, and A_1, A_2 and $\pm$ indicate whether the wave function is symmetrical with respect to the exchange of two nuclei and with respect to the reflection about the *ac* plane respectively. C is the normalization factor, equal to $1/2\sqrt{2}$ when $m = \pm m'$ and $1/2$ when $m \neq \pm m'$.

The energy of electron coupled interaction is to be calculated on the basis of the above wave functions. Since two functions $\Psi(m, m', A_{1,2}, \pm)$ and $\Psi(m, -m', A_{1,2}, \pm)$ have equal unperturbed energies, we should take into account the mixing of these two states, if there were interaction between them. However, in the case of the spin quantum number equal to a half odd integer as in the present case, the off diagonal element connecting the above two states vanishes identically, so that the wave functions of (21) are by themselves correct eigenfunctions. The hyperfine energies for them are

$$\left.\begin{aligned}E(m, m', A_1, \pm)&=C^2[(m, m'|H_{AB}|m, m')+(m, m'|H_{AB}|m', m)\\&\qquad\pm(m, m'|H_{AB}|-m, -m')\pm(m, m'|H_{AB}|-m', -m)]\ ,\\E(m, m', A_2, \pm)&=C^2[(m, m'|H_{AB}|m, m')-(m, m'|H_{AB}|m', m)\\&\qquad\pm(m, m'|H_{AB}|-m, -m')\mp(m, m'|H_{AB}|-m', -m)]\ ,\end{aligned}\right\}\tag{22}$$

where $|m, m')$ means the wave function $\psi_m(A)\psi_{m'}(B)$ and so on. Although rigorous calculation of (22) is somewhat tedious, we may neglect the terms of higher order than η since η is sufficiently small; $\eta=-0.15$. First, we consider the case of $m\neq m'$. Then (22) is rewritten as

$$\left.\begin{aligned}E(m, m', A_1, \pm)&=Jmm'+Kf(m, m')\pm\eta Kg(m, m')\pm\eta Kh(m, m')\ ,\\E(m, m', A_2, \pm)&=Jmm'-Kf(m, m')\pm\eta Kg(m, m')\mp\eta Kh(m, m')\ ,\end{aligned}\right\}\tag{23}$$

where the four terms correspond to the four terms of (22) in that order. Nonvanishing values of f, g, h are

$$\left.\begin{aligned}f(m, m\pm1)&=\frac{1}{2}(I\mp m)(I\pm m+1),\\g\left(\pm\frac{3}{2}, \pm\frac{1}{2}\right)&=g\left(\pm\frac{1}{2}, \mp\frac{3}{2}\right)=\frac{1}{12}\left(I-\frac{1}{2}\right)\left(I+\frac{1}{2}\right)^2\left(I+\frac{3}{2}\right),\\h(m, -m\mp1)&=\left\{\frac{1}{8}+\frac{I(I+1)}{24m(m\pm1)}\right\}(I\mp m)(I\pm m+1)\ .\end{aligned}\right\}\tag{24}$$

Next, in the case of $m=\pm m'$, it can be proved that Eq. (23) and (24) still hold, although the correspondence between the terms of (22) and (23) is not as above in this case.

Hyperfine energies of the eigenstates calculated by (23) and (24) are listed in Table I.

Table I. Hyperfine energy levels $\left(I=\frac{5}{2}\right)$.

$\frac{1}{2}$	$-\frac{1}{2}$	$-\frac{1}{4}J+\frac{9}{2}K$			$-\frac{1}{4}J-\frac{9}{2}K$

Allowed transitions between these states are listed in Table II and III with their frequencies and relative intensities. Intensities of some hyperfine component lines depend on the direction of the radiation field, but since the dependence is not so prominent, we consider in the following only the average spectrum over all the directions of the radiation field, although slight variation of the spectrum with the direction of the radiation field has been observed in qualitative agreement with our theory.

The pattern of the hyperfine structure

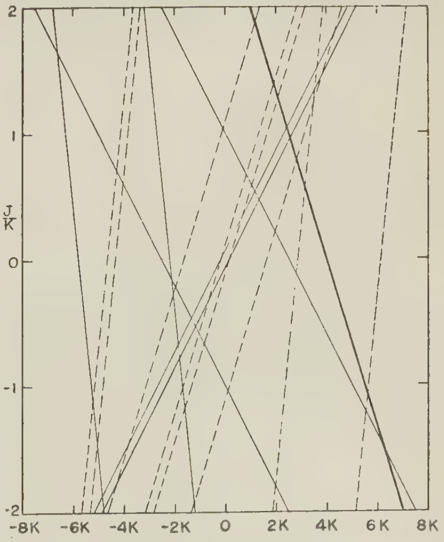

Fig. 1. Frequencies of hyperfine component lines for the transition $m=3/2\rightarrow1/2$ as function J/K. Bold lines, solid lines and broken lines represent the frequencies of hyperfine component lines with a unit intensity, a half intensity and a quarter intensity, respectively.

depends on the ratio J/K. In Figs. 1 and 2 the frequencies of hyperfine component lines are plotted as functions of J/K. Best agreement with experiment has been obtained for the pattern of the $m=3/2\rightarrow 1/2$ transition by putting $J=K=3.0$ kc. Comparison of observed and calculated spectra is shown in Figs. 3 and 4 for the transitions $m=3/2\rightarrow 1/2$ and $m=5/2\rightarrow 3/2$ respectively. The observed spectrum for the $m=5/2\rightarrow 3/2$ transition has not a well resolved structure, and it may be due to a large broadening of hyperfine component lines.

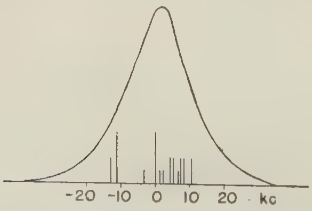

Fig. 4. Hyperfine structure of the $m=5/2\rightarrow 3/2$ spectrum.

§ 4. Discussion of the Electric Structure of the Chemical Bond

In the preceding section values of J and K have been determined to be both equal to 3.0 kc. According to (18), the equality of J and K would be ensured only when $s=1$, that is, only when the bond has 100 % s character. However, (18) can not be considered as very accurate, since we have introduced various approximations in deriving it. Thus, we must confine ourselves to the discussion of the order of magnitude of these constants. Now, since J and K are sensitive functions of s, we can obtain a rather precise value of s from the observed magnitude of J and K. Before doing so, we must estimate the values of several quantities involved in (18). The value of $\beta\gamma\hbar\left\langle\frac{1}{r^3}\right\rangle$ is very accurately known to be $\frac{15}{16}\times 827.265$ Mc[11] from the hyperfine structure of the atomic spectra of iodine, but $\beta\gamma\hbar|\psi(0)|^2$ can only be estimated by the conventional approximate formula $|\psi(0)|^2=Z\delta^2/\pi a_0^3 n'$,[12] where Z is the atomic number, δ Slater's orbital exponent, n' the effective principal quantum number, and a_0 is the Bohr radius. $\varDelta E$ may be put equal to be about 5 ev.[13] Then the values of J and K in (18) are functions of s. If we put $s=1$, J and K become about 78 kc, while if we put $s=0$, J becomes about 0.6 kc. To fit J and K with the observed magnitude, s must be about 0.22, that is, the s character of the bond is about 22 %.

We can discuss the electronic structure of the chemical bond in an iodine crystal in more detail by also using the previously known quadrupole coupling constants. Solid iodine has a layer structure[8] and the molecules in each layer are believed to be held together by auxiliary bonds, since the internuclear distance between nuclei of neighboring molecules is smaller than the sum of van der Waals radii. According to the crystalline structure, each atom is involved in two auxiliary bonds, one directed nearly along the z axis while the other directed nearly along the y axis. The auxiliary bonds have been discussed by Townes and Dailey[14] as due to the resonance switching of the bonds, and later by Robinson, Dehmelt and Gordy,[15] as due to the excitation of electrons to d orbitals. In this paper, we postulate that the auxiliary bonds are formed by excitation of electrons to d orbitals, since the resonance switching of the bonds would be accompanied with the rotation of the principal axes of field gradient tensor in contradiction to the experiment.

We denote by a the fractional importance with which the auxiliary bond is formed, and denote by d the d character of the intramolecular bond. Then theoretical expression for the quadrupole coupling constants are

$$\left.\begin{aligned} eQq_{zz} &= eQq_{\text{atom}}\left(1-s+d-\frac{1}{2}a\right), \\ \eta &= -\frac{3}{2}a\,. \end{aligned}\right\} \qquad (25)$$

We have neglected higher order terms such as sd, sa in the above expression. eQq_{atom} means the quadrupole coupling constant for an iodine atom. Its value is known to be -2×1146.356 Mc.[11] Putting $eQq_{zz}=-2157$Mc,[1,2,3] $\eta=-0.15$ and $s=0.22$, we obtain $a=0.1$ and $d=0.33$.

The nature of the bonds in halogen molecules has been discussed theoretically by Mulliken,[16] and it has been concluded that the s character in the F_2 molecule is about 2% and the s character in the Cl_2 molecule is about 10%, so that the present value of 22% for the s character in the I_2 molecule is quite reasonable. The value of d and a are also of reasonable order of magnitude.

We express our hearty thanks to Prof. M. Kotani and Prof. C. H. Townes for their encouragements and discussions, and to Prof. S. Kojima for suggesting this problem.

Some Factors Affecting the Decay of Secondary Electron Emission of Silver-Magnesium Alloys

By Masaki HIRASHIMA* and Shoichi MIYASHIRO

Research Laboratories, Tokyo-Shibaura Electric Co.,
Kawasaki City

(Received April 6, 1957)

The secondary emission yield is observed to decay very rapidly under electron bombardment especially during the exhaust process using oil diffusion pump. In this paper, factors affecting the decay, a method of remedy to make the decayed yield to recover, and effects of various gases and vapors on the yield are discussed. A major cause of the secondary yield decay is attributed to the deposition of amorphous carbon, which is produced on the dynode surface through the decomposition of hydrocarbon or carbon-containing gases by the electron beam. Heating the contaminated dynode at high temperatures in oxygen atmosphere for some period results in a recovery of the yield. Keeping the dynode at high temperatures during electron bombardment is effective in bringing about a marked decrease in the decay. From the data on the temperature dependence of the decay, the heat of adsorption of a gas which is considered to be the source of contamination, is calculated to be about 1.6 kcal/mole. N_2, CO and CO_2 do not exert any harmful effects upon activated dynodes, while H_2 exerts somewhat harmful effects, and, particularly, electric discharge in H_2 should be avoided. The most unfavorable gas is the grease vapor. The process of contamination is briefly discussed.

§ 1. Introduction

In the course of experiments carried out to determine optimum activating conditions of silver-magnesium alloy secondary electron emitters, using water vapor and oxygen as oxidizing agents, we were confronted with some difficulty in obtaining reproducible results. It was also noticed that the secondary electron yield, δ, decayed so rapidly during the measurements that the values of yield measured at the beginning and at the end of the experiment under the same condition differ considerably from each other. It was considered necessary, therefore, to search into factors affecting the decrease in the yield prior to the determination of optimum activating conditions.

It is the object of this paper to describe the results thus obtained. A probable cause of the decay of secondary yield will be discussed in some detail, and effects of various gases or vapors on the yield will also be described.

§ 2. Measurements of Secondary Yield on the Pump

2.1 *Apparatus*

The description which follows pertains to the measurements on experimental tubes on the pump, except where otherwise noted. In order to save time and labor for making a number of experimental tubes to be used to determine optimum activating conditions, we carried out experiments with experimental tubes on the pump in place of sealed-off tubes. A schematic diagram of the apparatus used is shown in Fig. 1. Water vapor or oxygen was employed as oxidizing agent, and such gases as carbon monoxide, carbon dioxide, hydrogen, and nitrogen were used to study their effects on the secondary yield. The pressure of these gases was measured by the Pirani gauge. Most of the experimental tubes used in the following experiments were of usual construction with an exception of the provision of a shutter for protecting the contamination deposits on the dynode from the tungsten filament, as roughly sketched in the figure. The specimens used were Ag-Mg ribbons 20 mm in length, 5 mm in width, and about 0.1 mm in thickness and contained about 2 per cent Mg in weight. The Mg content has nothing to do with the following discussions.

---

* Now at Department of Communication Engineering, Tokai University, Tomigaya, Yoyogi, Shibuya-ku, Tokyo.

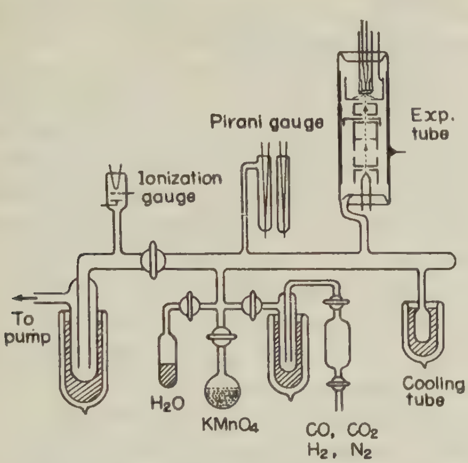

Fig. 1. Schematic view of the apparatus for measuring the yield decay and the effect of various gases on the yield.

These specimens were well polished before formed into ⊔ shape, by the polishing process described in a previous paper.[1)]

2.2. *Dependence of the Secondary Yield on Activating Time.*

At the start, the secondary yield was measured with a dynode not subjected to an activating treatment. It was assumed that since the dynode was not activated, the maximum secondary yield would be of the order of unity. This was, however, not the case, and somewhat larger value of the yield could perhaps be attributed to MgO film formed on the surface during glass-working and bulb-baking stages. Water vapor was then admitted into the experimental tube at a certain pressure; the dynode was heated at the desired temperature for a prescribed period by passing an electric current through the ribbon, and the temperature was measured by means of a thermojunction welded to its back; the current was stopped and the tube evacuated. After the bulb was baked out, the electrodes were degassed by induction heating, and the tungsten filament was flashed as usual, with the shutter closed, and the experimental tube was ready for measurement of the yield against primary voltage. These measurements were carried out in succession as many times as desired. The curves of Fig. 2 are typical results of such measurements. If maxima of these curves, δ_{max}, are plotted against the activating time, an activation curve such as shown in Fig. 3 is obtained. The curve shows a pronounced maximum, and even with prolonged activation with water vapor as the oxidizing agent, the yield could not be recovered.

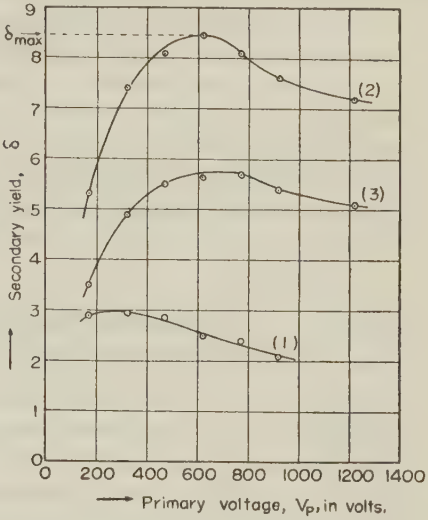

Fig. 2. Yield vs. primary voltage curves. Activating condition: $P_{H_2O} \approx 6 \times 10^{-2}$ mmHg.; Temp. = 620°C; Time: 0 min. (curve 1), 3 min. (curve 2), 6 min. (curve 3).

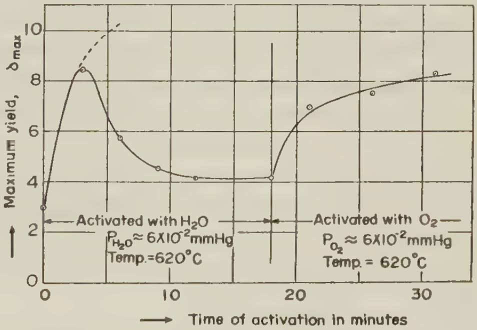

Fig. 3. Activation curve of Ag–Mg dynode.

When oxygen was employed in place of water vapor as the oxidizing agent at this stage, the secondary yield recovered to a higher value, reaching a nearly steady value after 15 to 30 minutes of activating time according to the oxygen pressure and the dynode temperature.

After a number of similar experiments were carried out with a variety of water vapor pressures and dynode temperatures, it was found that the maxima of the activation curves always occurred at the first measuring points. This fact seems to suggest that something unfavorable to secondary electron emission was produced on the dynode surface upon bombardment by primary electrons even for a short time during the yield measurement. In fact, when the dynode was taken out of the experimental tube, purple- or blue black-colored staining was observed on the portion of the surface bombarded by the primary beam, and the diameter of the stain was quite equal to the primary beam diameter.

2.3. *Decay of the Secondary Yield and Primary Electron Bombardment.*

It was our next step to determine whether the contamination deposit stated above is formed only through the bombardment by primary electron beam, or due to evaporation of contaminant from the tungsten filament. The simplest way to do this is to cut off the primary beam for a short time during the course of the decay. If the contamination deposit in question came from the filament, it would have nothing to do with the primary electron bombardment. Curve A of Fig. 4 shows, however, that this is not the actual case. The fact that the cessation of the primary beam with the filament being lit resulted in no decay of the secondary yield indicated that the evaporation of contaminants from the filament need not be taken into account in the present case. The only cause of contamination deposit is then attributed to the primary electron bombardment. This point was also confirmed by experiments carried out with experimental tubes of special construction using magnetically deflected primary electron beams.

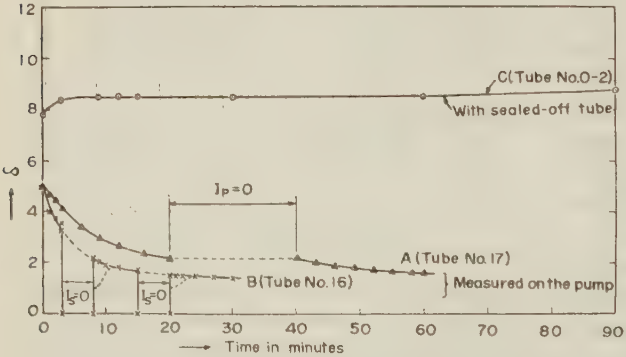

Fig. 4. Effect of cessation of primary electron bombardment and of secondary electron extraction on decay characteristics.

Intermittent suppression of the secondary electrons by applying the collector a negative potential with respect to the dynode, while the primary beam was held constant throughout the measurements, gives no effect upon the yield decay as shown by curve B of the same figure. On suddenly recovering the collector voltage from a negative value with respect to the dynode ($V_c=-15$ volts) to the normal positive value ($V_c=50$ volts), the gradual rise of the curves as shown dotted in Fig. 4 B was observed in cases where insulators such as glass exposed to stray electrons were present; stored charge on these is believed to be the cause of this phenomenon.

The result of a similar experiment with a sealed-off tube is also illustrated in the same figure by curve C. No decay is observed in this case, and only with prolonged primary electron bombardment a normal decay due to the decomposition of MgO into Mg and O_2 was noticed.

2.4. *Effects of Primary Electron Energy and Current Density on the Yield Decay.*

As it has become evident that the primary electron beam plays a major role in producing the contamination deposit, it is important next to know the effect of the primary electron energy and current density on the yield decay. As seen from Fig. 5, yield decay does not depend too much on electron energy in the range covered by our experiments.

On the other hand, the primary current density exerts a marked effect on the yield decay, as seen from Fig. 6. In this figure, curves A and B have been obtained with the same primary voltage ($V_p=620$ volts) but with different values of primary current ($I_p=1\mu A$ and $2\mu A$, respectively). Comparison of these two curves indicates that the time required for the yield to decay to the same value of δ is inversely proportional to the primary current, and that the same quantity of charge laid down by the bombarding beam on the dynode gives rise to equal decay of the secondary yield when the primary voltages are kept equal.

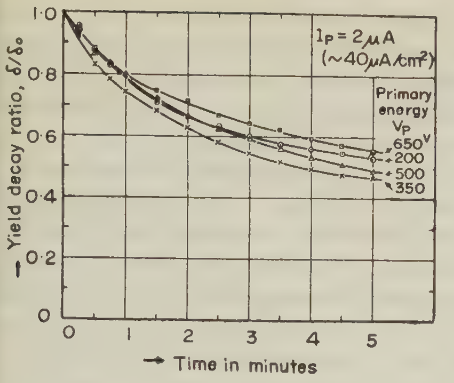

Fig. 5. Effect of primary electron energy on the decay.

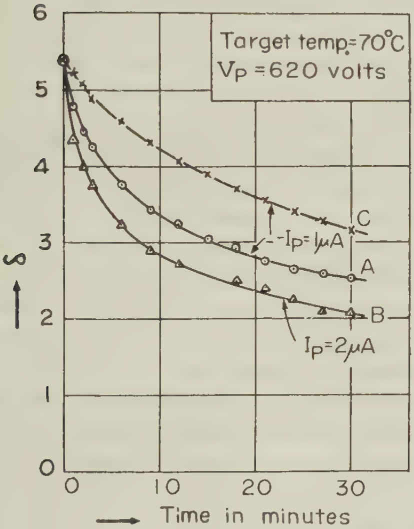

Fig. 6. Effect of primary current density on the yield decay.
Curves A and B: on oil diffusion pump
Curve C: on mercury diffusion pump.

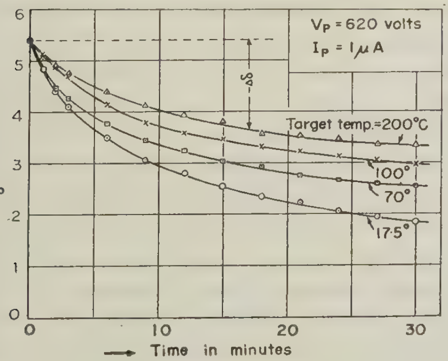

Fig. 7. Effect of target temperature on the decay.

2.5. *Effect of the Dynode Temperature on the Decay.*

In order to see the effect of the dynode temperature on the decay, dynode temperature was varied over the range from room temperature to 200°C. In the range of temperatures covered by our experiments, keeping the dynode at higher temperatures during the primary electron bombardment resulted in a considerable decrease in the decay of the yield, as shown in Fig. 7.

§ 3. The Cause of the Yield Decay during Primary Electron Bombardment

It is evident that the cause of the yield decay should be attributed to residual gases in the system, as shown by curve C of Fig. 4 for a sealed-off tube. A glance at Fig. 3 through Fig. 7 affords an impression that electron bombardment gives rise to something on the bombarded surface which is a poor secondary electron-emitting substance. Fig. 3 indicates definitely that the yield decay is not caused by the decomposition of MgO into Mg and O_2 by electron bombardment. A number of papers have been published on the so-called "electron-bombardment contamination" in the field of electron microscopy.[2)3)4)5)] In the field of secondary electron emission, Lempicki seems to be the first to publish the result of experiments on the yield decay during primary electron bombardment,[6)7)8)] and he attributed this to the deposition of silicone on the surface which was decomposed by electron bombardment from the silicone vapor originated from the pump oil. The pump oil used in the present experiments was not the silicone oil but the alkyl-naphthalene oil, although silicone grease was used in the taps. These taps were cooled with water during the experiments.

The curve of Fig. 3 seems likely to reveal that something deposited on the dynode surface by electron bombardment does not have great enough affinity for oxygen to deprive oxygen of water molecules. Referring to Fig. 8 which represents the relation between the dissociation pressure of various oxides and the reciprocal of temperature,[9)] it is considered that the substance deposited on the dynode surface by electron bombardment must form an oxide whose dissociation pressure should lie above the H_2O curve. Therefore, the probable substance is assumed to be carbon. The fact that the contamination deposits disappear completely when they were heated in air to about 800°C for about one minute indicates this to be the actual case. Although an electron diffraction study is unable to give any concrete conclusion to its identification, the patterns obtained reveal that it is amorphous and of carbonaceous nature. The gas that is produced by subjecting the stained dynode to activation with oxygen, therefore, will be either CO or CO_2.

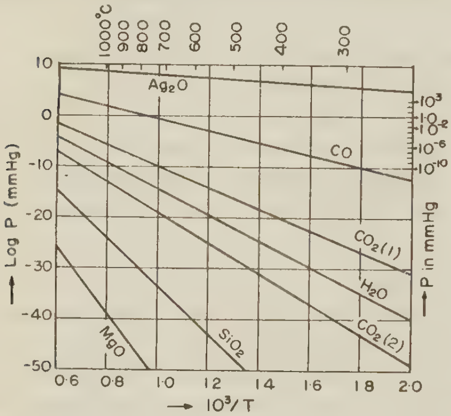

Fig. 8. Dissociation pressure of various oxides.
$CO_2(1)$: $C+O_2=CO_2$
$CO_2(2)$: $2\,CO+O_2=2\,CO_2$

§ 4. The Process of Contamination of the Dynode Surface

In conformity with the work of Hillier[2], and of König[3] the present investigation has shown that the contamination deposit has an amorphous structure and is of carbonaceous nature as stated above. This suggests that the source material is organic in nature or carbon-containing gas, and that contamination is formed by the reaction of the electron beam with the vapor or gas molecules on the dynode. The source of these organic vapors or gases may come from oil, grease, etc. in the system. The conversion of these organic substances to form the contamination deposit must take place on the surface of the dynode and not in the vapor, because the contamination deposit is formed only on the portion of the surface bombarded by primary electron beam. On the dynode surface, there may exist an adsorbed layer of hydrocarbon or carbon-containing gas which effectively increases the concentration of molecules. Whatever electronic mechanism causes the formation of contamination, the orignal organic or gas molecules are effectively fixed by the electron beam. The electron energies necessary to bring about the chemical reactions are relatively small in comparison with the beam energies employed,[10] which would explain why there is no great dependence of contamination on the electron energy (see Fig. 5).

The contamination process is continuous with time for so long as the electron beam is operative, so that a steady state condition must be set up between the rate of conversion of hydrocarbon molecules to contamination on the surface, and the net rate of supply of fresh molecules from outside. It has been established that no build-up of carbon layer takes place on the surface in the absence of the electron beam. And if any hydrocarbon or carbon-containing gas is present on the surface, it must result from an equilibrium between molecules arriving on the surface and those leaving it. At low surface concentrations, the contamination rate will be directly proportional to the surface concentration of molecules and to the current density. We have already seen that this was the actual case (Fig. 6).

We agree with A. E. Ennos[4] in attributing the replenishment of the hydrocarbon or carbon-containing gas film to the arrival of hydrocarbon or gas molecules by condensation from the surrounding vapor or gas. The concentration of these molecules, which are in dynamic equilibrium with the vapor, is dependent upon the pressure of the vapor, the temperature of the surface and the binding energy of the vapor molecules on the surface. At very high temperatures, no vapor molecules can exist for a significant time on the surface, but as the temperature is lowered, the average time for which a molecule can stay on it increases, with consequent increase in surface concentration. The degree of adsorption will be directly proportional to the pressure of the vapor since for the low vapor pressures which exist in a normal kinetic vacuum system, it is reasonable to assume that the surface concentration of vapor molecules never exceeds monolayer except under conditions of very low surface temperature. The fraction of the surface covered with molecules will then be given by a formula due to Langmuir:[11]

$$\theta=\frac{ap}{1+ap}\approx ap=\frac{\alpha_0\varepsilon^{Q/RT}}{k_0(2\pi MRT)^{1/2}}p, \qquad (1)$$

since p is very small in the present case

($\sim 10^{-6}$ mm Hg). Here α_0 is the condensation coefficient, Q is the activation energy necessary to evaporate 1 mole of the condensate or the heat of adsorption, R the gas constant, M the molecular weight of the condensate, k_0 a constant, T the absolute temperature and p the pressure.

In view of the experimental results obtained by Ennos[5] showing that the thickness of contamination deposit is nearly a linear function of bombarding time in the initial stage, it will not be unreasonable, as a first approximation, to assume that the square of the drop in the secondary yield from the initial value, $(-\Delta\delta)^2$, is proportional to the quantity of deposited carbon. m:

$$(-\Delta\delta)^2 \propto m. \tag{2}$$

On the other hand, the contamination rate, dm/dt, should be proportional to the primary current, i_p, and also to θ:

$$\frac{dm}{dt} \propto i_p \theta \,. \tag{3}$$

Taking K as the proportional constant, we obtain

$$\frac{dm}{dt} = K i_p \theta \approx K i_p \frac{\alpha_0 \varepsilon^{Q/RT}}{k_0 (2\pi MRT)^{1/2}} p \,. \tag{4}$$

Squaring both sides and assuming i_p and p constant, the following relation is obtained:

$$\log\left(\frac{dm}{dt}\right)^2 T = \text{constant} + \frac{2Q}{RT} \times 0.4343. \tag{5}$$

In Fig. 9 $(-\Delta\delta)^2$, taken from Fig. 7, is plotted against time. The slope of the linear parts of these curves gives dm/dt. If we plot $\log (dm/dt)^2 T$ against $1/T$, a straight line is obtained as shown in Fig. 10, whose slope giving Q, the heat of adsorption, as 1.6 kcal/mole. In the absence of data on the heat of adsorption of gases on MgO surface, we can not deduce from the above result what kind of gases plays the major role in the contamination in question.

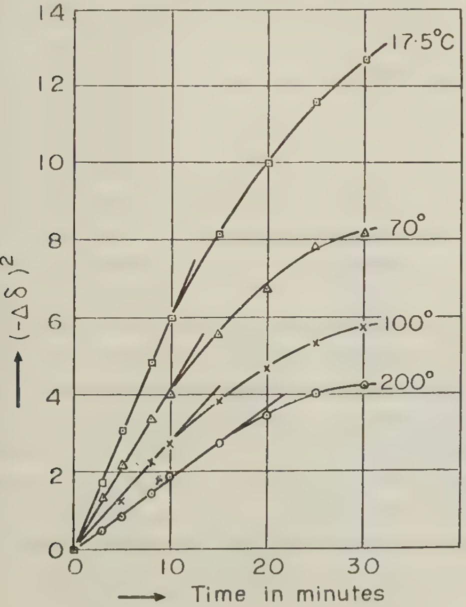

Fig. 9. $(-\Delta\delta)^2$ vs. time plot.

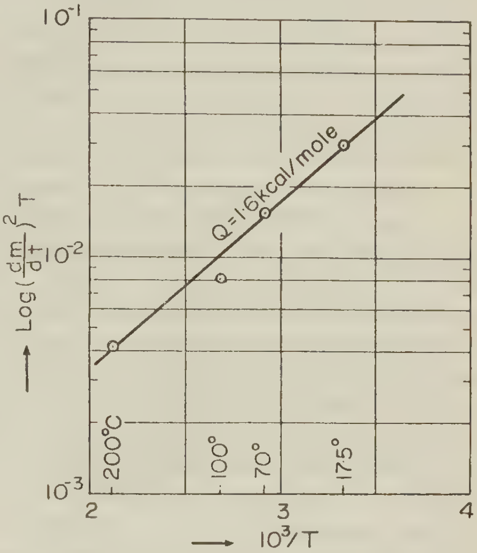

Fig. 10. Heat of adsorption.

When the oil diffusion pump is replaced by a mercury diffusion pump, it is observed that the yield decay shows a marked decrease as shown by curve C of Fig. 6. From this, we may conclude that gases or vapors originated from the pump oil play a significant role in producing contamination deposit in the present case.

§ 5. Effects of Heating Well-Activated Dynodes in Various Gases upon the Yield

5.1. *Effect of Heating in Vacuo.*

It is important to know the effect of heat treatment of an activated dynode in vacuum upon its secondary yield. From our experiments it has been shown that heat treatment at 300°C for about 5 minutes in vacuum causes the yield to increase slightly, but heating up to higher temperatures (over ca. 500°C) causes a considerable decrease in the yield.

5.2. *Effect of Air.*

Short-time exposure of an activated dynode kept at 590°C to air did not produce any change in the yield.

5.3. *Effect of Heating in Hydrogen and of Electric Discharge in Hydrogen.*

Heating of an activated dynode in line hydrogen at 1 atmospheric pressure up to about 600°C for 30 minutes causes the yield to decrease by approximately 30% or more, while a similar heat treatment in dry hydrogen at a pressure of the order of 10^{-2} mm Hg. does not affect the yield to a marked degree. This is probably due to partial decomposition of MgO film by hydrogen.

A more pronounced effect on the secondary yield is produced by subjecting the dynode to an electric discharge in an atmosphere of hydrogen. Furthermore, it was observed that the effect was more pronounced with the dynode negative and the collector positive, than with the dynode positive and the collector or the other electrodes negative. A decrease in the yield of about 40% was not rare. The reason for this effect might be considered as roughening of the dynode surface due to positive ion bombardment, giving rise to labyrinth-like structure of the surface.

5.4. *Effect of Heating in Nitrogen.*

Heating an activated dynode in dry nitrogen to about 600°C has no noticeable effect upon the secondary yield.

5.5. *Effect of Heating in Carbon Monoxide and Carbon Dioxide.*

At first, it was expected that such gases as CO and CO_2 would be decomposed on the dynode surface by being deprived oxygen atoms by magnesium atoms, thereby giving rise to carbon deposit on that surface. Contrary to our expectation, however, heating an activated dynode at 400–600°C for about 15 minutes or so in an atmosphere of dry CO or CO_2 at a pressure of about 1×10^{-2} mm Hg did not result in a decrease in the secondary yield. Rather, in conformity with the data obtained by Wargo et al,[12)13)] a virgin dynode is activated in CO and CO_2 atmospheres.

5.6. *Effect of Grease Vapors.*

From our preliminary experiments carried out some time ago it has been known that the vapor of grease used in taps has unfavorable effects upon the secondary yield. This has been confirmed again by the following experiment.

An experimental tube containing a dynode activated with oxygen is evacuated on the pump. The vacuum system is equipped with an appendage in which a small quantity of vacuum grease* is contained. Within this grease is embedded a Ni-W thermojunction by which the temperature of the grease may be measured. After the vacuum system was evacuated to as perfect a vacuum as possible, the system is shut off from the pump by a tap, the grease is heated from outside of the appendage by a gas flame, the vapor of the grease is admitted into the system directly or through a liquid-air trap, and then the dynode is heated to the desired temperature for a prescribed period. After the system has been exhausted again, the degassing of the bulb and of the electrodes is done as usual, and then the secondary yield is measured as a function of the primary voltage. It is found from this experiment that the grease vapor has the most influence in causing the secondary yield to decrease, and the dynode seems to be permanently damaged by the silicone grease vapor, as reported by Lempicki[6)].

A mass spectrographic study of the vapor of the silicone grease at 100°C gives the following result:

Table I

Components	Percentage
H_2	7.57
H_2O	69.85
CO	16.50
N_2	2.50
O_2	None
CO_2	1.05
Mass No. 73	2.55
Others	Trace

The vapor from the grease above 100°C was not measured because of the perplexing effects of the grease on the apparatus. Table I does not contain any harmful components of the grease vapor for the dynodes in question except for an unknown component of mass number 73, so far as our experiments on the effects of gases on the secondary yield are concerned. The component with mass number 73 seems to be hydrocarbon vapor, and along with vapors evolved from the grease at higher temperatures than 100°C which might contain some unfavorable components, it is very likely to be the source of the contamination deposit in the present case.

---

* Dow Corning High Vacuum Grease (silicone grease).

§ 6. Concluding Remarks

It has been found that the major cause of the yield decay of Ag-Mg alloy secondary electron emitters under electron bombardment during exhaust on the pump is not the decomposition of MgO film due to electron bombardment, but is the deposition of contaminant which is believed to be amorphous carbon decomposed from hydrocarbon vapors or carbon-containing gases by the electron beam. The contamination deposit is formed only on the portion of the surface of the dynodes bombarded by the primary electron beam. It seems to be very probable that the same phenomena occur more or less even in sealed-off tubes. Therefore, this should be taken into account, in connection with the interpretation of life test result of dynode materials.

Acknowledgments

We wish to take this opportunity to express our hearty thanks to Dr. N. Saito, who, together with Mr. K. Motoyama, has provided us with the data on the analysis of the grease vapor by means of a mass spectrograph, and to whom we are indebted for the many illuminating discussions throughout the present investigation. We also wish to thank Mr. Y. Fukao for the electron diffraction study of the contamination deposits; Messrs. Y. Nakayama, K. Noga, and M. Kondo for their discussions; and Mr. H. Muramatsu for preparing the Ag-Mg alloys. Many thanks are also due to Mr. S. Satoh for his ever willing assistance on the various phases of the experimental work.

Conical Spiral Structure and Laminar Cleavage of Graphite

By Takuro TSUZUKU*

Tokai Electrode Research Laboratory, Daigiri, Fujisawa-City, Japan

(Received January 30, 1957)

Apparently circular crystals of graphite prepared from carbon black were investigated by electron microscope. These crystals show circular growth patterns and produce spotty electron diffraction rings accompanied by ellipses and diffuse bands. Moreover, the circular crystal folded in half presents a fan-shaped appearance instead of a semi-circular form; *i.e.*, two radii along the folded line makes an angle smaller than 180°.

These facts verify that the apparently circular crystal is really a stack of conical graphite sheets, each of which is successively rotated about the common axis in *c*-direction. It is pointed out that such a conical crystal can be formed by a spiral mechanism.

Laminar cleavage of conical crystals was observed, and the gliding mechanism connected with the spiral structure has been explained in terms of dislocations. From the spots distribution on the electron diffraction rings produced by some cleft sheets, the crystal has been concluded to be in the form of polygonal cone.

§ 1. Introduction

Previously the present author and his co-worker[1] have reported that hexagonal single crystals of graphite 1–5 μ in diameter were produced by heat treatment of carbon black 'Seast 116**' at 2500°C. From the pyramidal structure stepped by 150–300 A in height, the crystals were concluded to be grown by Frank's spiral mechanism[2].

In the subsquent course of the study by electron microscope, apparently circular crystals were found besides the hexagonal ones. A set of round growth patterns was observed on the face of each crystal, suggesting that the crystal might be formed also by the spiral mechanism. It should be remarked that the circular crystals produce spotty Debye-Scherrer rings while the ordinary spiral mechanism leads to the formation of pyramidal monocrystals which may produce single crystal diffraction patterns. This apparent discrepancy suggests that there exist some unknown aspects of the crystal structure, which will be investigated and revealed in the following sections.

The experimental work has been mainly carried out by means of a three-stage electron microscope[3] (HU-9 Type made by the Hitachi Co., Ltd***.) which enables us to observe a micrograph and a diffraction diagram from the same small object in the restricted area about 2×2 sq. microns.

§ 2. Conical Spiral Structure

2*A*. *General Observations*

Photo. 1 reproduces a pair of electron micrograph and diffraction diagram of an apparently circular crystal of graphite.

A set of circular loops observed in the micrograph (Photo. 1a) represents the growth front of each layer. Since the central part is hardly penetrated by the electron beam, it is concluded that the crystal has a pyramidal form stepped by the circular growth fronts. Two straight lines running toward the centre from the round external edges, *A* and *B*, are worthy of special attention in the respect that the fan-shaped portion bounded by these two lines (*A* and *B*) and the round edge (arc *AB*) is more transparent for electron beam than the rest. This suggest that the fan-shaped portion adheres to the surface of the supporting mount (collodion film) intersecting the incident beam nearly vertically while the rest are so appreciably inclined as to lengthen the

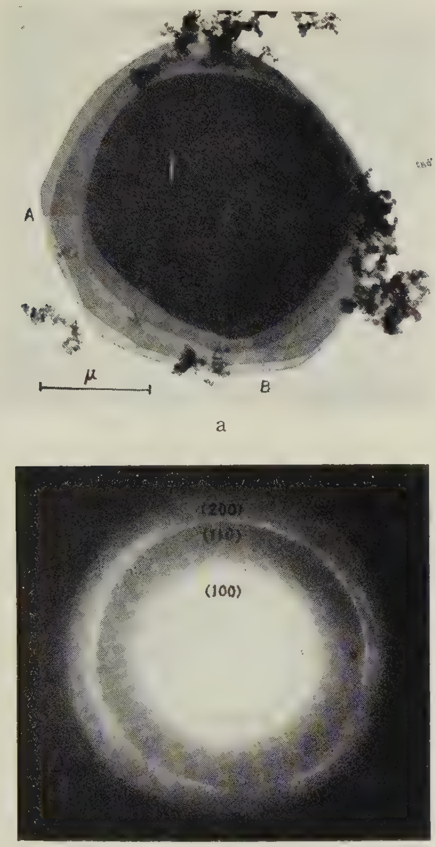
path of electron beam in the crystal.

In the diffraction diagram (Photo. 1b) we can see spotty Debye-Scherrer rings accompanied by elliptic arcs and diffuse bands. Since all the rings have indices of the type (*hko*), the crystal has been concluded to consist of numerous thin graphite layers each of which has the common axis in *c*-direction but is disoriented in *a*-direction. This seems, at first sight, to be associated with Warren's *turbostratic structure*[4] which implies stacking of graphitic monolayers parallel one to another but with random orientation about the layer normal. However, the *turbostratic structure* is generally seen in poorly- or non-graphitized carbons, and it produces quite diffuse patterns of (*hk*) 2-dimensional reflections in the diffraction diagram. All the rings obtained in this experiment are too clear to be those of turbostratic carbon.



a

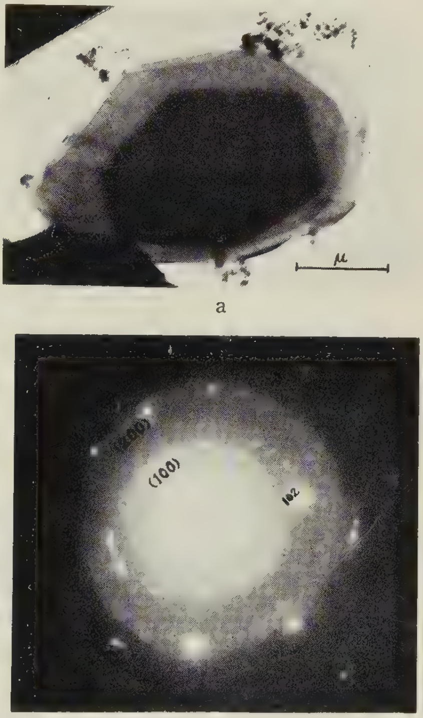
b

Photo. 1. Original form of conical crystal.

As well known, elliptic diffraction patterns are produced when electron beam is obliquely projected to the basal plane of thin layered crystal of fibrous structure. A typical elliptic pattern is reproduced in Photo. 2b. It is seen in the corresponding micrograph (Photo. 2a) that the crystal is obliquely suspended on the grid-mesh. The oblique angle, α, is given by

$$\alpha=\cos^{-1}(L_s/L_l)\ , \qquad (1)$$

where L_s and L_l represent the length of two principal axes of the ellipse, short and long respectively. For Photo. 2 the angle α is computed at 19°±2°, 26°±3° and 32°±3°.



a

b

Photo. 2. Typical oblique photograph of graphite.

Conclusively, we can suppose that the spotty diffraction rings in Photo. 1b are produced by the abovesaid fan-shaped portion in Photo. 1a where the basal plane is vertical to the electron beam, and that the three ellipses are produced by the rest which are oblique to the electron beam. It should be remarked, moreover, that all the diffraction patterns are to be ascribed to the thin peripheral parts of the crystal because the central part is hardly penetrated by the electron beam as observed in the micrograph.

2B. *Evidences of Conical Form*

In order to explain the ellipses and diffuse bands indicated in Photo. 1b, it is convenient to assume that the crystal is not merely a stack of thin graphite layers but of conical form. The setting pose of the conical crystal is illustrated in Fig. 1. The fan-shaped portion bounded by dotted lines A and B in the figure may correspond to those in Photo. 1a, adhering to the supporting film, and the thin peripheral parts are expected to be quite flexible and wavy somewhat like a lolus leaf.

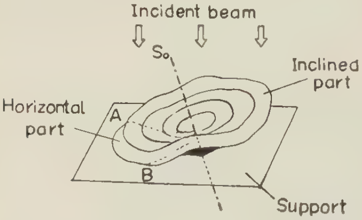


Fig. 1. Setting pose of a conical crystal corresponding to Photo. 1.

An important microscopic image consistent with these expectations is given in Photo. 3 where the crystal form is clearly exhibited by metallic (germanium) shadow-casting. It is very striking that the crystal is so concave as to prove the conical structure, and the peripheral parts are surely in wavy form and seem quite flexible. On the other hand, the conical form is confirmed by another fact that the folded crystals do not show perfect semi-circles but indicate fan-shaped appearance. In Photo. 4a, for example, two radii along the folded lines make an angle of 167.5° instead of 180°. From this, the angle φ made by the cone axis and the perpendicular to the generating line of the original cone is computed at

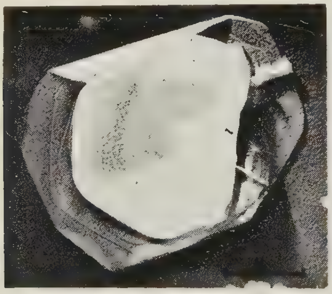

Photo. 3. Lotus-leaf-like form exhibited by metallic shadowing.

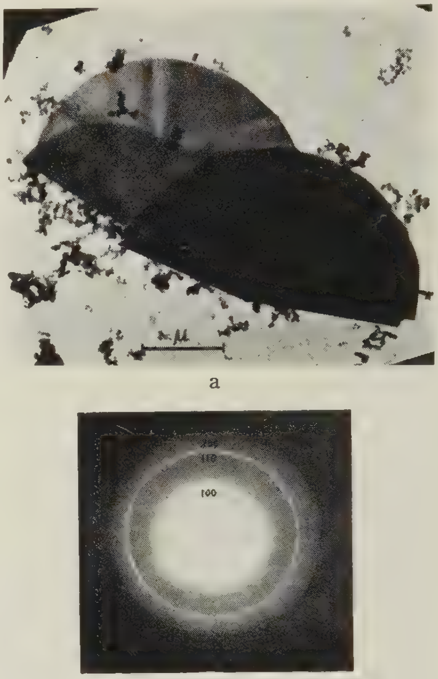
$$\varphi=\cos^{-1}(167.5/180)\approx 21.5°,$$

which gives a measure of the shapness of the cone.

Thus, the apparently circular crystal is concluded to be a stack of conical graphite sheets which intersects with electron beam (Fig. 1] so as to produce Debye-Sherrer diffraction rings, ellipses and diffuse bands together with



a

b

Photo. 4. Folded conical crystals.

2C. *Spiral Formation Mechanism*

Such a conical crystal can be formed by spiral growth mechanism as follows: When a thin graphite layer is twisted after the mechanical buckling producing the centra screw dislocation, it partly overlaps by an angle θ (*i. e.* rotational slip proposed by Wil-man[5]), forming a cone as shown in Fig. 2(a). The further growth of the crystal results in the conical spiral structure as in Fig. 2(b) where a helical twist boundary is introduced between the succesive layers. This mechanism seems particularly to conform to graphite because the interplanar binding is very weak in contrast with the extremly strong cohesion in the aromatic net plane.

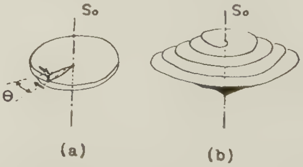


Fig. 2. Formation of conical crystal by spiral mechanism.

The twisting angle θ can be estimated from the microscopic observation and diffraction data. For example, θ of the specimen in Photo. 4a is $2\times(180°-167.5°)=25°$ on the assumption that the crystal is folded in completely flat form. Exactly speaking, however, this assumption is not suitable, because, in Photo. 4b, the Debye-Scherrer diffraction rings split into two maxima in the direction corresponding to that nearly vertical to the folded line in Photo. 4a. This means that the folded halves are inclined one to another, and the angle of inclination, α, is computed at about 15° from the distance between the two maxima. The geometrical relation between θ and α is illustrated in Fig. 3, by which the correct value of θ is computed at about 22°. In connection with this, the value of angle φ mentioned in the last sub-section should be revised as follows,

$$\varphi=\cos^{-1}\{\pi-(\theta/2)\}/\pi \quad \text{(general expression)}$$
$$=\cos^{-1}(169/180)\approx 20°.$$

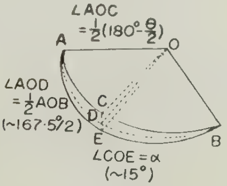

Fig. 3. Imperfectly folded crystal, illustrating the case of Photo. 4.

§ 3. Laminar Cleavage

3A. *Gliding of Conical Csystal*

In Photo. 5 we can observe nearly circular crystal flakes arranged in a row extending over up to 80 microns. The similar forms exhibited by adjacent flakes prove that they have been generated by the gliding of a crystal which is probably of such conical structure as mentioned in the last section. The shearing force promoting the glide might have been given in the process of specimen preparation for microscopy (rubbing method), because some scratches running nearly parallel

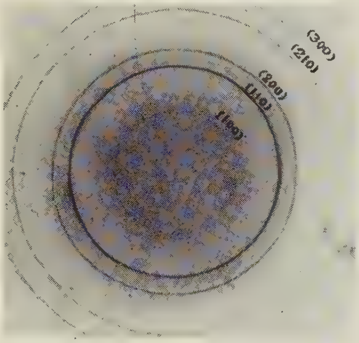
a



b

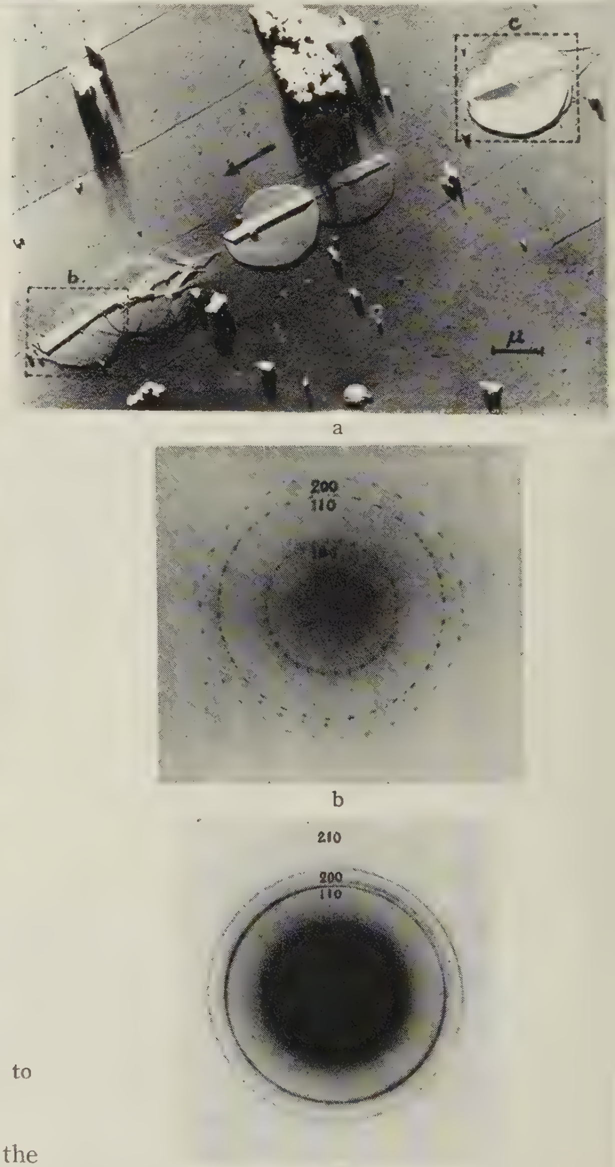
Photo. 7. A dark-field image corresponding to Photo. 6.

to the gliding direction are observed on the supporting film in the micrograph.

It is noticeable that some flakes in the upper-left part of the row exhibit each two radii making an angle smaller than 180°, somewhat like the folded crystal shown in Photo. 4a. This provides an evidence of the conical structure. On the other hand, the flakes in the under-right part are nearly circular and are traversed by a midrib-like fold along the gliding direction. Since the folded crystals are larger in diameter than circular ones, the original conical crystal, the parent of these flakes, might have been situated at the upper-left corner of the micrograph (indicated by arrow).



a

b

c

Photo. 8. Cleft sheets of two types, flat and concave ones.

At first sight, it would seem improbable that these flat discs glide away from a conical spiral. This is possible, however, if one assumes the mechanism as follows (*cf.* Fig. 4):

a) The central screw dislocation S_0 intersecting the active slip plane (conical plane) is so immobile that each gliding sheet may get over it successively, cancelling the initial spiraled structure of the sheet one by one.

b) The cancellation of the screw dislocation is similar to that demonstrated by Dawson and Anderson[6] on *n*-nonatriacontane crystal.

c) In order that each conical sheet is developed into flat one, a fairly sharp fold should be produced along the direction of the locus of the central screw axis, which may surely correspond to the abovesaid midrib-like one.

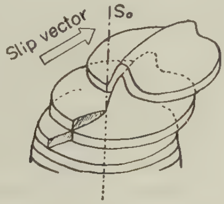


Fig. 4. Diagramatic representation of gliding of a conical spiraled crystal.

3B. *Another Mode of Cleavage*

In Photo. 6a. one can see another important aspect of the gliding of a conical crystal. Some broken sheets are observed at the place indicated by the arrow *S*, which suggests that the gliding in this case is not so simple. Besides, it should be remarked that the midrib-like striations are terminated at the centres of circular flakes indicated by the arrows *B* and *D''*. In order to explain these facts, another gliding mechanism of spiraled crystal should be introduced.

Firstly, if each glinding sheet gets over the central screw axis, it breaks itself into two semi-circular platelets (Fig. 5).

Secondly, if adjacent several sheets glide as a whole over the underneath, the initial screw dislocation is not cancelled but is cut into some shorter segments holding the conical spiral structure in each cleft sheet.

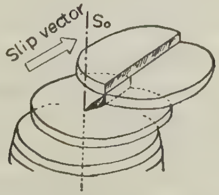

Fig. 5. Gliding of a spiraled crystal different from that shown in Fig. 4.

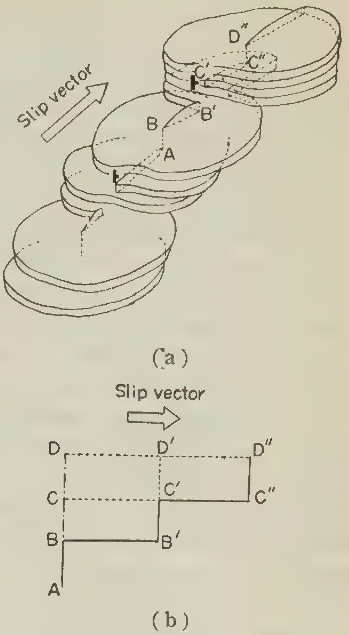

Fig. 6. Schematic illustration of the gliding shown in Photo. 6a; the central screw dislocation AD becomes zig-zag form.

These mechanisms are used to explain Photo. 6a. The arrows *B* and *D''* in Fig. 6 (a), corresponding to those in Photo. 6a, indicate the positions of emergence of such dislocation segments on the cleavage surfaces. A schematic picture representing the behavior of the dislocation line in this case is drawn in Fig. 6(b); the initial dislocation *AD* is transformed into such zigzag one consisting of five segments as below,

$$AD \longrightarrow AB + BB' + B'C' + C'C'' + C''D''$$

(screw) (screw) (edge) (screw) (edge) (screw),

where the signs in the round brackets denote the types of those dislocation segments just above them. Among these segments, *BB'* and *B'C'* are so to say imaginary dislocations lying on the upper and side exposed surfaces respectively. *AB* and *C''D''* are the very segments of screw type considered above. Thus, the midrib-like striations in this case can be attributed not only to the locus of the central screw axis but to the ledges of the edge-type components *BB'* and *C'C''* which terminate at the centres of discs. In connection with this, the diagramatic representation in Fig. 6

(a) enables us to understand the reason why the striation BB' in Photo. 6a is apparently jointed to the round edge of the right-hand adjacent disc.

Photo. 6b is the diffraction diagram corresponding to Photo. 6a, in which the Debye-Scherrer rings exhibit two intensity maxima respectively, suggesting that the two halves of each disc are slightly inclined one to another.

Photo. 7a reproduces a dark-field micrograph of the same specimen as that in Photo. 6a, and it is participated by only such a portion of the diffracted electron wave that passes through the aparture corresponding to the circular restricted area in Photo. 7b. Although the resolution is lowered owing to aberations, the above mentioned structural markings (midrib-like folds, dislocation ledges and other bending lines) are rather distinctly observed than in Photo. 6a. From the nearly uniform brightness of this image, it is concluded that any restricted portion of the diffraction rings corresponds to the whole parts of the specimen projected on the paper surface. Furthermore, can see numerous *double diffraction fringes* nearly all over the dark-field image, which have been discussed by Finch-Wilman and Mitsuishi-Nagasaki-Uyeda[7] independently. These observations are well consistent with our proposal, *i. e.* stacking of thin crystal layers successively rotated about the common axis in *c*-direction.

3C. *Glide Motion of Dislocations along Helical Interface*

As pointed out by Read[8] and other authors, the translational slip of a spiraled crystal along the helical plane leads to the intersection of moving dislocations with the screw axis and produces the dislocation jogs which generally slow down the glide motion. Moreover, except in the special case where the moving dislocations are of pure edge-type, each jog leaves behind a trail of lattice vacancies or interstitial atoms which may require considerable energy for the creation. At first sight, these difficulties would seem to make immpossible to explain the gliding of conical crystals in terms of the dislocation theory.

These difficulties can be removed, however, by introducing an assumption that the dislocation density is kept uniform all over the helical slip plane throughout the gliding process. The simplest example is schematically illustrated in Fig. 7, where the crystal is represented by a continuous plane in the form of a helicoid and the dislocations lie on the successive layers one to one as indicated by A_0D_0, C_0D_0, $E_0F_0\cdots$. When the shearing force is exerted on the crystal, these dislocations glide over the spiral ramp from right to left (as shown by arrows) and get to split in every two segments through the intersection with the central screw axis. It may be convenient to express this splitting process in the following formulae,

$$A_1B_1 \rightarrow A_1S + SB_1\ ,$$
$$C_1D_1 \rightarrow C_1S + SD_1\ ,$$
$$\cdots\cdots\cdots\cdots\ etc.\ ,$$

where S denotes the central screw axis. In ordinary circumstances, further glide makes those segments to move on the different levels of the spiral ramp, and the jogs are inevitably formed. In the present case, however, none of jog is necessarily produced, because the foregoing split of moving dislocations can be immediately followed by the recombination between the segments lying on the same levels of the spiral, which are to be expressed as below,

$$A_1S + SD_1 \rightarrow A_1D_1\ ,$$
$$C_1S + SF_1 \rightarrow C_1F_1\ ,$$
$$\cdots\cdots\cdots\cdots\ etc.$$

In the other words, the recombination forms again the system of moving dislocations which can continue to glide over the helical plane, as indicated by A_2D_2, $C_2F_2\cdots$. in Fig. 7.

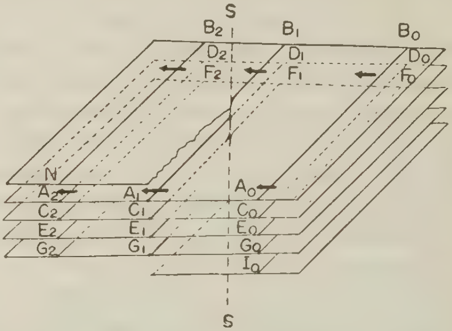

Fig. 7. 'Split and recombination' of moving dislocations.

In the case of the conical crystal, the slip along the helical twist boundary is generally represented by a moving set of crossed grid of screw dislocations. Parallel dislocations forming the grid sweep over the spiral ramp, repeating the aforesaid 'split and recombination' one after the another, so as to keep the dislocation density uniform all over the interface. This means that the orientation difference between the adjacent conical layers, defined by $\theta=2\tan^{-1}(b/h)$ (b; Burgers vector, h; dislocation spacing), is not altered throughout the gliding process, and that a local distortion is not produced anywhere on the helical interface. Therefore, in principle, it is expected that a conical crystal is ultimately resolved into individual monocrystal sheets, each of which has the unit thickness corresponding to one revolution of the spiral. In the actual case, however, the glide motion is usually so turbulent that the abovesaid theoretical expectation may not be satisfactorily realized. For example, as observed in Photo. 6a, the continuous spiral layer is broken off at places into flakes, which consists of multiple layeas producing spotty electron diffraction rings.

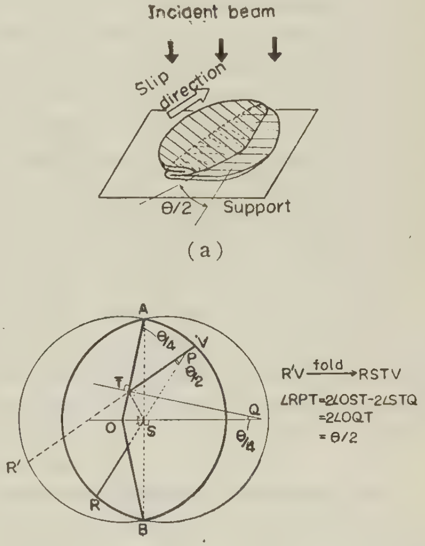
§ 4. Polygonization of Cone

4A. *Microscopic Observation*

Photo. 8a gives an image of gliding in which a conical crystal has been cleft so remarkably that individual sheets are almost separated from each other. Most of the cleft sheets are in flat form accompanying the midrib-like folds mentioned in the last section; *e.g.* the sheet indicated by the notation b. The sheet denoted by c is exceptionally thick, and is not flat but concave upward. Comparison between the largest diameters suggests that the sheet c is the parent of other flat ones.

4B. *Equidistant Spot Distribution on Diffraction Rings*

Photo. 8b reproduces the diffraction diagram of the sheet b. Each diffraction ring consists of thirty principal spots making angular intervals of 12° at the centre and those weak spots which are slightly displaced from the principals. The angular interval of these diffraction spots is closely related to the twisting angle θ at the first stage of the cone formation. Photo. 8b can be explained by assuming, for example, that the sheet consists of five revolutions of a conical spiral layer, θ of which is equal to 12°. However, this explanation is not necessarily unique, because the microscopic image shows that the sheet is folded into three. If a conical monocrystal layer of graphite corresponding to one revolution of the spiral is folded into flat form as shown in Figs. 8 (a) and (b), two halves on the both sides of the midrib-like fold are mutually disoriented by $\theta/2$ in a-direction. Accordingly, if the sheet b consists of three revolutions of the conical spiral and θ is equal to 24°, it may produce the diffraction spots at intervals of 12° similar to those in Photo. 8b.



(a)

(b)

Fig. 8. Remarkable veining during the glide leads to triple folding of sheet in nearly flat form.

It is noteworthy that the thickness of the cleft sheet is expected to be multiple of the spiral pitch defined by the Burgers vector of the initial screw dislocation. This is consistent with the prediction on the gliding mechanism described in sub-section 3*C*. On the other hand, one finds that the numerical value of θ supposed here, either 12° or 24°, is in simple relation with the three-fold symmetry of graphite lattice. This suggests that the rotational slip is governed by certain crystallographic law to some extent, but requires for its affirmation further investigations in future.

The weak spots accompanying the principals are firstly due to the midrib-like fold (△OAB in Fig. 8(b)), but may partly be of seperate origin, *e.g.* the contribution of the right-hand neighbour sheets partly projecting into the rectangular area (broken lines in the micrograph) restricted by the aperture.

4C. *Evidence of Polygonal Form*

Photo. 8c gives the diffraction diagram of the sheet *c* in Photo. 8a. The spotty diffraction rings and the accompanying elliptic arcs suggest, in connection with the concave form observed in the micrograph, that the conical structure is held to some extent. It should be remarked, moreover, that in this diagram the diffraction spots on (100)-, (110)- and (200)-rings are counted to two hundred and fourty respectively. These observations present another important aspect of the conical crystal as described in the following paragraphs.

Let suppose a conical crystal laid on the supporting mount as one puts a bowler. As mentioned before, only the peripheral part which is turned up like the rim of bowler participates in electron diffraction. Then, let trace a spiral path arround the cone axis starting from the most exterior layer of the conical crystal toward the centre. Then, one finds that the crystal orientation in *a*-direction changes successively with the shift of the position (the angular displacement about the cone axis) at the rate of θ per 2π (in radians). Accordingly, so long as θ is not much large, one revolution of the spiral layer corresponding to one round of the path may produce every six arcs of (100)-, (110)- and (200)-reflections in the diffraction diagram, and each arc makes an angle as large as θ at the centre. When θ is 24°, for example, one revolution corresponds to six arcs making the central angle of 24°, twice to successive 24° (48° in total), and finally the third revolution may complete a set of continuous diffraction rings.

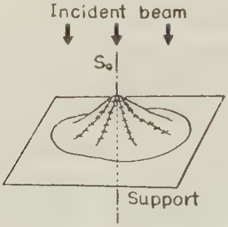


Fig. 9. Polygonization of conical crystal.

From such a viewpoint, it is of considerable importance that the diffraction rings observed are not continuous but spotty. This means that the peripheral part discretely changes the orientation arround the cone axis (along the spiral path considered before), and can be explained only by assuming that the cone is in polygonal form as illustrated in Fig. 9; *i. e.*, the discrete change in orientation is expected to occur at intervals of $2\pi/N$ radians, where N denotes number of the spots on each diffraction ring. For example, in the case of Photo. 8c, the interval is computed at 1.5° (=360°/240), and if θ is equal to 24° the crystal should be a hexadecagonal cone (24/1.5 =16) consisting of two and half revolution of the spiral layer at least.

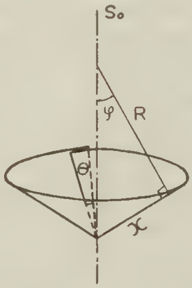

Fig. 10. Schematic illustration of $R-x$ relation.

4D. *Considerations*

It is easily understood that the aforesaid polygonization is closely associated with those edge dislocations of one sign which are produced by the plastic bend deformation of lattice into conical form. According to the schematic illustration given in Fig. 10, the radius of curvature and the average density of dislocations are expressed by

$$R=x/\tan\varphi=x/\sqrt{\{2\pi/(2\pi-\theta)\}^2-1} \qquad (3)$$

and

$$\rho=1/Rb=\tan\varphi/xb=\sqrt{\{2\pi/(2\pi-\theta)\}^2-1}/xb\,, \qquad (4)$$

where x is the distance from the cone top and b is the magnitude of the Burgers vector. Substituting $\theta=24°$ and $b=10^{-8}$ cm to eq. (4), for example, one can obtain a typical $\rho-x$ relation curve in Fig. 11. As seen there, the dislocation density rapidly decreases with increasing x, from the central part toward the exterior. The average density $\bar{\rho}$ is calculated by substituting half length of the generating line of the cone, $\bar{x}$, into eq. (4). For the example shown in Fig. 11, assuming $\bar{x}=0.5\,\mu$ (taken from the sheet *c* in Photo. 8a), $\bar{\rho}$ is computed at about $8\times10^{11}\text{cm}^{-2}$ which is of same order as in cold-worked metals.

The polygonization occurs through the climb motion of these dislocations in order to form the tilt boundaries, involving the migration of point lattice defects to or from the edges of their half planes. Since the specimen were treated at about 2500°C, well above the temperature at which graphite softens[9] (about 2000°C) this self-diffusion process is expected to occur quite rapidly. According to the schematic illustration in Fig. 12, the orientation difference ϕ at the polygonization boundary is approximately expressed by

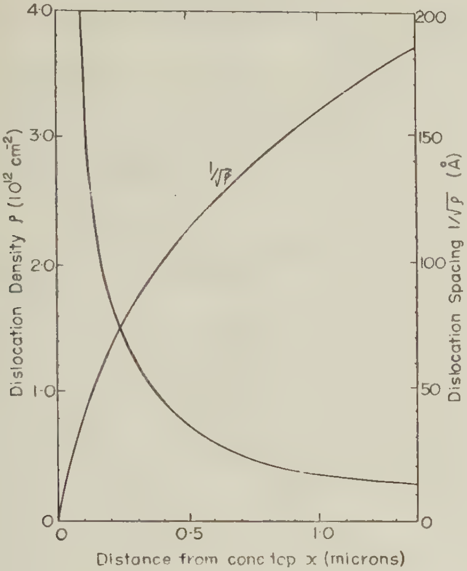

Fig. 11. $\rho-x$ and $1/\sqrt{\rho}-x$ relation curves when $\theta=24°$ and $b=10^{-8}$ cm.

$$\begin{aligned}\phi &\approx 2\cos^{-1}[\sin(2\pi/n)\cdot\cos\varphi/\sin\{(2\pi-\theta)/n\}]\\ &=2\cos^{-1}[\sin(2\pi/n)\{1-(\theta/2\pi)\}\\ &\quad\times 1/\sin\{(2\pi-\theta)/n\}]\,,\end{aligned}\tag{5}$$

where n is number of the polygonized domains. Substituting $\theta=24°$ and $n=16$ to this, ϕ is computed at about 9° for the sheet c in Photo. 8, which implies that the dislocation spacing in the boundary is about 12.5 b.

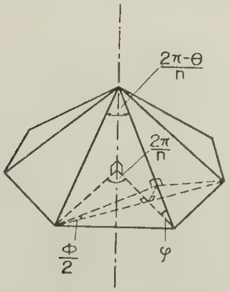

Fig. 12. Geometrical relation between ϕ, φ and θ.

On the other hand, one has to take note of the following fact; when the crystal is extremely thin it is only elastically bent, producing no dislocation. As a rough approximation, one can assume that the average dislocation spacing $1/\sqrt{\rho}$ gives the critical thickness deciding whether the bent crystal contains dislocations or not. A $1/\sqrt{\rho}$ *vs.* x relation curve is also indicated in Fig. 11. This curve suggests that if the thickness of the spiraled layer is about 100 A, for example, the central-side part of $x<0.4\,\mu$ is subjected to plastic deformation which may lead to the polygonization, whereas the exterior-side only to elastic circumferential bending.

It should be noted, however, that the foregoing discussion has revealed only the so-called geometrical aspect of the problem, taking no account of the energy condition and other mechanical circumstances associated with the creation of dislocations. In order to reveal the physical aspect, the author thinks, it must be settled first to overcome the general difficulties similar to those in the problem of fracture mechanism, which is to be attempted in future.

§ 5. Summary and Conclusion

By means of electron microscope apparently circular crystals of graphite were found. They have round growth patterns and show laminar cleavage accompanied by the formation of midrib-like folds. Moreover, they produced spotty electron diffraction rings accompanied by ellipses and diffuse bands. All these facts support that the apparently circular crystals are of conical layered structure.

Such a conical crystal can be formed by the spiral growth mechanism, if a thin monocrystal layer is mechanically buckled, producing the central screw dislocation, and then subjected to the *rotational slip* arround the screw axis so as to overlap by an angle.

The laminar cleavage has been explained also in terms of the dislocation theory by supposing that the gliding of conical sheets occurs along the helical interface so as to keep the density of moving dislocations uniform.

From the spots distribution on the diffraction rings produced by some cleft sheets, the crystal is concluded to be in the form of polygonal cone. It is theoretically verified that the polygonization of this kind is probable to occur under some restrictions concerning the thickness and the curvature of the conical spiral layer.

These results suggest that some important aspect of structure and properties of graphite can be revealed from the viewpoint of the dislocation theory, and further investigations along this course are expected to be attemted in future.

Fine Structures of X-ray Absorption Spectra of Crystalline and Amorphous Germanium

By Toshio SHIRAIWA, Tsutomu ISHIMURA and Masao SAWADA

Department of Physics, Faculty of Science, Osaka University

(Received March 18, 1957)

The X-ray absorption spectra of crystalline and amorphous germanium were photographed and fine structures at the K absorption edges were observed to 500 ev. in the crystalline and to 350 ev. in the amorphous state. The shape of the fine structure of amorphous germanium is like that of crystalline germanium though the small fluctuations disappear and the energy values measured from the main edge are smaller than the values of corresponding absorption maxima and minima of the crystalline germanium. From the comparison of the fine structures of both states we suggest that a structure which is like the diamond lattice of crystalline Ge with the smaller spacing exists in the amorphous Ge and this result coincides with the result of analysis of the X-ray diffraction pattern by Richter.

§1. Introduction

It has been reported that the fine structures existed even in the absorption spectrum of an amorphous substance¹⁾. The amorphous samples used in the above experiment was electrodeposited nickelsulfur and the fine structure obtained was of nearly the same form but of less appearance in the higher energy region as that of crystalline state. However, for reasons of their crystalline states being two-phase region of Ni and Ni_3S_2 which complicated the analysis of the fine structures, and also of the low resolving power of the spectrograph, the comparison between both states was not accomplished in detail. In the present experiment we treated germanium, as its amorphous state is that of a single element and the crystal structure was a comparatively simple diamond lattice.

The amorphous germanium can be prepared by evaporation method as a form of a thin film ($< 10^{-4}$ cm) and it is stable at room temperature[3]. The electron[2] and X-ray diffraction patterns have been studied by few authors and especially the Fourier analysis of the X-ray diffraction pattern has been done by Richter and Fürst according to Debye and Menke's method.

§ 2. Experiment

The crystalline or metallic germanium was 99.999% pure and the amorphous samples were prepared by evaporation in high vacuum. The furnace was made of tungsten plate and the substrate was a collodion film formed on a copper plate. The copper plate was a part of the bottom of a container of liquid air (A) and the radiation from outside to the substrate was interrupted by a wall of another liquid air bottle (B) except a hole (C) for the molecular beam of evaporated material. (See Fig. 1)

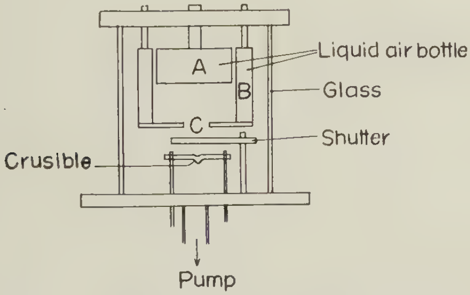

Fig. 1. A schematic diagram of the evaporation apparatus.

The prepared amorphous samples were studied by X-ray diffraction with a vacuum camera and Cu $K\alpha$ radiation monochromatized by a pentaerithrit crystal. But, as a pattern of the collodion film overlapped on the amorphous haloes, we dare not analyse them. Amorphous haloes coincided with other author's results in their positions but were accompanied by diffuse weak lines. The small angle part of the diffraction was photographed by a Guinier's type camera, which had a bended quartz monochrometer and the distance from the sample to the film was 20 cm, and the small angle diffraction pattern was not recognized and this fact showed that there was no small particle. According to Richter the evaporated germanium exists in an amorphous state only in a case of a thin film and in a thick film it is in a crystalline state. So, in our sample it was assumed that the process of crystalization partly had been developed but there were no perfect crystalline particle and the amorphous phase was still maintained.

The spectrograph was Johann's type and a radius of Rowland circle was 25 cm. The crystal was a quartz plate of 0.1 cm thickness and the first order reflection of (130) plane was used. The half width of Cu $K\alpha_1$ line was 0.6 x.u. with 7 mm opening of crystal surface and it can be thought that the crystal was bended considerable precisely. The dispersion at germanium K edge was 4.14 x.u./mm. In order to avoid the disturbing strong W $L\gamma$ series lines an X-ray tube of a gas-ion type with Mo target was used and for the reference lines W $L\gamma_3$ and other lines of shorter wavelength of W $L\gamma$ series were photographed after an exposure of the absorption spectrum was finished. The photo-plate was Fuji A–1 and situated tangentially to the Rowland circle. The angle between a photoplate and a tangent to the Rowland circle at the center of the crystal was computed from intervals between three reference lines.

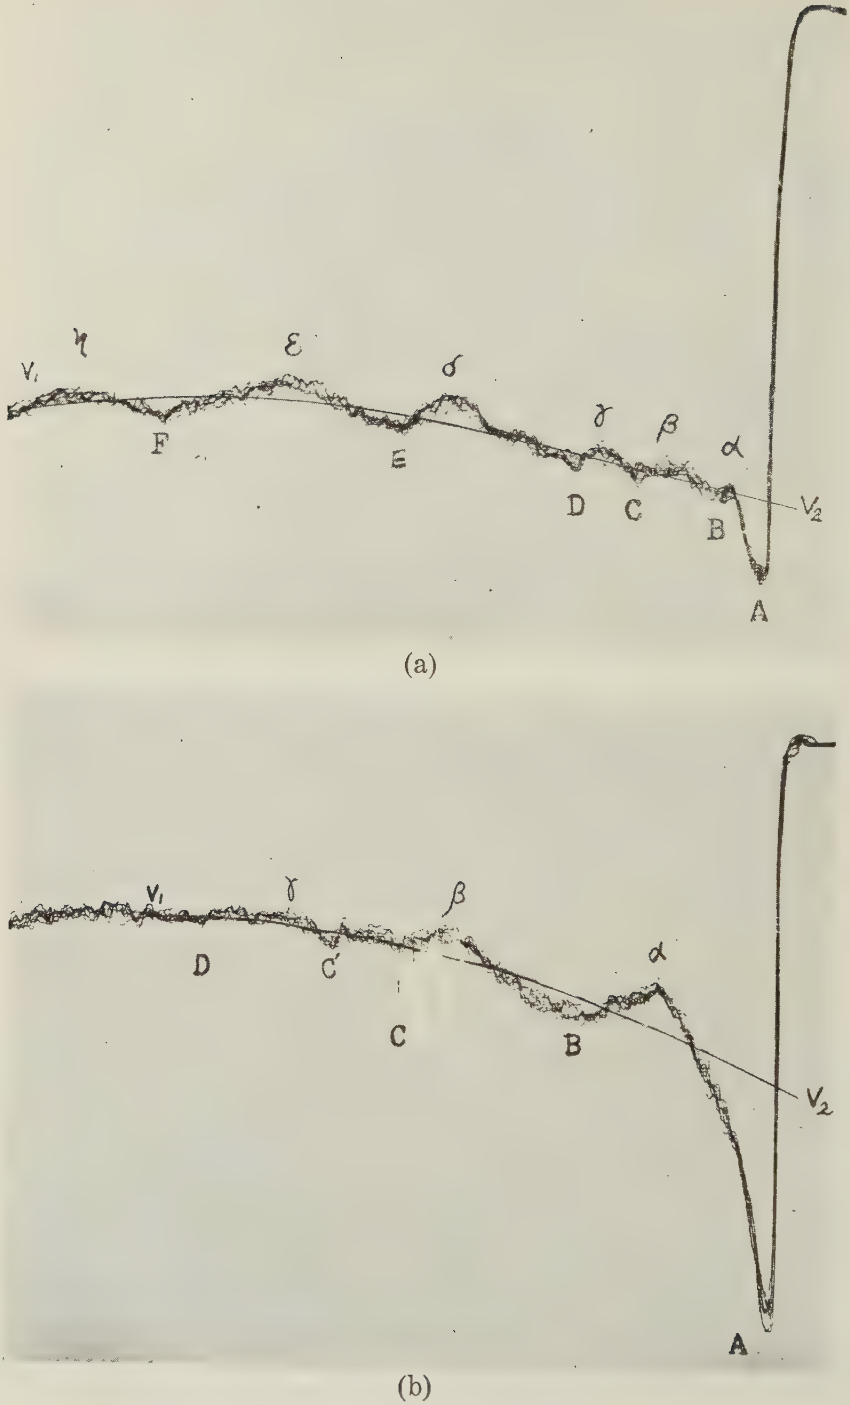
The time of exposure was about 80∼100h. with 20 k.v.p. and 8 mA for the crystalline specimen. For the specimen of amorphous samples a few tens sheet of thin films were assembled and the fairly larger exposure time was needed because of the absorption of collodion films.

For the measurement of intensity, absorbers of aluminium foil of four sorts of thickness were put in front of a photo-plate and spectrograms of various relative intensities were photographed on the same plate.

The photometer curves were recorded by a pen recorder type microphotometer with a photo-cell and the effect of grains were eliminated by registering records of about twenty curves on the same chart paper. (Photo. 1)

§ 3. Results and Discussion

The values of wavelengths of K absorption edge and absorption maxima and minima of the fine structure and energy separations measured from the main edge are listed in Table I. Wavelengths of reference lines were referred to Cauchois and Hulubei's table[4].



(a)

(b)

Photo. 1. Photometer curves of the absorption spectra near the *K* absorption edges of (a) crystalline Ge and (b) amorphous Ge.

The absorption spectrogram of a crystalline germanium has been photographed by Hulubei and Cauchois[5] and a fine structure extended to 300 eV. from the edge was observed. They resolved the structure more finely than us in the neighbourhood of the edge, and in higer energy region than 70 eV. their result coincided with our measurement.

Fig. 2 (a) and (b) show the curves of values $\mu_r=\mu-\mu_0/\mu_{edge}-\mu_0$, of a crystalline and an amorphous Ge respectively. In the above formula μ is the absorption coefficient and μ_0 is the value if the fine structure does not occur and this value was obtained from the point on the line V_1V_2 in Photo. 1 which was drawn to path the mean points of the fine structure. The μ_{edge} is the absorption coefficient at longer wavelength side of the edge, that is $\mu_{edge}-\mu_0$ is the difference at the edge.

The abnormal absorption minima A appeares next to the edge which has been noticed by Cauchois and Mott[6] as a white line in a crystalline states is also present strongly in the amorphous phase.

The wavelength of the edge slightly increases in the amorphous phase and this shows that the germanium atom in the amorphous structure have the isolated atomic feature compared to the crystalline phase.

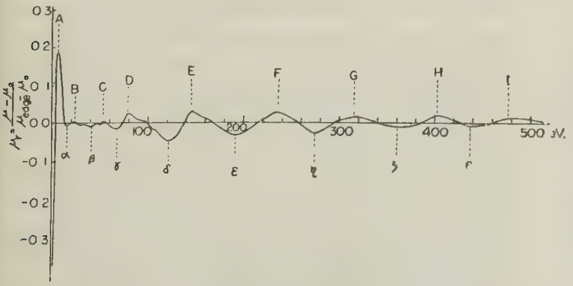

Fig. 2 (a). Showing the behavior of the fine structure of crystalline Ge. μ_γ is the ratio of the change of the absorption coefficient to the *K* absorption jump.

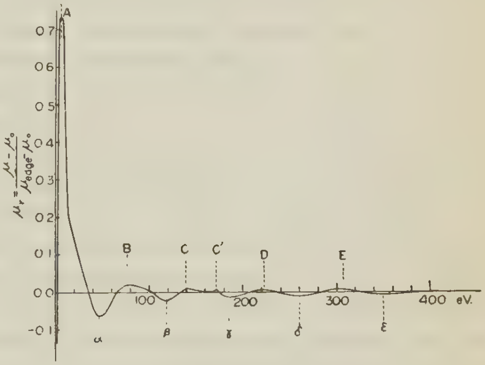

Fig. 2 (b). Showing the behavior of the fine structure of amorphous Ge.

In the case of crystalline state, the weak absorption minima (α, β, γ) appear next to the white line A and in the amorphous phase the broad band α appears instead of these weak structures. From the results of Fourier analysis, Richter suggested that the tetrahedron composed by five atoms which constitutes the diamond lattice in the crystalline germanium is still retained in the amorphous phase (Fig. 3), and he called this tetrahedron as a structure unit (Baueinheit) and combining these structure units he considered a model of the amorphous structure like diamond lattice but of less regularity. If the fine structure of the absorption spectrum is caused by the regular atomic arrangement increase of the irregularity in the amorphous substance will obscures the fine structure and this suggesion illustrates the phenomena that the α, β and γ of the crystal phase change into a broad band α in the amorphous phase, and small structures appeared between D and δ in the crystalline phase disappear in the amorphous phase.

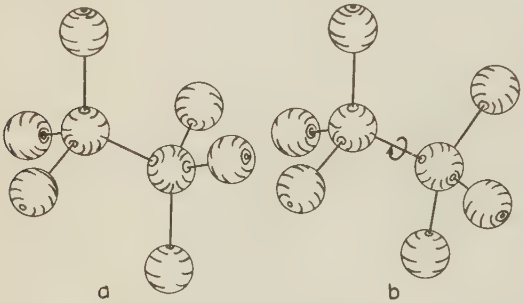

Fig. 3. Tetrahedron bonds (a) in a crystalline Ge and (b) in an amorphous Ge. Richter illustrated that the irregularity of the amorphous Ge was due to the rotations of tetrahedrons around the axis combining centeral atoms of the tetrahedrons.

In the higher energy region than 100 eV. the curves of μ_r in both phase are similar and when the values of abscissa of Fig. 2 (b) are multiplided by 1,036 for the amorphous phase, both maxima and minima are almost coincident though the magnitude in the amorphous phase is smaller than the crystalline. Their reduced values are listed in the last column in Table I. On the other hand it has well been known that the energy values of the fine structure measured from the main edge are inversely proportional to the square of the lattice constant when the crystal lattice is the same. So we may say that the structure of amorphous germanium is nearly the same structure with larger spacing than the crystalline germanium.

Generally (for ex. As, Se, etc.) the density in amorphous phase is smaller than in the crystalline and Richter analysed the X-ray diffraction patten on the assumption that the density decreased 20% in the amorphous phase. From our result the decrease of density is estimated at 5.4% but the real density will deviate from this value by the absorbed atoms or molecules which constitute partly the amorphous structure in the process of the condensation of germanium atoms.

Richter's result that the structure units of tetrahedrons constitute the amorphous germanium agrees with our result apart from the displacement of the wavelength of the edge, that is, in our result the bonds of atoms are weak in the amorphous phase, which suggest the increase of the inter atomic distance but in Richter's result the distance to the first nearest neighbors decreases.

In the higher energy region the magnitude of variation of μ_r becomes smaller in the amorphous state compared to that of the crystalline state with increasing energy. This phenomenon was recognized in an earlier experiment on Ni–S and these phenomenon will be probably due to the decrease of regularity of atomic positions or finite crystal size.

According to Richer the regularity of atomic positions was recognized within about 7 Å from a centered atom and this distance corresponds to the distance to the mid point between the third and the fourth nearest neighbors in the lattice of metallic germanium. Therefore, if the sample used by us and by Richter are the same the fine structure are determined by some ndighboring atoms surrounding the atom which absorbs X-ray energy in the region to the considerably high energy.

§4. Summary

The *K* X-ray absorption spectra of metallic and amorphous germanium were photographed and from the comparison of both fine structures the structure of amorphous germanium was infered, as a one coincident with Richter's result, namely, the structure unit like lattice was retained in the amorphous phase, and it was shown that the fine structure of the absorption spectrum was determined by the neighboring atoms arround the atom which absorbed the X-ray quantum.

Fine Structures of X-ray K Absorption Spectra of Copper in Various Copper Compounds

By Kenjiro TSUTSUMI, Akira HAYASE and Masao SAWADA
Department of Physics, Faculty of Science, University of Osaka

(Received April 1, 1957)

By using the North American Philips Diffraction Unit and Wide Range Goniometer modified to a tube spectrometer described by Coster and De Lang, the fine structures of the X-ray K absorption edges of copper in following compounds were recorded: cupric chloride ($CuCl_2$), cupric chloride dihydrate ($CuCl_2 \cdot 2H_2O$), cupric bromide ($CuBr_2$), cupric sulfate pentahydrate ($CuSO_4 \cdot 5H_2O$), cupric nitrate trihydrate ($Cu(NO_3)_2 \cdot 3H_2O$), cupric carbonate ($CuCO_3$), cupric formate tetrahydrate ($Cu(HCOO)_2 \cdot 4H_2O$), cupric acetate monohydrate ($Cu(CH_3COO)_2 \cdot H_2O$), bis glycino copper monohydrate ($Cu(C_2H_4NO_2)_2 \cdot H_2O$), bis glycino copper hydrate ($Cu(C_2H_4NO_2)_2 \cdot H_2O$), copper phthalocyanine β-form ($CuC_{32}H_{16}N_8$), copper phthalocyanine α-form ($CuC_{32}H_{16}N_8$), cuprous chrloride ($CuCl$), cuprous bromide ($CuBr$) and cuprous iodide (CuI). The recorded curves of the fine structures of the Cu K absorption edges of these compounds, except α- and β-phthalocyanine, were found to be very similar in forms and the wavelength values of these structures also nearly coincided within experimental errors. We consider that this is due to the fact that the copper atom is surrounded by the various kinds of atoms in octahedral configuration in many cases and above exceptional case (α- and β-phthalocyanine) in planer configuration. We conclude that the fine structures of the Cu K absorption edges of these compounds are mainly determined by the immediate surroundings of the atom in question in our experimental energy region from the main edges.

§ 1. Introduction

On the short wavelength side of the X-ray absorption edges, typical for a certain element, the absorption coefficient has not a monotonic variation but fluctuates over a distance of several hundred volts from the main edge in the case of crystalline solids or polyatomic molecules in which the absorption element forms a constituent. This phenomenon, the so-called "fine structure of X-ray absorption edges," finds its explanation in the scattering of a K photoelectron in the crystalline solid or in the polyatomic molecule that contains the absorbing atom. According to Kronig¹⁾ the origin of this phenomenon in the case of crystalline solids is as follows. X-rays are absorbed by the electrons which make transitions from the X-ray K levels to empty levels lying above the Fermi distribution. When atoms are grouped in the crystal lattice, these empty levels are grouped into zones, characteristic of the crystal as a whole and extended sometimes several hundred volts out beyond the ordinary atomic optical levels, and exist as forbidden and allowed bands. As the absorption coefficient is proportional to the product of the transition probability and state density, a fine structure occurs. From the Kronig's theory the fine structures of the absorption edge must be highly depend upon the type of the crystal lattice in which the absorbing element is imbeded. This can experimentally be tested in several ways²⁾ and many peculiarities of the fine structures of the X-ray absorption edges can be fully understood in the basis of Kronig' theory. However, there seemed to be at first sight some discrepancy between theory and experiment in some special cases, for instance in the case of ionic crystals and complex compounds, and it has been demonstrated that the immediate surroundings in the crystal lattice of the atoms in question are also of great importance.³⁾ Thus in the case of the chemical compounds, the situation is more complex due to the presence of several kinds of atoms, the greater complexity of the lattice structure and the fact that a given sort of atom may have different valences and even different surroundings in the same lattice. Many investigations[4)] have been carried out on compounds of the various elements for the various purposes. It is therefore of some importance to extend the experimental data of the fine structures of the X-ray absorption edges of various chemical compounds, and to investigate the relation of the fine structures of the absorption edges to the chemical bond to the absorbing elements, the immediate surroundings in the crystal lattice of the atom in question and the crystal lattice in which the absorbing element is imbeded. Therefore the present authors investigated the fine structures of the X-ray *K* absorption edges of copper in following cupric and cuprous compounds: cupric chloride ($CuCl_2$), cupric chloride dihydrate ($CuCl_2 \cdot 2H_2O$), cupric bromide ($CuBr_2$), cupric sulfate pentahydrate ($CuSO_4 \cdot 5H_2O$), cupric nitrate trihydrate ($Cu(NO_3)_2 \cdot 3H_2O$), cupric carbonate ($CuCO_3$), cupric formate tetrahydrate ($Cu(HCOO)_2 \cdot 4H_2O$), cupric acetate monohydrate ($Cu(CH_3COO)_2 \cdot H_2O$) bis glycino copper monohydrate ($Cu(C_2H_4NO_2)_2 \cdot H_2O$), bis glycino copper hydrate ($Cu(C_2H_4NO_2)_2 \cdot xH_2O$), copper phthalocyanine α-form ($CuC_{32}H_{16}N_8$), copper phthalocyanine β-form ($CuC_{32}H_{16}N_8$), cuprous chloride ($CuCl$), cuprous bromide ($CuBr$) and cuprous iodide (CuI).

§ 2. Experiments

X-ray Diffraction Unit and Wide Range Goniometer of North American Philips Company Inc. (Norelco)[5)] are used. The unit is mechanically so arranged as to maintain a 1:2 ratio of the rotational speed between the crystal holder of the center of the goniometer and the Geiger-Müller counter as required for Bragg reflections. This unit is an installation to record the ordinary powder diffraction pattern. This unit is modified to a tube spectrometer described by Coster and De Lang[6)] who used the customary single crystal spectrometer removing its slit and used the line focus of the X-ray tube as the source and also as the slit, and could get the sufficient resolving power and intensity by their method. We attached Geiger-Müller counter to their method and let the crystal and the counter rotate automatically, therefore we could get the absorption spectrum by recording automatically on the strip-chart. The details of this modified method will be published in another paper[7)]. The effective target area of this unit is about $1.2 \times 10\ \text{mm}^2$, and we take off X-rays in 3° angle to the target surface, then the width of the effective target is about 0.06 mm. The X-rays of various wavelengths which satisfy the Bragg condition in the center of the spectrometer will be able to pass the receiving slit in front of the Geiger-Müller counter (Fig. 1). The width of the receiving slit was 0.003 in. and the distance between the focus of the X-ray tube and the center of the spectrometer and that between the center of the spectrometer and the receiving slit are 17 cm each. The X-ray divergency caused by the width of the effective target area and the width of the receiving slit (collimating slit system) has a relation[8)] to the resolving power of this spectrometer. In our case the maximum divergency of the slit system is about 0.0004 radians. As a reflecting crystal LiF was used. The resolving power of this instrument is rather well, and taking into consideration the undesirable influences of the slit width of the photometer and the grain size of the photographic plate it is sufficient to use this instrument for such research of the extended fine structures of the X-ray absorption spectra. The fine structures of the X-ray Cu *K* absorption spectra of the substances already described in introduction were recorded on the strip-charts. They are reproduced in Fig. 2 to Fig. 16. The X-ray tube with a cobalt taget at hand was loaded with 15 kV, 10 mA. Considering the time constants of the rate-meter and the recorder,

the scanning speed of the Geiger-Müller tube 1/8° per min was used in all cases, and the time constant of the rate-meter was 2 or 4 sec, and one scale division of the stripchart correspondings about 9 X-ray quanta. The absorbers were held in front of the Geiger-Müller tube, and the best results were obtained by mixing a small amount of grease for vacuum seal with the powdered sample and spreading the mixture on a thin paper up to the required amount 10 mg/cm² to 30 mg/cm². This grease also protect against the various chemical attack with moisture. The first order reflection of general rays from the cobalt target was used. As we can directly measure the primary X-ray intensity and the

transmission X-ray intensity in this case, this recording method is easily changed so as to enable the measurement of the absorption coefficient. Table I, II, III and IV show the wavelength values of the fine structures of Cu K absorption edges of these compounds thus measured and Table V, VI, VII and VIII show energy separations of these fine structures from the K main absorption edges of copper. In the case of cuprous bromide and cuprous iodide, the fine structures of the Cu absorption edges were very faint so that we took the photographs of the Cu absorption edges of copper halide (CuI, CuBr, CuCl, $CuBr_2$, $CuCl_2$) with a bent crystal focusing spectrograph of the Cauchois type. The fine structures of the Cu absorption edges of CuI and CuBr were also very faint on the photographic plates, but we measured the wavelength values by means of a comparater with low magnification approximately five. These results fairly well coincided with those of recording method.

§ 3. Results and Discussions

The various compounds which have been treated in this paper are classified in three cases and discussed respectively as follows.

Case A. Cupric compounds:

$CuCl_2$, $CuCl_2\cdot 2H_2O$, $CuBr_2$, $CuSO_4\cdot 5H_2O$, $Cu(NO_3)_2\cdot 3H_2O$, $CuCO_3$, $Cu(HCOO)_2\cdot 4H_2O$, $Cu(CH_3COO)_2\cdot H_2O$, $Cu(C_2H_4NO_2)_2\cdot H_2O$, and $Cu(C_2H_4NO_2)_2\cdot xH_2O$.

In the case of the above compounds, it will be seen that the fine structures of the Cu K absorption edges of those compounds are very similar in forms by comparing each recorded curve in Fig. 2 to Fig. 11. As one sees from Table I and Table II, the wavelength values of the large absorption minima β, δ and maxima A, C, E, nearly coincide within the limit of experimental errors. This is clearly seen in Fig. 17 which shows a diagram of energy separations of the fine structures of the Cu absorption edges of these compounds from the main edges. It is regarded that this is due to the following facts. In these compounds the copper atom is bounded to the surrounding atoms by the bonds which one considered to be essentially ionic bond or essentially covalent bond or their mixture, and the bonding types are not the same in the all compounds. But, in these compounds the copper atom is surrounded by four atoms of nitrogen, oxygen, or halogens at the corners of the pseudo-square, and by two atoms of various kinds which situated upwards and downwards of the central copper atom at a little larger distance from the copper atom than those of four atoms at the corners of the square from the same copper atom. By these six atoms the elongated pseudo-octahedron[9] is formed. If the fine structures of the absorption edges are mainly determined by the immediate surroundings, they must be similar in all cases of these compounds. The little differences of forms of the fine structures of absorption edges of these compounds are du to the differences of the forms of these pseudo octahedrons. The crystal structures of thes compounds and their bonding types are ver complicated and are not the same in all com pounds but in the energy region here studie we can not find any difference which is cause by the crystal lattice as expected from Kronig' theory and also by bonding types. The distanc from the immediate surroundings to the ator in question has not also significant influenc on the fine structures of the absorption edges It is rather probable that the fine structure are determined by the radii of copper atom in question which are considered to be nearl equal in all these cases.

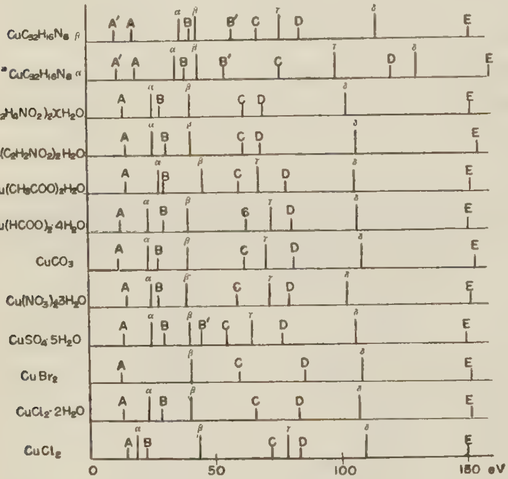

Fig. 17. Diagram of the energy separations of fine structures of absorption edges from the main edges.

Case B. Copper phthalocynaine (α- and β form)

In the case of β-phthalocyanine (Kienle' nomenclature) this is in the metastable state and its crystal structure and the atomic ar rangement of this molecule are not well studied In the case of α-phthalocyanine[10] the atomic arrangement is very much resemble as the preceding compounds, namely the copper atom is surrounded by four nitrogen atoms at the coners of the pseudo-square but in this case the distances of two copper atoms coordinated upwards and downwards the central one are each 4.76 Å. As this distance (Cu–Cu) is larger compared to that of the nitrogen atom from the central copper atoms (Cu–N) it is considered that these two copper atoms have less influence on the electric field around the centra copper atom than four nitrogen atoms. I seems to us that this is the reason why the fine structures of the Cu K absorption edges of phthalocyanines differ from those of preceding cupric compounds.

Case. C; CuI, CuBr, *and* CuCl

Among above cuprous compounds, the fine structures of Cu K absorption edges of Cu and CuBr were very faint. As all these com pounds crystallize in the lattice of Zn–S type (Zincblende type)[11] and the copper atom ha the identical position in all cases, the similarity of the fine structures of absorption edges ac cording to Kronig's theory was expected. Bu we failed to compare well these structures Stephenson[4] reported that the fine structure of the Cu K absorption edges of CuBr are n repeatable structures.

Summary

In general the wavelengths of main edges of copper do not greatly change in every cases, but tend to slightly displace towards the shorter wavelength sides with valencies than that of pure metallic copper. In the energy regions here studied the fine structures of absorption edges of copper are mainly determined by the immediate surroundings of the atom in question. There are no difference which should be caused by the crystal lattice according to the Kronig's theory. Coster¹²⁾ and others¹³⁾ show that even the fine structures of absorption edges of metals are influenced by the surrounding atoms. Also Kiestra¹⁴⁾ remarks that the fine structures are determined by the immediate surroundings of the atom in question in the regions about 40 eV to 150 eV from the main absoption edges. This statement is well supported in our present experimental results.

Recently we saw the manuscript by Cotton and Hanson¹⁵⁾ after we had written this paper. In our cases the fine structures close to the main edges were not studied and some of the small maxima and minima of these structures might not be measured. As many compounds in our experiment are not the perfectly ionic crystals, Cotton and Ballhausen's theory¹⁶⁾ can not directly be applied to these compounds.

We wish to express our sincere thanks to the members of Nitta and Watanabe laboratory where some of the samples were prepared.

Influence of Temperature on the Pure Nuclear Quadrupole Resonance in Hexachloroethane

By Itaru TATSUZAKI and Yasaburo YOKOZAWA

Research Institute of Applied Electricity, Hokkaido University, Sappro

(Received January 18, 1957)

The temperature dependences of the frequencies and the widths of absorption lines of pure nuclear quadrupole resonances in hexachloroethane were studied. The change of resonance frequencies with temperature was explained as influences both of a torsional vibration of one end of CCl_3 groups with respect to the other end and of a rotational vibration of those groups as a whole around the C–C axis, the frequency of the latter vibration being changed with temperature owing to a thermal expansion of the lattice. The line widths at half-maximum intensity were about 2 Kc/s at temperatures of 77°K and 90°K, and about 10 Kc/s at 196°K, although no absorption was detected at room temperature. The broadening of the resonance spectrum seems to be explainable by a reorientational motion around the C–C axis with much lower frequency than the resonance one.

§ 1. Introduction

Although the resonance spectra of pure nuclear quadrupole of $Cl_3C \cdot CCl_3$ were observed at 20°K and 77°K by R. Livingston1), no absorption spectrum was detected at room temperature. The melting point of this molecule is 185°C and any phase transition which disturbs the observation of the spectra between 77°K and the room temperature has not been known. The purpose of the present work is to find the cause which may disturb the observation at room temperature, by the study of the temperature dependences of both the frequencies and the widths of absorption lines measured at 77°K, 90°K and 196°K. The temperature dependences on the resonance frequencies are explained as influences both of a torsional vibration of one end of CCl_3 groups with respect to the other and of a rotational vibration of the groups as a whole around the C–C axis, the frequency of the latter vibration being changed with temperature owing to a thermal expansion of the lattice. The full line widths at half-maximum intensity were about 2Kc/s at 77°K and 90°K, and about 10 Kc/s at 196°K. The broadening of the resonance line widths can not be explained by relaxation mechanisms due to these vibrations, which are given first by H. Bayer2) for ClHC=CHCl. Y. Ayant3),4) reported that the reorientational motion with much lower frequencies that the resonance one could broaden the line width exponentially with the increase of temperature. If the effect of this reorientational motion is applied to the width at 196°K, it is found that the resonance line is never detected at room temperature.

§ 2. Experimental Apparatuses and Procedures

The spectrometer used in this work was a super regenerative type with a Collpitts circuit which was similar to that reported by K. Torizuka5). A frequency modulation was applied for the oscillator and a detected signal was observed either on a C.R.O. or an automatic recorder, the latter employing the method of a narrow band amplifier and a phase sensitive detector. The modulation frequency was 270 c/s and the band width of the narrow band amplifier was about 10 c/s. The time constant of recording system was about 1 sec. The velocity of frequency sweep was about 0.1∼0.2 Kcps/sec and its sweeping was established with a capacitor driven by a phonomotor. The shape of the detected signal very sensitively depended both on the quench amplitude and on quench frequency as pointed by K. Tsukada6). In order to obtain the derivative curve of pure absorption, both the quench amplitude and quench frequency had to be experimentally adjusted by observing the signal. The resonance frequency was determined by observing the beat frequency between the oscillation of spectrometer and a higher harmonic of a heterodyne frequency meter. For the measurement of the width, signals of the higher harmonic frequency modulated by 4 Kc/s was occasionally recorded. Both the heterodyne frequency meter and the modulating frequency were calibrated through radio station, J. J. Y.. The sample used in this work was Kanto Chemical Company reagent grade powdered material and had a melting point of 185°C in a sealed capillary tube. The powder of $Cl_3C{\cdot}CCl_3$ put in a thin glass tube was placed inside the six turned r–f coil of tuning circuit and was cooled to 77°K, 90°K and 196°K, being immersed in liquid nitrogen, liquid oxygen and solid carbon dioxide respectively. In order to avoid the broadening of the absorption line owing to the temperature inhomogeneity in the sample, the measurements were made about one hour after the sample was placed in a cooled Dewer vessel.

§ 3. Preliminary Discussions

A) *Temperature Dependence of the Resonance Frequency*

It is well known that the quadrupole resonance frequency generally decreases in magnitude with the increase of temperature*. This effect was explained by H. G. Dehmelt, H. Krüger⁷⁾ and Bayer²⁾ as an influence of the lattice vibration in solid. Recently, T. Kushida⁸⁾ extended their theory to more general case. According to Bayer's model the direction of the maximum principal axis of field gradient tensor (z′-axis) vibrates around the z-axis.

The z-axis is the direction of the maximum principal axis when there is neither molecular vibration nor lattice vibration. If the z′-axis inclines by a small angle θ from the original direction, z-axis, the Hamiltonian operator of interaction between the field gradient tensor and the nuclear quadrupole moment is given by

$$\boldsymbol{H}=\frac{eQq}{4I(2I-1)}\left\{\left(1-\frac{3}{2}\theta^2\right)(3\boldsymbol{I}_z^2-I(I+1))+3\theta(\boldsymbol{I}_z\boldsymbol{I}_y+\boldsymbol{I}_y\boldsymbol{I}_z)-\frac{3}{4}\theta^2(\boldsymbol{I}_+^2+\boldsymbol{I}_-^2)\right\} \quad (1)$$

assuming the asymmetery parameter is zero.

The notations in Eq. (1) have their usual meanings. The frequencies of the molecular vibration and the lattice vibration are much higher than the resonance frequency. Therefore, θ^2 in the first term of Eq. (1) can be replaced by its average $\overline{\theta^2}$. Accordingly, the resonance frequency $\nu(T)$ is expressed as

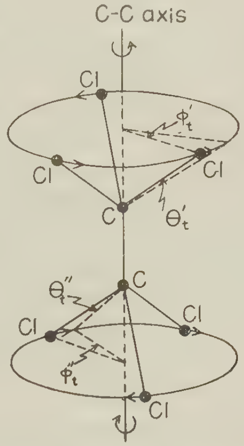

Fig. 1. Molecular structure of hexachloroethene and its torsional vibration. The parameters¹¹⁾ at 15°C are C–Cl=1.76 Å~1.77 Å, C–C=1.54 Å and ∠ClCCl=109.8°.

$$\nu(T)=\nu_0\left(1-\frac{3}{2}\overline{\theta^2(T)}\right), \quad (2)$$

where ν_0 is the resonance frequency when $\theta=0$ and equals to $eQq/2h$ for a nucleus with spin 3/2. The symmetry of $Cl_3C{\cdot}CCl_3$ is D_{3d} as shown in Fig. 1 and the frequencies of normal vibrations in the molecular vibration are well known⁹⁾ except A_{1u} mode of a torsional vibration. The A_{1u} mode is both Raman and infra-red inactive owing to D_{3d} symmetry of $Cl_3C{\cdot}CCl_3$. However, the height of potential wall against this vibration is estimated approximately 7~15 Kcal/mole by an electron diffraction investigation¹⁰⁾. It is assumed that the potential function hindering the torsional vibration has the form of

$$V=\frac{1}{2}V_0(1-\cos 3\phi_t) \quad (3)$$

where, ϕ_t is the relative angle of rotation of two groups CCl_3 and V_0 is the wall height. It follows that the torsional frequency ν_t is given by

$$\nu_t=\frac{3}{2\pi}\sqrt{\frac{V_0}{2I_r}} \quad (4)$$

---

* It is reported there are some exceptions.: $K[Cu(CN)_2]$, (Krüger and M. Berkhaut: Zeit. für Physik **132** (1952) 171), WCl_6 (R. P. Hamlen and W. S. Koski: J. Chem. Phys. **25** (1956) 360).

where I_r is the reduced moment of inertia, 243.5×10^{-40} gr-cm². The available structure parameters to determine I_r is refered to the results of X-ray analysis[11]. From Eq. (4), ν_t is 60 cm⁻¹ assuming $V_0=10$ Kcal/mole. This frequency is much lower than any other normal frequency of $Cl_3C\cdot CCl_3$. Therefore, it may be assumed that the contribution to the resonance frequency of any other normal vibration is negligible compared with that of the torsional vibration among molecular vibrations. Considering the symmetry of this molecule, it is assumed that a rotational vibration around the C–C axis is the most favourable lattice vibration in solid state. From these points of view, θ can be expressed as

$$\theta=\theta_t+\theta_r\ , \tag{5}$$

where θ_t and θ_r are deflection angles of the maximum principal axis of the field gradient tensor due to the torsional and the rotational vibration respectively. The direction of the maximum principal axis of the field gradient tensor is assumed to coincide with the direction of the C–Cl bond. For simplicity, assuming that the torsional vibration is incoherent with the rotational vibration, θ_t is independent of θ_r. Taking the time average, it follows

$$\overline{\theta^2}=\overline{\theta_t^2}+\overline{\theta_r^2}\ , \tag{6}$$

where

$$\overline{\theta_t^2}=\frac{1}{3}\sin^2\frac{A}{2}\frac{1}{I_r}\frac{h}{4\pi^2\nu_t}\left(\frac{1}{2}+\frac{1}{\exp(h\nu_t/kT)-1}\right) \tag{7}$$

and

$$\overline{\theta_r^2}=\frac{4}{3}\sin^2\frac{A}{2}\frac{1}{I}\frac{h}{4\pi^2\nu_r}\left(\frac{1}{2}+\frac{1}{\exp(h\nu_r/kT)-1}\right) \tag{8}$$

respectively, (cf. Appendix), and I is the moment of inertia of $Cl_3C\cdot CCl_3$ around the C–C axis, which is equal to $4I_r$ and A is the angle ∠CClC which is taken as 109.8°. Inserting the Eq. (6), (7) and (8) in Eq. (2), the next relation is obtained.

$$\frac{\nu_0-\nu(T)}{\nu_0}=\frac{1}{2}\sin^2\frac{A}{2}\frac{h}{4\pi^2I_r}\times\left\{\frac{1}{\nu_t}\left(\frac{1}{2}+\frac{1}{\exp(h\nu_t/kT)-1}\right)+\frac{1}{\nu_r}\left(\frac{1}{2}+\frac{1}{\exp(h\nu_r/kT)-1}\right)\right\} \tag{9}$$

B) *Temperature Dependences of the Line Width*

The causes of line broadening in a pure quadrupole resonance were reported by Bayer[2], Ayant[3),4] and E. R. Andrew[12]. These causes are (a) magnetic dipolar interaction between neighbouring nuclei and Zeeman effect in the terrestrial magnetic field, (b) fluctuation of θ^2 in the first term of Eq. (1) which does not give a relaxation, but has a relation with line broadening, (c) fluctuation of θ in the second term of Eq. (1) which induces a transition of $|\Delta m|=1$, (d) fluctuation of θ^2 in the third term of Eq. (1) which induces a transition of $|\Delta m|=2$, (e) imperfections in a crystal lattice which cause the field gradient to vary somewhat from molecule to molecule and (f) reorientational motion of CCl_3 group around the C–C axis, which limits a mean life time of the energy levels at each position, and gives a line broadening intensively depending on temperature.

The features of these causes are as follows. (a) does not depend on temperature. (b) and (d) depend on temperature and the line width is approximately proportional to square of temperature. (c) gives a negligible effect on the line width compared with (d). (f) depends on temperature remarkably. The full line width increases exponentially with the increase of temperature and is approximately, at half-maximum intensity[3),4],

$$(\Delta\nu)_{1/2}=\frac{\lambda}{\pi}\qquad \lambda=2\nu\exp\left(-\frac{W}{kT}\right), \tag{10}$$

where λ is a transition probability of the reorientational motion and W is a height of potential wall in which the molecule vibrates with frequency ν.

§ 4. Experimental Results and Discussions

The results of the experiment are listed in Table I. The resonance frequencies at 20°K and 77°K are quoted from Livingston's research[1] and values at 77°K are in agreement with those of the results of the present work within the experimental error of ±0.001 Mc/s.

The resonance absorption of Cl^{37} were observed at the frequencies expected from the known ratio of quadrupole moments. The existence of four absorption lines is in agreement with the result of X-ray analysis[11] which reported that this crystal contained four molecules in the unit cell. The value of ν_0 for each absorption line was determined by the extrapolation of the curve of resonance frequency against temperature to absolute

Table I. Resonance frequency and line width in $Cl_3C\cdot CCl_3$.

* From R. Livingston[1] for resonance frequency.

zero as shown in Fig. 2. They are 40.920, 40.852, 40.825 and 40.676 Mc/s respectively. As there is no available data, unfortunately, to determine the frequency of rotational vibration ν_r, the validity of Eq. (9) could not be examined directly from the resonance frequencies. If ν_r was calculated from Eq. (9) by the use of resonance frequency conversely, some informations would be obtained concerning the employed model in § 3. In the calculation of Eq. (9), the frequency of torsional vibration ν_t was assumed to be 60 cm^{-1} at each temperature, because the frequency of molecular vibration does not change with temperature. The calculated results are listed in Table II. As seen in Table II, each resonance line gives slightly different value for ν_r at the same temperature and moreover, each ν_r increases with the decrease of temperature. The small differences among ν_r's calculated from resonance frequencies seem to be due to the existence of anisotropic van der Waals interaction[11] between molecules in the crystal lattice. The variation of ν_r with temperature is explained by the consideration of variation of cohesive forces caused to the thermal expansion as suggested by B. Dreyfus and D. Dautreppe[13] in paradichlorobenzene. Assuming that the Grüneisen's formula is valid in the rotational vibration, γ is given by

$$\gamma = -\frac{d\log\nu_r}{d\log V}, \tag{11}$$

hence,

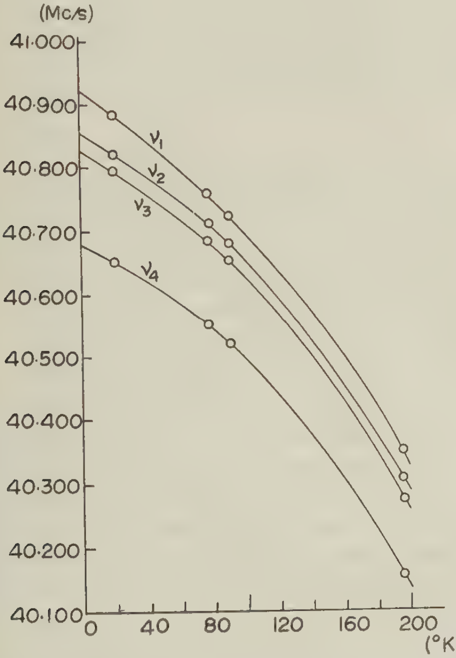

Fig. 2. Variation of the resonance frequency of Cl^{35} in $Cl_3C\cdot CCl_3$ with temperature.

* $\left(\frac{\nu_0-\nu}{\nu_0}\right)_r$ is contribution of rotational vibration to $\frac{\nu_0-\nu}{\nu_0}$.

$$\frac{\nu_r(t_1)}{\nu_r(t_2)} \simeq \exp\left[\gamma\alpha_v(t_2-t_1)\right] . \tag{12}$$

Where γ represents Grüneisen constant, V, volume and α_v, volume expansion coefficient, and $\nu_r(t_1)$ and $\nu_r(t_2)$ represent ν_r at temperatures of t_1 and t_2 respectively. γ is found to be 2.9 from Eq. (12) using the following sets of values: $\langle\nu_r(77)\rangle_{Av}=45.1\,\text{cm}^{-1}$, $\langle\nu_r(196)\rangle_{Av}=31.7\,\text{cm}^{-1}$ and $\alpha_v \simeq 1\times10^{-3}$[14]. Each $\langle\nu_r(t)\rangle_{Av}$ is given in Table II. In a similar way, from the values of $\langle\nu_r(90)\rangle_{Av}$, $42.3\,\text{cm}^{-1}$ and $\langle\nu_r(196)\rangle_{Av}$, γ becomes 2.7. Taking the mean value, γ is 2.8. On the other hand, Grüneisen constant, using thermodynamical relations, can be expressed as follows.

$$\gamma=\frac{\alpha_v V}{\kappa C_v} \qquad C_p-C_v=\frac{\alpha_v{}^2 VT}{\kappa} , \tag{13}$$

where κ is the compressibility, and C_p and C_v the molar heat at constant pressure and constant volume respectively.

By the X-ray analysis[11], the unit cell of this crystal at 15°C has a dimension of $a=11.56$ Å, $b=10.18$ Å, $c=6.42$ Å, and it contains four molecules and belongs to the space group Pnma. There is no data about C_p at 15°C but it has been measured at 22.25°C and is equal to 48.9 cal/mole[15]. The volume per mole is calculated to be 114.12 cc/mole using the volume expansion coefficient. From Eq. (13), using the numerical values, $\gamma=2.8$, $C_p=48.9$ cal/mole, $\alpha_v=1\times10^{-3}$, $V=114.12$ cc/mole and $T=295.25$°K, the value of κ is obtained as $37\times10^{-6}\,\text{Atm}^{-1}$, which is compatible with the compressibility of other organic compounds listed in Table III[16], taking the difference between solid and liquid into consideration. Recently, it is reported that the temperature dependence of the resonance frequency at atmospheric pressure has to be considered including the contribution of the effect of volume expansion on $|q|$[17]. Then, in order to do an adequate analysis of the observed temperature variation of the resonance frequency, it is required that the resonance frequency has to be measured as a function of volume for a series of different temperatures. From this point of view, the value of compressibility which is obtained by the present analysis seemes somewhat fortuitous.

Table III. Compressibility of organic molecule[16].

	Tem. (°C)	Pressure	$(\text{Atm}^{-1})\times10^6$
C_6H_6	0 (Solid)	100～300 Kg/cm²	31.69
	20 (liquid)	100～300 Kg/cm²	77.68
$CHCl_3$	18 (liquid)	0～8 Atm	97.43
C_6H_5Cl	17 (liquid)	0～8 Atm	71.41

The line widths of four absorption lines coincide with each other within an experimental error and their mean values are listed in Table I. Fig. 3 shows the derivative curves of absorption lines at 90°K and 196°K. The line width is defined as the interval between the two points where the integrated curve falls to half the maximum value. The difference between the widths at 77°K and 90°K is negligible, within the experimental error. The total width which is caused by b), c) and d) in § 3 is at most 50 c/s at 77°K and 90°K and is on the order of 500 c/s at 196°K, which are roughly estimated by considering the effect of a torsional and a rotational vibration using the formula given by Ayant[4]. Hence, it might follow that the main causes of the line widths at 77°K and 90°K are those stated in the item a) and e). It seems reasonable to consider that the causes of the broadening of

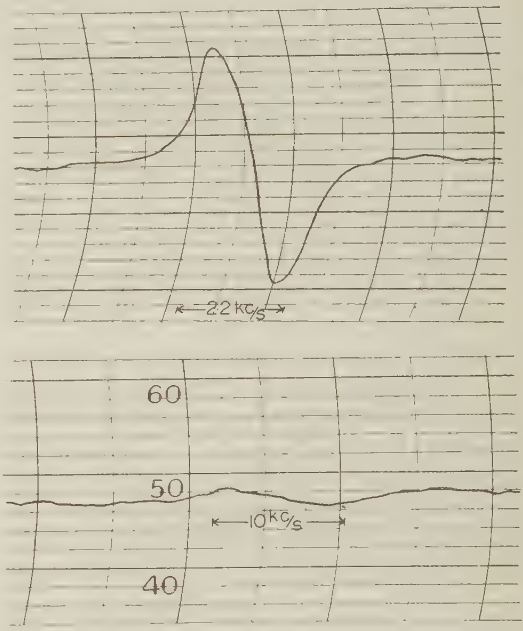

Fig. 3. Derivative curves of $Cl_3C{\cdot}CCl_3$. Upper curve, at 90°K. Frequency was swept at a rate about 0.1 Kc/s per second and the paper speed was six divisions per minute. Lower curve, at 196°K. Frequency was swept at a rate about 0.2 Kc/s per second and the paper speed was two divisions per minute.

absorption line at 196°K are those stated in the item a), e) and f). Among these causes, it is estimated that the one stated in the item f) is the most important, which represents a slow reorientational motion around the C–C axis, because the item a) and e) are nearly independent of temperature.

From this point of view, the line width due to the reorientational motion is of the order of 8±1 Kc/s at 196°K. It is expected that the reorientational motion consists of the torsional and the rotational reorientation. The line width is given by

$$(\varDelta\nu)_{1/2}=\frac{2\nu_t \exp\left(-\frac{V_0}{kT}\right)}{\pi}+\frac{2\nu_r \exp\left(-\frac{W}{kT}\right)}{\pi}\,, \tag{14}$$

where W is the height of potential wall where $Cl_3C\cdot CCl_3$ vibrates as a whole and the numerical values of other parameters are given above.

In Eq. (14), it is found that the contribution of the first term is negligibly small, and that the reorientational frequency is 25±3 Kc/s and using $\langle\nu_r(196)\rangle_{Av}=31.7\,\mathrm{cm}^{-1}$, W becomes to be about 7.0 Kcal/mole. Through out the present work, it is assumed that $|q|$ does not change with volume expansion. Actually, however, $|q_0|$ will increase as volume expands. In molecular crystals such as paradichlorobenzene, it is considered, $|q_0|\propto V^n$, with $0<n<0.04$[17]. Assuming $|q_0|\propto V^{0\sim0.04}$ also in $Cl_3C\cdot CCl_3$, the value of ν_r is between 26 and 31.8 cm⁻¹ at 196°K in the absorption line ν_2 by the use of Eq. (9), where $\nu_0\propto V^{0\sim0.04}$. If the value $\nu_r=26\,\mathrm{cm}^{-1}$ is inserted in Eq. (14), it is found that the value of W is nearly equal to 7.0 Kcal/mole, the value of which is obtained with $\nu_r=31.7\,\mathrm{cm}^{-1}$. The intermolecular distance are of the order of 3.7∼4.1 Å, as given by Sasada and Atoji[11]. These distances are slightly larger than the two times of van der Waals radius of Cl atom, 3.6 Å. It is plausible that the reorientational motion as a whole is apt to occur than the torsional reorientation. Being accepted the above broadening mechanism at 196°K, it was clarified that the absorption line could not be detected at room temperature, because of an extraordinary broadening with the increase of temperature.

The measurements reported in this paper yield some information about the temperature dependences of the resonance frequencies and the line widths of $Cl_3C\cdot CCl_3$. There are many molecular crystals whose pure quadrupole resonance are not detected at room temperature, though the large signals are detected at the temperature of liquid oxygen. This failure of detection is not explained by the decrease of population difference, accompanied with the increase of temperature, between the two energy levels which are concerned in transition.

$Cl_3C\cdot CCl_3$ in this work was chosen only for reason that this molecule was employded broadly in other fields of study, such as, X-ray analysis, Raman and infra-red spectra, electron diffraction, and specific heat etc. The measurements were carried out only at temperatures of 77°K, 90°K and 196°K, because of difficulty of keeping temperature constant in other temperatures within ±0.01°C, which was necessary for measuring of the line width.

Appendix

In a torsional vibration, ϕ_t' and ϕ_t'' are angles specifying the twist of the two parts of the molecule. The classical energy of the torsional vibration is given by

$$\frac{1}{2}I_r\dot{\phi}_t^2+\frac{1}{2}V_0\frac{9}{2}\phi_t^2\,, \tag{A1}$$

where

$$\phi_t=\phi_t'-\phi_t''\,,\qquad |\phi_t'|=|\phi_t''|\,. \tag{A2}$$

The normal coordinate is given by

$$q_t=\sqrt{I_r}\,\phi_t\,. \tag{A3}$$

Assuming that the time dependency of q_t is simple harmonic, q_t is expressed as

$$q_t(t)=D_t\sin 2\pi\nu_t t\,. \tag{A4}$$

Being the mean energy of the classical harmonic oscillator equated with the mean energy of the corresponding Planck's oscillator as usual, the following relation is derived.

$$h\nu_t\left(\frac{1}{2}+\frac{1}{\exp(h\nu_t/kT)-1}\right)=4\pi^2\nu_t^2\overline{q_t^2(t)}\,. \tag{A5}$$

With assumptions, $|\phi_t'|=|\phi_t''|$ and ϕ_t' is coherent with ϕ_t'',

$$\overline{q_t^2(t)}=I_r\overline{\phi_t^2}=4I_r\overline{\phi_t'^2}\,. \tag{A6}$$

From the geometrical configulation, θ_t is connected with ϕ_t' as follows,

$$\theta_t=\phi_t'\frac{2}{\sqrt{3}}\sin\frac{A}{2}\,. \tag{A7}$$

Hence Eq. (7) is obtained. In the similar way, Eq. (8) is obtained.

Acknowledgement

The authors wish to express hearty thanks, to the members of the Symposium on the Nuclear Quadrupole held in May 1956 at Research Institute for Fundamental Physics of Kyoto University, for their kind discussions and valuable suggestions. They thank Mr. Junichi Hori of Hokkaido University who has benefited them with many illuminating discussions. They also thank Mr. Yoshio Shindo of this institute for the aid in the construction of the frequency meter. The present work was supported in part by a Grant of Aid for Developmental Scientific Research in the Ministry of Education.

Note:

After this paper was prepared, we found that M. Buyle-Bodin (Ann. de Physique **10** (1955) 533) treated the reorientational motion of $Cl_3C \cdot CCl_3$. He found the height of potential wall was about 6 Kcal/mole insead of our 7 Kcal/mole. Taking the difficulty accompanied with a measuring of the line width it seems that these values give a reasonable order of the height of potential wall.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 7, JULY, 1957

Effect of the Basic Strength of Attached Groups on Light Absorption Spectra II: Near Ultraviolet Absorption Spectra of Para-substituted Aniline Derivatives

By Reikiti ITOH

Kobayashi Institute of Physical Research
Kokubunzi, Tokyo

(Received January 25, 1957)

The absorption spectra of para-substituted aniline derivatives of the type of $A_lC_6H_4B$, where A_l is one of the electron donating groups such as NH_2, $NHCH_3$, NHC_2H_5, $N(CH_3)_2$, $N(C_2H_5)_2$ etc. and B is one of the electron attracting groups such as COOH, $COCH_3$, CHO, NO_2 etc., change with the basic strength of the group A_l. The first absorption maxima of these molecules between 2800 and 4000 A are originated from the second absorption maxima of unsubstituted molecules (in 2600～2900 A region) under the influence of the group A_l. This is explained by semi-empirical MO theory with perturbation. The effects of B groups are taken into consideration by the delocalization of the molecular orbitals of benzene molecule, while the effects of A_l groups are calculated through the method of electron migration, in which the non-bonding π electrons on the nitrogen atom of A_l migrate to the parent molecule. The induction effect of the substituted alkyl group in A_l, which determines the degree of the electron migration, can be estimated from the relative basic strength of the end group, i.e. dissociation constant of amine NHR_2. The calculated absorption energies are in good agreement with the observed values if we take the solvent effect into consideration.

1. Introduction

In most of the previous discussions of ab-
orption spectra in aromatic molecules1), there
no quantitative consideration concerning the
ffect of basic character of substituents on
bsorption energies. There exists qualitative
elation between the shift of the absorption spec-
ra of substituted products of aromatic mole-
ules and the basicities of the substituents. In
he previous paper2), the author derived a qu-
ntitative relation between the absorption fre-
uencies of triphenylmethane dyes3) and the
asicities of the substiuted aminoalkyl groups
R$_2$ on the ground of semi-empirical LCAO
O method. It was found that the fre-
uencies of absorption vary linearly with the
asicities of the terminal groups attached to
he derivatives of Döbner's Violet and Rosani-
ne. The similar correlation is found for
arasubstituted aniline derivatives4), in which
eplacement of amino group NH_2 with one of
he more basic amino alkyl groups NR_2
auses a red shift of the main absorption
aximum. We denote this type of molecule
y $B(C_6H_4)A_l$, where B is an electron attract-
g group such as H, COOH, $COCH_3$, CHO, NO_2, etc. and A_l is one of the electron donating, alkyl substituted amino groups, such as HN_2, $NHCH_3$, NHC_2H_5, $N(CH_3)_2$, $N(C_2H_5)_2$, etc..

The present work is concerned with the study of the relation between basic strength of substituted amino-alkyl group and the position of absorption maximum using the semi-empirical MO method, in which the interaction between the NR_2 radical and the rest of the molecule, C_6H_4B, is taken into account through the second order perturbation. Thus, in the following sections, the theoretical explanation of electronic spectra in para-substituted aniline derivatives is extended.

§ 2. Interaction between the Parent Molecule and NH_2 Group

In the molecules $BC_6N_4NH_2$, the amino group is an electron donor on account of its non-bonding electron pair on the N atom which is in the valence state of trivalent sp^3. Then, the attachment of NH_2 to BC_6H_4 causes a perturbation to electronic states of the molecule due to the effect of electron migration from the amino group to the parent molecule. In our case, we owe the method of calculation for the perturbation to the theory of electron migration which is orignated by Sklar[5)] and later discussed by Herzfeld[6)] on monosubstituted benzene derivatives.

Here, we assume that the wave function of the migrating electron, $\Phi(\nu)$, is

$$\Phi(\nu)=\sum a_k\psi_k+b\phi_N \qquad (1)$$

with the normalization condition

$$\sum a_k^2+2b\sum a_kT_k+b^2=1, \qquad (2)$$

$$T_k=(\psi_k|\phi_N)=\int\psi_k\phi_N\,d\tau\,,$$

where ψ_k's are vacant orbitals of parent molecule and ϕ_N is $2p\pi$ orbital of non-bonding electrons in N atoms, and T_k is the overlap integral between ψ_k and ϕ_N. The Hamiltonian is the form of

$$H(\nu)=H_p(\nu)+H_s(\nu), \qquad (3)$$

where H_p is the potential of parent molecule and H_s is that of amino group for the migrating electron. Here, interaction parameters a_k and b are determined by the variational method minimizing the energy of orbital $\Phi(\nu)$ by the use of expressions (1), (2) and (3), and are given by the formula

$$a_k/b=\frac{\rho_k+T_k\chi}{\chi-\omega_k}\,, \qquad (4)$$

were

ρ_k: resonance integral between ψ_k and ϕ_N,
χ: coulomb integral of the amino group,
ω_k: energy levels of vacant orbitals ψ_k.

These are given as follows:

$$\begin{aligned}2\rho_k&=2(\psi_k|H|\phi_N)\\&=(\psi_k|H_p|\phi_N)+(\phi_N|H_e|\psi_k)+T_k(\chi+\omega_k), \qquad (5)\\ \chi&=(\phi_N|H_s|\phi_N),\quad \omega_k=(\psi_k|H_p|\psi_k).\end{aligned}$$

Thus for non-zero values of a_k, the energy of parent molecule goes down by the amount of ΔU which is calculated by the expressions (2) and (4), and neglecting $(\psi_k|H_s|\psi_l)$ and $(\phi_N|H_p|\phi_N)$

$$\begin{aligned}\Delta U&=(\Phi|H|\Phi)-(\phi_N|H|\phi_N)\\&=\sum a_k^2\omega_k+2b\sum a_k\rho_k+b^2\chi-\chi\\&=\sum a_k^2(\chi-\omega_k). \qquad (6).\end{aligned}$$

Corresponding to the two non-bonding electrons in the substituent and two electronic states of the parent molecule, the ground state g and the excited state e, there are two expressions for ΔU, that is,

$$\Delta U_g=2\sum a_k^2(\chi-\omega_k),$$

$$\Delta U_e=a_1^2(\chi-\omega_1)+2\sum a_k^2(\chi-\omega_k)-a_2^2(\chi-\omega$$

ΔU_g and ΔU_e are the stabilization energies d to the migration to the parent molecule in t ground state and in the excited state spectively, where suffixes 1 and 2 mean t highest occupied orbital in the ground and the excited state respectively. Then it easily found that $\chi<\omega_1<\omega_2<0$, and the sh of absorption energy due to the substituti of NH_2 is given by

$$\Delta Ue-\Delta Ug=a_1^2(\chi-\omega_1)-a_2^2(\chi-\omega_2). \qquad ($$

Here we simplify the expression by introdu ing the assumption that b is close to uni and a_k is very small. Then we have

$$hc\,\Delta\tilde{\nu}_{01}=\frac{(\rho_1-T_1\chi)^2}{\chi-\omega_1}-\frac{(\rho_2-T_2\chi)^2}{\chi-\omega_2}\,,$$

where $\Delta\tilde{\nu}_{01}$ is the shift of the absorbed wa number from that of the parent molecule d to the substitution of NH_2 and h is Planck constant and c the velocity of light.

§ 3. Effects of Alkyl-substituted Ami Groups

Up to this point, we have ignored the di ference among the substituents A_i, but no let us consider the various electron donati groups A_i as follows[2)]:

i	1	2	3	4	5
A_i	NH_2	$NHCH_3$	NHC_2H_5	$N(CH_3)_2$	$N(C_2H$
pK_{b_i}	4.75	3.36	3.33	3.29	3.02

where pK_b, the basic strength of amine NHR is calculated with activity coefficient in th place of concentration. If A_j group is mo basic than A_i, the density of σ electrons N atom of A_j will be larger than that of and this causes the difference in the exte of π electron migration to the parent mol cule by induction effects. Then coulomb i tegrals of A_i and A_j are different by a sma amount $\Delta\chi_{ij}$;

$$\chi_j=\chi_i+\Delta_{ij}, \qquad (9$$

where $\Delta\chi_{ij}$ is positive if A_j is more basic tha A_i, and expression (8) becomes

$$hc\,\Delta\tilde{\nu}_{0j}=\frac{(\rho_1-T_1\chi_j)^2}{\chi_j-\omega_1}-\frac{(\rho_2-T_2\chi_j)^2}{\chi_j-\omega_2}\,. \qquad (1$$

In the following we ignore the differen between the overlap integrals T_1 and T_2 ar use a single T in common. Now, we ca calculate the expression (8) for i and j using the relation (9). Expanding with $\Delta\chi$

and neglecting higher order terms of $\Delta\chi_{ij}$ we have the following expressions:

$$hc\,\Delta\tilde{\nu}_{ij}=hc(\tilde{\nu}_j-\tilde{\nu}_i)=hc(\Delta\tilde{\nu}_{0j}-\Delta\tilde{\nu}_{0i}), \qquad (11)$$

$$\Delta\tilde{\nu}_{ij}=-A\,\Delta\chi_{ij}-B(\Delta\chi_{ij})^2, \qquad (12)$$

where

$$A=\frac{(\rho_1-T\chi_i)T}{\chi_i-\omega_1}-\frac{(\rho_2-T\chi_i)T}{\chi_i-\omega_2}+\frac{(\rho_1-T\chi_i)^2}{(\chi_i-\omega_1)^2}-\frac{(\rho_2-T\chi_i)^2}{(\chi_i-\omega_2)^2},$$

$$B=-\frac{T}{4}\left(\frac{1}{\chi_i-\omega_1}-\frac{1}{\chi_i-\omega_2}\right)-\frac{(\rho_1-T\chi_i)T}{(\chi_i-\omega_1)^2}+\frac{(\rho_2-T\chi_i)T}{(\chi_i-\omega_2)^2}-\frac{(\rho_1-T\chi_i)^2}{(\chi_i-\omega_1)^3}+\frac{(\rho_2-T\chi_i)^2}{(\chi_i-\omega_2)^3}. \qquad (13)$$

In our case, according to the condition

$$\chi_i<\chi_j<\omega_1<\omega_2<0$$

we have

$$(\chi_i-\omega_2)<(\chi_i-\omega_1)<0\,.$$

From this and the inequality $\rho_1<\rho_2<0$ which can be seen from the expression (5), it follows that $A>B>0$ and $\tilde{\nu}_j<\tilde{\nu}_i$, which gives the qualitative explanation for that the molecule with A_j has the absorption maxima at lower frequencies than those with A_i, if A_j is more basic than A_i.

Ih the previous paper the author has shown that the coulomb integrals of NH_2 groups can be estimated by their relative basic strength pK_b by the formula

$$\Delta\chi_{ij}=k(pK_{b_i}-pK_{b_j}), \qquad (14)$$

where k is a parameter determined by the expression (12) so as to agree with the observed shift of absorption maximum between aniline and dimethyl aniline. As shown later, $k=0.4146$ is obtained in eV unit which is nearly equal to the k value in the case of triphenylmethane dyes, i.e., $k=0.4605$ eV.

Using the expression (14), we are able to rewright the expressions (11) and (12) in the following form

$$\tilde{\nu}_j=\tilde{\nu}_i-A\,(pK_{b_i}-pK_{b_j})-B\,(pK_{b_i}-pK_{b_j})^2, \qquad (15)$$

where $A>B>0$ and A is smaller than unity. This leads to the observed linear relation between the absorption wave numbers and pK_b of the substituents.

§ 4. Forms of the Orbitals ψ_1 and ψ_2

For the evaluation of numerical values in the expressions (8) and (12), it is necessary to determine the values of ω_1, ω_2, χ_1 and ρ_k which are given by

$$(\psi_1|H_p|\psi_1)=\omega_1,\ (\psi_2|H_p|\psi_2)=\omega_2,\ (\phi_N|H_s|\phi_N)=\chi_1,$$
$$2\rho_k=(\psi_k|H|\phi_N)+T(\chi_1+\omega_k),\quad T=(\psi_k|\phi_N),$$

respectively. The value of ω_1 is taken to the ionization potential of parent molecule BC_6H_5 and ω_2 is determined by

$$\omega_2-\omega_1=hc\,\tilde{\nu}_0\,. \qquad (16)$$

where $\tilde{\nu}_0$ is the absorption wave number of the secondary band in BC_6H_5 molecule. Further, χ_1 is taken to the ionization energy[12)] of N atom in the valence state, from $N(sp^4, V_3)$ to $N^+(sp^3, V_4)$, this is -12.24 eV. Values of ρ_k and T depend on the form of MO's in the parent molecule, and it is convenient to choose the linear combinations of atomic orbitals for MO's in the following form

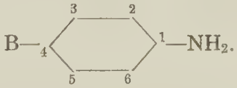
$$\psi_1=c\psi_1'+(1-c^2)^{1/2}\,\phi_B\,,$$
$$\psi_2=c\psi_2'+(1-c^2)^{1/2}\,\phi_B\,, \qquad (17)$$

where[5)]

$$\psi_1'=\frac{1}{\sqrt{12}}(2\phi_1+\phi_2-\phi_3-2\phi_4-\phi_5+\phi_6)\,,$$

$$\psi_2'=\frac{1}{\sqrt{12}}(2\phi_1-\phi_2-\phi_3+2\phi_4-\phi_5-\phi_6)\,, \qquad (18)$$

ϕ_i is the $2p\pi$ orbital on the ith atom and ϕ_B is molecular orbital of the electron attracting group B in the system of nomenclature



Here, the parameter c gives a measure of degree of localization of electrons in the benzene ring against the electron attracting group B. If we assume that the degree of localization in ψ_1' and ψ_2' can be expressed by the same parameter c which is closed to unity and ϕ_B is normalized molecular orbital, then, ψ_1 and ψ_2 constitute a nearly orthonormal system and will be able to be used as the orbitals of the parent molecule in the ground and the first excited state respectively. Nagakura[7)] has determined the parameter c in the case of intra-molecular charge transfer spectra by the variation method using LCAO MO for the ground state of monosubstituted benzene derivatives. These spectra are nearly equal to the primary bands of the molecules, however, it is allowed to use the same parameter c to the secondary absorption of that molecule about which ψ_1 and ψ_2 orbitals are concerned, because of the approximations in the theory of LCAO MO in benzene where four observed spectra are degenerated under the difference in energies of ψ_1' and ψ_2' orbitals. These spectra are shown in Table I for comparison.

Table I. Comparison of the spectra and values of c.

group B	observed secondary band in eV		calculated intramolecular charge transfer spectra in eV		values of c
	ω_1	ω_2	W_n	W_e	
NO_2	10.15	5.75	9.76	6.33	0.912
CHO	9.82	5.39	9.84	5.31	0.931
$COCH_3$	9.77	5.31	9.82	5.16	0.936
COOH	10.12 (9.52)	5.56 (4.96)	11.34	3.35	0.968
H	9.52	4.66	—	—	1.000

Literatures:

a) As for ionization potentials of C_6H_5B, see the reference (10) and as for the secondary absorption band see the references (8) and (9).

b) For the charge transfer spectra, see reference (7).

That the ionization potential of C_6H_5COOH is not known experimentally is probably due to the fact that it likely dissociates into anion $C_6H_5COO^-$ in the solution, and here value 10.12 eV is estimated from the values of analogous molecules, and for the anion $C_6H_5COO^-$, the value of 9.52 eV in parenthesis is assumed. Though existence of the secondary bands for nitrobenzene and benzaldehyde is not certain in the absorption spectra of these molecules, there are shoulders which are considered to be the positions of the secondary bands as shown in Fig. 1.

Using the orbitals ψ_1 and ψ_2 of the expressions (17) and (18), we have for ρ_k and T in the first order approximation

$$\rho_k=\frac{c}{\sqrt{12}}\cdot\frac{s}{s_0}\left[\gamma_0+s_0(\chi_1+\omega_k)\right],$$

$$T=\frac{c}{\sqrt{12}}\cdot\frac{s}{s_0}, \tag{19}$$

where γ_0 and s_0 are the resonance and overlap integrals of the $2p\pi$ atomic orbitals in benzene (C–C distance 1.39 A) respectively, and for aniline we make use of the relation proposed by Wheland[11], $\gamma/\gamma_0=s/s_0=0.8$, where γ_0 and s_0 are taken to be -5 eV and 0.2 respectively.[18]

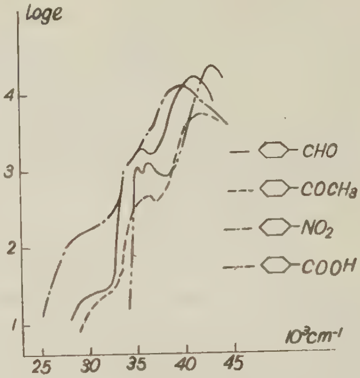


Fig. 1. The absorption maxima at 40000 cm^{-1} region are the primary bands of monosubstituted benzene derivatives. Those of 35000 cm^{-1} region are the secondary bands and those of 30000 cm^{-1} region are the bands due to $n-\pi$ transition. The solvents of the above two solutes are ethylalcohol and those of remains are hexane.

§ 5. Comparison between the Calculated and the Observed Spectra

As the orbitals ψ_1 and ψ_2 and values of their energies ω_1 and ω_2 and coulcomb integrals χ_i were given in § 4, interactions between the parent molecules and substituents A_i can be determind completely. There remains only one parameter k unknown. Now, k is determind so as expression (12) to match with observed spectral shift, for example, from aniline to dimethyl aniline, and thus $k=0.4146$ eV is obtained. In the cases of triphenylmethane dyes $k=0.4605$ eV was obtained. Relative values of χ for various A_i groups are shown in Table II.

Table II. Difference of pK_b and corresponding $\Delta\chi_{ij}$

i–j	pK_b	$\Delta\chi$ in eV
1–1	0	0
1–2	1.39	0.332
1–3	1.42	0.347
1–4	1.46	0.460
1–5	1.73	0.514

Using equations (8) and (12), we compute the absorption wave number $\tilde{\nu}_j$ by the relation

$$\tilde{\nu}_1=\tilde{\nu}_0+\Delta\tilde{\nu}_{01}\,,$$
$$\tilde{\nu}_j=\tilde{\nu}_1+\Delta\tilde{\nu}_{1j}\,. \tag{20}$$

Results are assorted in Table III, IV and V. These results are shown in Fig. 2, 3, 4 and

5, where the absorption wave numbers are plotted against the basicity of the substituents.

Table III. Values of A and B

3 group	H	COOH	COCH$_3$	CHO	NO$_2$
A	0.250	0.371 (0.231)	0.259	0.265	0.336
B	0.105	0.196 (0.098)	0.118	0.125	0.179

Values in parenthesis correspond to $\omega_1 = -9.52$ eV. A and B are defined by Eq. (13).

Table IV. Calculated spectral shifts in cm^{-1} unit.

B	H	COOH	COCH$_3$	CHO	NO$_2$
0–1	2404	3130 (2210)	2348	2380	2807
1–2	1444	2251 (1339)	1517	1573	2041
1–3	1476	2299 (1371)	1565	1605	2098
1–4	1525	2428 (1412)	1605	1654	2154
1–5	1880	2961 (1743)	1993	2049	2686

Values in parenthesis correspond to $\omega_1 = -9.52$ eV.

Table V. Comparison with experiment in cm^{-1} unit.

The observed values are taken mostly from the paper of W. D. Kumler[4)] except the case of B=COOH, the value of which is taken from the paper of W. W. Robertson[13)]. The solvent is ethyl-alchol in all cases. Value with asterisk is an assumed one based on the estimation from general spectral shifts given by Lewis[4)] who found an average shift of 130 A in a large number of dyes occuring when an alkyl group replaces a hydrogen and that of 30 A average when an ethyl replace a methyl group. Values in parenthsis corespond to $\omega_1 = -9.52$ ev.

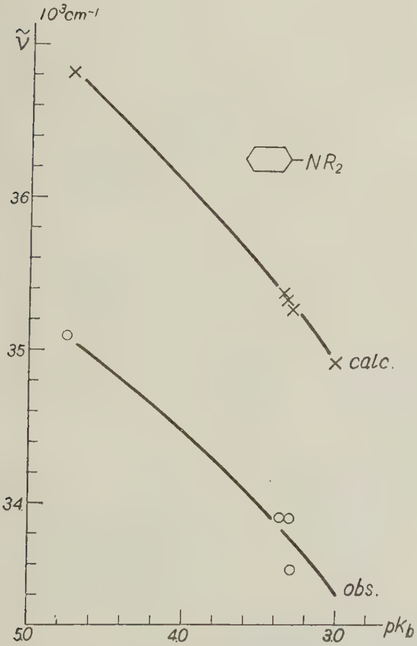

Fig. 2. Comparison with experiment. If the calculated absorption energies in vacuum are stabilized in ethylalcohol by about 2000 cm^{-1}, $\tilde{\nu}_{\text{calc}}$ agrees well with observation within the variance of the solvent effects.

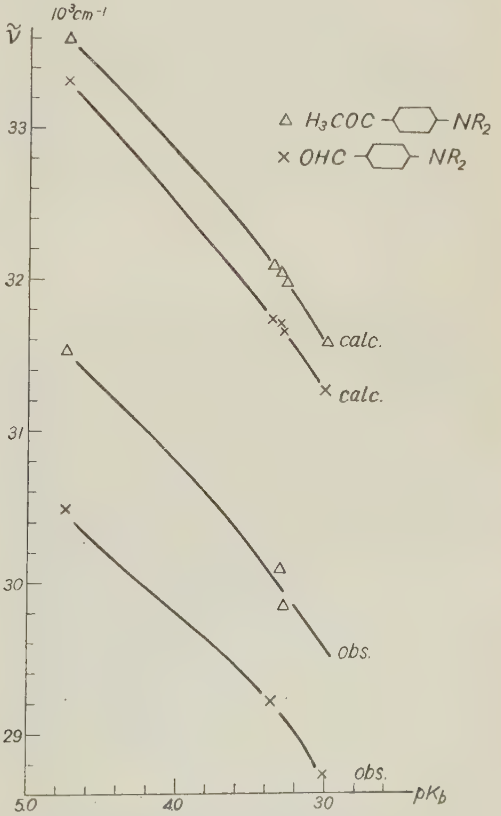

Fig. 3. Comparison with experiment. $\tilde{\nu}_{\text{calc}}$'s for the two cases agree with observations within the variance of the solvent effects.

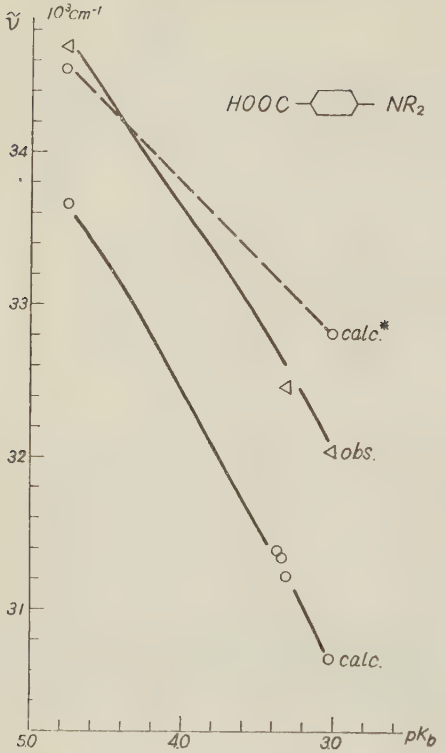

Fig. 4. Comparison with experiment. That $\tilde{\nu}_{obs}$'s are higher than $\tilde{\nu}_{calc}$'s is probably due to the dissociation of proton in the carboxyl group in alcohol. If we change the value of ionization potential from $\omega_1 = -10.12$ eV to $\omega_1 = -9.52$ eV taking the dissociation effect into consideration, $\tilde{\nu}_{calc}$'s move to the dotted line.

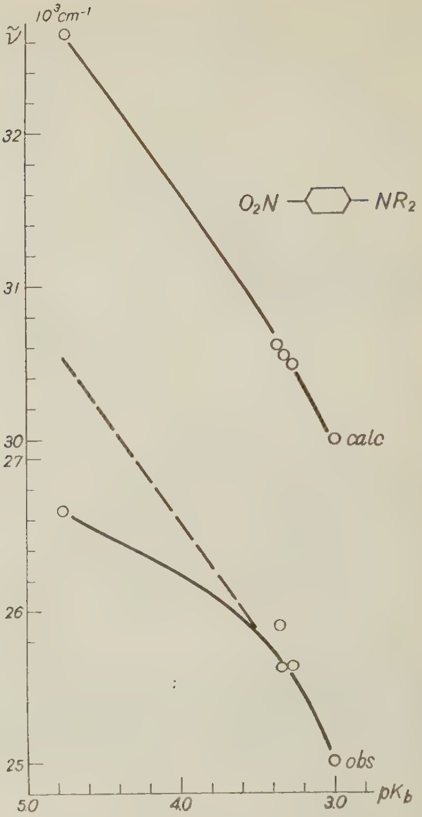

Fig. 5. Comparison with experiment. In this case, differences between $\tilde{\nu}_{calc}$ and $\tilde{\nu}_{obs}$ amount to 5000–6000 cm^{-1} owing to the two sort of solvent effects, the one is due to the dielectric character of solvent being about 2000 cm^{-1}, the other is due to the hydrogen bond formations with nitro group causing the shift of about 3000 cm^{-1} and with amino group causing the shift of about 1000 cm^{-1} which is shown by the deviation from the dotted line in the figure.

§ 6. Discussions

As seen from the comparison with observation, there are several points we have to put considerable importance on the solvent effect which seems to appear in two ways. The one is the dielectric character of solvents which shifts the absorption maxima towards lower frequencies and the other is the effect of the hydrogen bond formed between the solute and solvent molecules which produces the larger shift towards longer wave length. As in our calculation these effects have not been taken into consideration, it should be necessary to discuss the magnitude of these effects separately for the sake of comparing our result with the observation.

1) Derivatives of aniline, *p*-aminoacetphenone and *p*-aminoacetaldehyde.

In these groups, the calculated absorptio energies, $\tilde{\nu}_j$, are in good agreement with th observation, if we take the solvent effect int consideration, which makes the calculate frequencies in vacuum shift to lower values[15 by the amount of 2000 cm^{-1}. Here it shoul be noted two things:

a) The values of absorption wave lengt for each B group is in the order of

$$H < COOH < COCH_3 < CHO < NO_2 ,$$

which coincides to the order of electron attracting character of B groups and agree well with observation.

b) The parallelism between the calculate and the observed $\tilde{\nu}_i$'s against pK_{b_i} in Figs 2, 3, 4 and 5 shows the applicability of th expression (14) and possibility of estimatin the values of coulomb integrals of A_i fro their pK_b data.

) Derivatives of *p*-aminobenzoic acid.

Molecules in this group are probably in nic forms in solution owing to the dissocia-on of proton in COOH group, and the ioni-ation potential of benzoic acid has not been easured. This suggests two things:

a) The calculated $\tilde{\nu}_i$'s should be larger than he observed values as in the case of B groups ther than COOH. This contradiction may rise from the assumed value of the ioniza-ion potential ω_1 of benzoic acid, and if we hange ω_1 tentatively from -10.12 eV to -9.52 eV and ω_2 from -5.56 eV to -4.96 eV, $_{\text{calc}}$ comes to the higher value than $\tilde{\nu}_{\text{obs}}$ as hown by the dotted line in Fig. 4.

b) If these molecules are anions, induction ffects of alkyl groups may be greater than hose in the neutral molecules because of the egative charge. This fact explains the arger slope $\tilde{\nu}_i - pK_b$ line in this case.

) Derivatives of *p*-nitroaniline.

In these molecules, there may be formed ne or two hydrogen bonds between the solute nd the solvent molecules, one side at NH_2 roup (in dioxane) and other side, if any, at O_2 group (in alcohol or water). Kumler nd Strait[16)] pointed out that the shift in he absorption wave length with different olvents in the case of *p*-nitroaniline is in uch closer relation with the ability of the ydrogen bond formation of the solvent with he solute than it is with the dielectric con-tant of the solvent. Thus in going over rom hexane to dioxane the shift in wave ength is 350 A, i.e., from 3200 A to 3550 A, nd from hexane to water it is 380 A, i.e., rom 3550 A to 3930 A. The difference in the ielectric constant of the first two solvents is .3 and that of the second two is 78.9. On he other hand, *p*-nitroaniline can not form ydrogen bond with hexane, but can form hem at one end of the molecule with dioxane nd at both ends with water. These effects uggest the following:

a) There are the differences of about 000 cm^{-1} between the observed absorption nergies with singly hydrogen bonded cases for example, *p*-dimethylamino- and *p*-diethyl-minonitrobenze, etc.) and the calculated ab-orption energies. The difference may be artly attributed to the hydrogen-bonded ffect mentioned above being about 3000 cm^{-1} and partly to the normal solvet effects which amount to about 2000 cm^{-1}.

b) If hydrogen bonds are responsible for the solvent effect, then one can expect smaller shift for *p*-nitrodimethylaniline, which can form hydrogen bond only at one end by changing the solvent from hexane to alcohol than for *p*-nitroaniline, which can form hydrogen bonds at both ends, by changing the solvent similary. This is observed to be the case, the shift for the fomer being the 380 A (from 3520 A to 3900 A) and for the latter 550 A (from 3200 A to 3750 A). The effect of the second hydrogen bond of *p*-nitroaniline can be seen in Fig. 5 where the deviation from the datted line is about 1000 cm^{-1}, corresponding to the hydrogen bond effect between amino group and alcohol. The shift is also observed in the absorption of aniline[17)] for which the energy shift is also of the order of 1000 cm^{-1} going over from heptene (2853 A) to dioxane (2906 A). These solvent effects appearing in $\tilde{\nu}_{\text{obs}}$ - pK_b diagrams about which several points were mentioned above show that the $\tilde{\nu}_{\text{calc}}$ - pK_b lines are probaly true in vacuum or in the non-polar solvent and thus our conclusion that the first primary bands of $BC_6H_4NR_2$ molecules are caused by the substitution effect of NR_2 groups on the secondary bands of BC_6H_5 molecules would be accepted.

A Study on the Effects of Off-Resonance on the Spin-Echo Signals

By T. Ghose, S. K. Ghosh and D. K. Roy

Institute of Nuclear Physics, Calcutta, India

(Received March 11, 1957)

A comprehensive study of the off-resonance effects on the different spin-echo signals obtained with three rf-pulses has been made—both theoretically and experimentally. The main experimental bearing of this investigation lies in choosing the most suitable angles of the rf-pulses for which the fluctuations in the current, driving the electromagnet, will cause minimum effect on the amplitudes of the echo signals used for relaxation time measurements. Besides this, the above study has also been used for explaining another phenomenon associated with offresonance.

§ 1. Introduction

The spin echo technique is now being widely used for relaxation time measurements. Hahn(1) first introduced methods of measuring relaxation times T_1 and T_2 from the primary and stimulated echoes. Relaxation time T_2 is measured from the variation of the primary echo amplitude with the interval between the two pulses. T_1, the spin-lattice relaxation time can be measured from the variation of the stimulated echo $P_{(123)}$ by changing the interval between the second and third pluse, while the interval between the first and the second pulse is held fixed. A high degree of stability of the magnetic field is essential in these studies of the growth or decay of any echo signal in order to avoid the change in amplitude due to off-resonance during the time of observation. As this condition is not perfectly satisfied in the case of an electromagnet, the angle of the-pulses should be so chosen that the echo amplitude vs. off-resonance curve has the flattest peak. Hence the need arises for studying the off-resonance. Pfeifer(2) has formerly treated the case of the primary echo from such a consideration. He
the treatment has been applied to the case
the stimulated echo $P_{(123)}$. The investigati
also brings out the fact that the maximum
this echo does not necessarily occur at t
resonance value of the field for differe
angles of the rf-pulses—as is true for t
case of the primary echo. Moreover, by e
tending the theoretical analysis to the oth
echoes obtained with three rf-pulses, anoth
observed phenomenon associated with t
superposition of different echoes has been e
plained.

§ 2. Effects of Off-resonance on the Amp
tude of the Stimulated Echo $P_{(123)}$

The classical analysis of the spin ec
phenomena has previously been done
Hahn(1) and also by Das and Saha(3) under t
simplifying conditions of exact resonance a
H_r, the rf-field amplitude $\geqslant(\Delta H)_{Av}$, the latt
being the average value of the inhomogenei
over the sample volume. Under these si
plifying assumptions, contribution of the
mode to the total signal comes out as ze

when the average was taken over different isochromatic groups $\Delta\omega$. But in the case of off-reasonance, the contribution of the U-term does not vanish, the assumption $H_r \gg (\Delta H)_{Av}$ remaining intact. The U and V terms for the case of the stimulated echo at the echo maxima, i.e. at $t-\tau_1+\tau_2$ are then given by:

$$\begin{aligned} U_{t=\tau_1+\tau_2} &= \frac{\omega^* \omega_r^3}{\alpha^4} \left[\frac{4\omega^{*2}}{\alpha^2} \sin^2 \frac{\alpha t_{\omega_1}}{2} \sin^2 \frac{\alpha t_{\omega_2}}{2} \sin^2 \frac{\alpha t_{\omega_3}}{2} \right. \\ &\quad + \sin \alpha t_{\omega_1} \sin^2 \frac{\alpha t_{\omega_2}}{2} \sin \alpha t_{\omega_3} \\ &\quad - \sin \alpha t_{\omega_1} \sin \alpha t_{\omega_2} \sin^2 \frac{\alpha t_{\omega_3}}{2} \\ &\quad \left. + \sin^2 \frac{\alpha t_{\omega_1}}{2} \sin \alpha t_{\omega_2} \sin \alpha t_{\omega_3} \right] \\ &\quad \exp\left[-(\tau_2-\tau_1) \left(\frac{1}{T_1} - \frac{1}{T_2} \right) - (\tau_1+\tau_2) \frac{1}{T_2} \right] \end{aligned} \tag{1}$$

$$\begin{aligned} V_{t=\tau_1+\tau_2} &= \frac{1}{2} \frac{\omega_r^3}{\alpha^3} \left[-\frac{4\omega^{*2}}{\alpha^2} \sin^2 \frac{\alpha t_{\omega_1}}{2} \sin^2 \frac{\alpha t_{\omega_2}}{2} \sin \alpha t_{\omega_3} \right. \\ &\quad + 4 \frac{\omega^{*2}}{\alpha^2} \sin \alpha t_{\omega_1} \sin^2 \frac{\alpha t_{\omega_2}}{2} \sin^2 \frac{\alpha t_{\omega_3}}{2} \\ &\quad + \sin \alpha t_{\omega_1} \sin \alpha t_{\omega_2} \sin \alpha t_{\omega_3} \\ &\quad \left. + 4 \frac{\omega^{*2}}{\alpha^2} \sin^2 \frac{\alpha t_{\omega_1}}{2} \sin \alpha t_{\omega_2} \sin^2 \frac{\alpha t_{\omega_3}}{2} \right] \\ &\quad \exp\left[-(\tau_2-\tau_1) \left(\frac{1}{T_1} - \frac{1}{T_2} \right) - (\tau_1+\tau_2) \frac{1}{T_2} \right] \end{aligned} \tag{2}$$

where, $\omega^* = \gamma H_0 - \omega$, H_0 being the central value of the magnetic field distribution,

$$\omega_r = \gamma H_r$$

$$\alpha^2 = \omega^{*2} + \omega_r^2$$

and t_{ω_1}, t_{ω_2}, t_{ω_3} are the widths of the three rf-pulses.

If all the pulses are of equal width t_ω, we have

$$\begin{aligned} U_{t=\tau_1+\tau_2} &= \frac{\omega^* \omega_r^3}{\alpha^4} \sin^2 \frac{\alpha t_\omega}{2} \left[\frac{4\omega^{*2}}{\alpha^2} \sin^4 \frac{\alpha t_\omega}{2} + \sin^2 \alpha t_\omega \right] \\ &\quad \exp\left[-(\tau_2-\tau_1) \left(\frac{1}{T_1} - \frac{1}{T_2} \right) - (\tau_1+\tau_2) \frac{1}{T_2} \right] \\ V_{t=\tau_1+\tau_2} &= \frac{1}{2} \frac{\omega_r^3}{\alpha^3} \sin \alpha t_\omega \left[\frac{4\omega^{*2}}{\alpha^2} \sin^4 \frac{\alpha t_\omega}{2} + \sin^2 \alpha t_\omega \right] \\ &\quad \exp\left[-(\tau_2-\tau_1) \left(\frac{1}{T_1} - \frac{1}{T_2} \right) - (\tau_1+\tau_2) \frac{1}{T_2} \right] \end{aligned} \tag{3}$$

The theoretical and experimental curves of the stimulated echo amplitude with different amounts of off-resonance are shown in Fig. 1 for different angles ($\gamma H_r t_\omega = \pi/2$ and $2\pi/3$). It is evident that for $\gamma H_r t_\omega = \pi/2$, there is very little change in the tip of the signal amplitude with off-resonance and the top of the curve is quite flat indicating that the measurements of relaxation time T_1 with stimulated echo has to be performed near about such an angle. It is also evident from the curve for $\gamma H_r t_\omega = 2\pi/3$, that the maximum does not occur at $\omega^* = 0$, wereas for the corresponding curve for the primary echo as given by Pfeifer shows that the maximum does occur at this point.

Experimental measurements of the amplitude variation of echoes with different off-resonance values were carried out by observ-

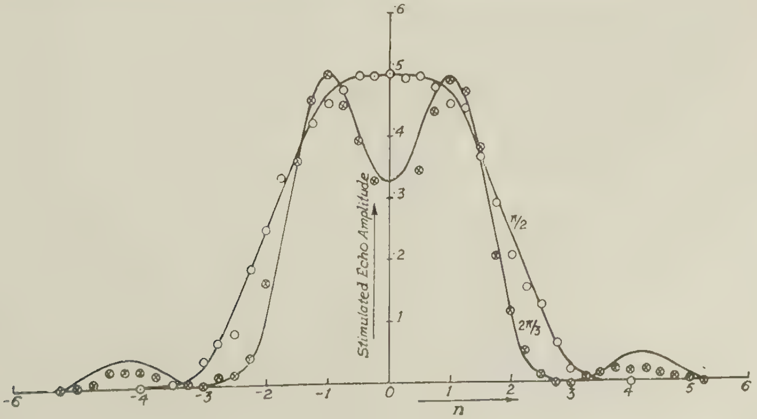

Fig. 1. Curves showing the variation of the stimulated echo amplitude with off-resonance. The theoretical curves are denoted by continuous lines; the encircled points represent the experimental values. $n = \omega^*/\omega_r$.

ing simultaneously the steady signal of a fluorine compound viewed on another oscilloscope. The steady signal was produced by an autodyne detector circuit having stable and easily variable frequency output. This frequency was accurately measured by beating with the signal produced by a 805C GR Signal Generator. Different amounts of off-reasonance was recorded accurately by noting the change in fluorine resonance frequency.

§ 3. Application of the Off-resonance Study

The analysis of the off-resonance signal amplitude of different echoes with three pulse system can be extended to the three other echoes at $t=2\tau_1$, $2\tau_2$ and $\tau_2-\tau_1$ and yields the following results,

$P_{(12)}$:

$$U=[a\cos\omega^*(t-2\tau_1)-b\sin\omega^*(t-2\tau_1)]\exp[-2\tau_1/T_2]$$
$$V=[b\cos\omega^*(t-2\tau_1)+a\sin\omega^*(t-2\tau_1)]\exp[-2\tau_1/T_2] \tag{4}$$

$P_{(13)}$:

$$U=[c\cos\omega^*(t-2\tau_2)-d\sin\omega^*(t-2\tau_2)]\exp[-2\tau_2/T_2]$$
$$V=[d\cos\omega^*(t-2\tau_2)+c\sin\omega^*(t-2\tau_2)]\exp[-2\tau_2/T_2] \tag{5}$$

$P_{(23)}$:

$$U=[e\cos\omega^*(t-2\tau_2+\tau_1)-f\sin\omega^*(t-2\tau_2+\tau_1)]\exp[-2\tau_2-2\tau_1/T_2]$$
$$V=[f\cos\omega^*(t-2\tau_2+\tau_1)+e\sin\omega^*(t-2\tau_2+\tau_1)]\exp[-2\tau_2-2\tau_1/T_2] \tag{6}$$

where,

$$a=\frac{1}{4}\frac{\omega^*\omega_r^3}{\alpha^4}(1-\cos\alpha t_{\omega_2})\Big[-\frac{\omega^{*2}}{\alpha^2}(1-\cos\alpha t_{\omega_1})(1-\cos\alpha t_{\omega_3})$$
$$+(1-\cos\alpha t_{\omega_1})-2\sin\alpha t_{\omega_1}\sin\alpha t_{\omega_3}+(1-\cos\alpha t_{\omega_1})\cos\alpha t_{\omega_3}\Big]$$

$$b=\frac{1}{2}\Big[\frac{\omega^{*2}\omega_r^3}{\alpha^5}(1-\cos\alpha t_{\omega_1})(1-\cos\alpha t_{\omega_2})\sin\alpha t_{\omega_3}$$
$$-\frac{1}{2}\frac{\omega^{*2}\omega_r^3}{\alpha^5}\sin\alpha t_{\omega_1}(1-\cos\alpha t_{\omega_2})(1-\cos\alpha t_{\omega_3})$$
$$-\frac{1}{2}\frac{\omega^{*2}\omega_r}{\alpha^3}\sin\alpha t_{\omega_1}(1-\cos\alpha t_{\omega_2})(1+\cos\alpha t_{\omega_3})$$
$$+\frac{1}{2}\frac{\omega_r}{\alpha}\sin\alpha t_{\omega_1}(1-\cos\alpha t_{\omega_2}\cos\alpha t_{\omega_3})$$
$$+\frac{1}{2}\frac{\omega_r}{\alpha}\sin\alpha t_{\omega_1}(\cos\alpha t_{\omega_3}-\cos\alpha t_{\omega_2})\Big]$$

$$c=\frac{1}{2}\frac{\omega^*\omega_r}{\alpha^2}(1-\cos\alpha t_{\omega_3})\Big[\frac{1}{2}\frac{\omega^{*4}}{\alpha^4}(1-\cos\alpha t_{\omega_1})(1-\cos\alpha t_{\omega_2})$$
$$+\frac{\omega_r^2}{\alpha^2}\sin\alpha t_{\omega_1}\sin\alpha t_{\omega_2}+\frac{1}{2}(1-\cos\alpha t_{\omega_1})\cos\alpha t_{\omega_2}$$
$$+\frac{1}{2}\frac{\omega_r^2}{\alpha^2}(1-\cos\alpha t_{\omega_1})-\frac{1}{2}\frac{\omega^{*2}}{\alpha^2}(1-\cos\alpha t_{\omega_1})\Big]$$

$$d=\frac{1}{4}\frac{\omega_r^3}{\alpha^3}\Big[-\frac{\omega^{*2}}{\alpha^2}(1-\cos\alpha t_{\omega_3})\Big\{\sin\alpha t_{\omega_1}(1-\cos\alpha t_{\omega_2})+2(1-\cos\alpha t_{\omega_1})\sin\alpha t_{\omega_2}\Big\}$$
$$+\sin\alpha t_{\omega_1}(1-\cos\alpha t_{\omega_2}\cos\alpha t_{\omega_3})+\sin\alpha t_{\omega_1}(\cos\alpha t_{\omega_2}-\cos\alpha t_{\omega_3})\Big]$$

$$e=2W(c)\frac{\omega^*\omega_r^3}{\alpha^4}\sin^2\frac{\alpha t_{\omega_2}}{2}\sin^2\frac{\alpha t_{\omega_3}}{2}$$

$$f=W(c)\frac{\omega_r^3}{\alpha^3}\sin\alpha t_{\omega_2}\sin^2\frac{\alpha t_{\omega_3}}{2}$$

$$W(c)=1+\frac{\omega_r^2}{\alpha^2}(\cos\alpha t_{\omega_1}-1)\exp(-\tau_1/T_1)$$

Now, if the third Pulse be applied very close (within T_2^*) to the second pulse, all the echoes due to the third pulse will be superimposed on each other. A single echo having approximately a gaussian shape will then be observed experimentally. If all the three pulses be of 90°, and third pulse be applied practically at the end of the second pulse then the total signal will be of double the magnitude due to the first two pulses alone if resonance be maintained. With a slight off-resonance and gradually increasing interval between the second and third pulses, the tip of the total signal goes through maxima and minima. The position of the tip also changes slightly due to increased separation between the two pulses. In case of exact resonance, there is no change in the amplitude of the total signal. The number of times that the total signal goes through maxima and minima depends on the amount off-resonance and the interval between the two pulses. Mathematically this can be seen from the expression for the total signal which is obtained by the superposition of all the terms shown in equations (4, 5, 6). As is evident, the echoes differ by phase factors of $\omega^*(\tau_2-\tau_1)$. By varying $(\tau_2-\tau_1)$, i.e. the interval between the third and the second pulse, the relative phases will change and hence there will be maxima and minima at intervals determined by multiples of $2\pi/\omega^*$. It is also seen from above that the number of times that the total signal passes through maxima and minima before the echoes are completely separated out depends on ω^*, i.e. the amount of off-resonance, and $\tau_2-\tau_1$.

The enhancement of the signal amplitude when the third pulse is applied near the second pulse may be used also for determining accurately the resonance value of the magnetic field. In the resonance condition, there will be no change of the amplitude if the interval between the third pulse and the second pulse be varied slightly.

The authors express their thanks to Prof. A. K. Saha for his encouragement during the progress of the work.

Microwave Spectrum of BrCN and Dependence of Quadrupole Coupling Constant on the Vibrational State

By Takeshi OKA and Hiromasa HIRAKAWA

Department of Physics, Faculty of Science,
University of Tokyo, Tokyo, Japan

(Received April 8, 1957)

The hyperfine structure of the J=1←0 and J=2←1 rotational transitions of BrCN has been measured. The values of eqQ(Br^{79}) and eqQ(Br^{81}) for each vibrational state were obtained as follows.

	Vibrational State (v_1, v_2, v_3)	From the frequencies of the J=1←0 transition	From the frequencies of the J=2←1 transition
eqQ(Br^{79}) in Mc/sec	(0,0, 0)	685.6±0.4	685.3±0.8
	(1,0, 0)	687.9±0.6	689.1±0.7
	$(0,2^0,0)$	681.6±0.7	680.2±0.9
eqQ(Br^{81}) in Mc/sec	(0,0, 0)	572.8±0.2	572.7±0.6
	(1,0, 0)	576.1±0.9	574.2±0.7
	$(0,2^0,0)$	568.9±1.5	567.3±1.5

Considerable increase of eqQ for the stretching vibration ($v_1=1$) is explained in terms of the decrease of the double bond character of Br–C bond, and the decrease of eqQ for the excitation of the bending vibration ($v_2=1$) is ascribed to the variation of the z component of q tensor.

§1. Introduction

The measurement of the quadrupole hyperfine structure of the spectrum of pure rotational transitions in a simple molecule gives the quadrupole coupling constant with considerable accuracy. As is well known, molecules in different vibrational states have different rotational constants, and if the microwave spectrum of a molecule in the excited vibrational state is measurable, it gives the quadrupole coupling constants in the excited vibrational states.

Tetenbaum and Javan measured the hyperfine structure of the $J=6\leftarrow5$ transition of BrCN and the $J=4\leftarrow3$ transition of ICN, respectively, and found the variation of eqQ with the excitation of the bending vibration[1),2)]. The hyperfine components of the $J=1\leftarrow0$ and the $J=2\leftarrow1$ transitions of ICN molecule in the (0, 0, 0), (1, 0, 0) and $(0, 2^0, 0)$ vibrational states were reported by the present authors, and the variation of eqQ was found to come not only from the excitation of the bending vibration but also from the excitation of the stretching vibration[3)]. Lower J transitions are more appropriate for this type of investigation.

In the present paper, the results of the measurement of the hyperfine components of the $J=1\leftarrow0$ and the $J=2\leftarrow1$ transitions of BrCN are described. The three vibrationa frequencies of BrCN are $\nu_1=580\ \mathrm{cm}^{-1}$, $\nu_2=$ 368 cm^{-1} and $\nu_3=2187\ \mathrm{cm}^{-1}$. The microwav spectrum of the molecule in the (0, 0 ,0), (1 0, 0) and (0, 2, 0) states were observed bu the study of the molecule in (0, 1, 0) state was given up as they show the complicate Stark behavior of the l-type doublets.

§2. Experiments and Results

The measured frequencies are listed i Tables I, II, III and IV. The errors of th observed frequencies mainly come from th weakness of the lines and from the hyperfin splittings due to the quadrupole moment o N^{14}. The errors are expected to be less tha 0.1 Mc/sec for almost all lines.

From these measured frequencies, the rotational constant B and the quadrupole couplin constant eqQ in each vibrational state wer derived by means of the least square fit t the formula

$$\nu=2(J+1)B+Y(F)\mathrm{eqQ}+Z(F)(\mathrm{eqQ})^2/B\ .$$

Some lines with large experimental error were not used in the analysis. In addition t the hyperfine structures due to the quadrupol moment of Br, some lines show further splittings due to the quadrupole moment of N^{1} From these splittings, eqQ(N^{14}) in BrCN i

Table I. Frequencies of the hyperfine components of the $J=1\leftarrow 0$ rotational transition of $Br^{79}CN$ molecule in Mc/sec.

(0, 0, 0)	$J=1\leftarrow 0$ $J=2\leftarrow 1$	4120.32 4120.278	4096.92 4096.825
(1, 0, 0)	$J=1\leftarrow 0$ $J=2\leftarrow 1$	4108.93 4108.864	4085.74 4085.425
(0, 2^0, 0)	$J=1\leftarrow 0$ $J=2\leftarrow 1$	4139.49 4139.189	4115.83 4115.820

§ 3. Discussions

From Table V it is seen that eqQ increases when the stretching vibration is excited. This is reasonable in view of the variation of the double bond character of Br–C bond. When the stretching vibration is excited, Br–C bond is elongated owing to the anharmonicity of the potential, and the double bond character of the Br–C bond decreases, and thus eqQ increases. The elongation of the bond is calculated from the variation of the moment of inertia of the molecule with the vibrational excitation. Since ν_1 vibration is concerned mainly with the stretching of the Br–C bond, C–N distance may be assumed to be constant. Accordingly, the elongation of the Br–C bond is calculated to be

$$\delta R=(M_{\mathrm{Br}}+M_{\mathrm{C}}+M_{\mathrm{N}})(I'-I)/2M_{\mathrm{Br}}[M_{\mathrm{C}}l_1+M_{\mathrm{N}}(l_1+l_2)]\ ,$$

where M_{Br}, M_{C}, M_{N} are the masses of Br, C and N atoms, l_1 and l_2 are the bond lengths of Br–C and C–N bonds in the ground vibrational state, and I' and I are the moments of inertia of the molecule in the (1, 0, 0) and the (0, 0, 0) states, respectively. I' is calculated from the values of B_v obtained by Tetenbaum taking into account the effect of Fermi resonance¹⁾. Substituting $l_1=1.789$ A, $l_2=1.160$ A⁵⁾ and $I'-I=0.465$ a.m.u. A², δR was calculated to be 0.0049 A both for Br^{79}CN and Br^{81}CN. It was reported in the preceding paper that the variation of q is given by the formula³⁾

$$\frac{q+\delta q}{q}=1+\frac{[\frac{1}{2}-\mathcal{E}(\frac{1}{2}-s+d)]x(2x+1)}{[-(1-s+d)(1-x)-(\frac{1}{2}-s+d)(1+\mathcal{E})x]}\cdot\frac{\delta R}{(R-R_1)}\ .$$

Using the values $s-d=0.15$⁶⁾, $\mathcal{E}=0.15$⁵⁾, $x=0.15$⁶⁾ and $\delta R=0.0049$, it is found that

$$(q+\delta q)/q=1.0044\ .$$

This is in fair agreement with the experimental values of $(\mathrm{eqQ})_{v_1=1}/(\mathrm{eqQ})_0$ listed in Table VII.

Tabla VII. Values of $(\mathrm{eqQ})_v/(\mathrm{eqQ})_0$

		Transition	(1, 0, 0)	(0, 2^0, 0)
observed	Br^{79}CN	$J=1\leftarrow0$	1.0034	0.9942
		$J=2\leftarrow1$	1.0055	0.9924
	Br^{81}CN	$J=1\leftarrow0$	1.0058	0.9905
		$J=2\leftarrow1$	1.0026	0.9932
calculated			1.0044	0.9910

It is seen from Table V that eqQ decreases when the bending vibration is excited. This decrease is expressed by the formula²⁾,

$$q_v=(1-3\bar{\theta}^2/2)q_0\ .$$

In the case of BrCN, $1-3\bar{\theta}^2/2$ is calculated to be 0.9910, using the data from the vibrational analysis. This should be compared with the experimental values of $(\mathrm{eqQ})_{v_2=2}/(\mathrm{eqQ})_0$ listed in Table VII.

§ 4. Acknowledgement

The authors are indebted to Prof. K. Shimoda for his kind guidance and encouragement during the course of this investigation. They are also grateful to Prof. Y. Morino of the Department of Chemistry for his continued interest in this work.

A Simpler Method for Removing Copper from Germanium

By Makoto Kikuchi and Sigeru Iizima
Electrotechnical Laboratory, Tokyo, Japan

(Received April 18, 1957)

On the course of study on the "thermal conversion" phenomenon, it has been found out that lattice defects (e.g. dislocations) act as *sinks* of Cu atoms. For instance, when the surface of a slice of n-type germanium single crystal was wetted with $Cu(NO_3)_2$ solution and then heated to 650°C, one portion of the specimen, where the dislocation density was very high, was not converted to p-type.

Utilizing this feature of lattice defects on the precipitation of Cu atoms, we have found out a new simpler method for removal of Cu from germanium crystal.⁽¹⁾ Experimental results are as follows.

After wetting the surface with $Cu(NO_3)_2$ solution, the specimens are heated to 650°C and Cu atoms of about $4\sim7\times10^{-14}/cm^3$ are introduced into the crystals. Surface contaminations are etched off with CP4.

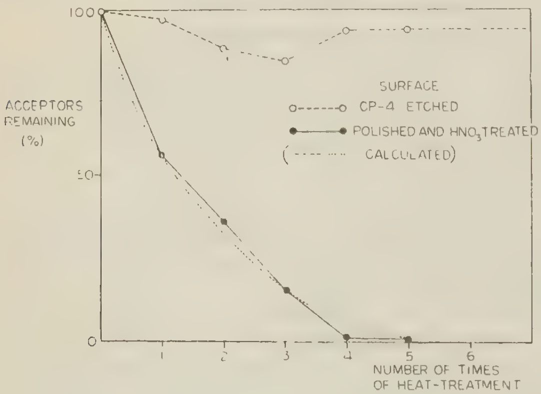

Fig. 1. Experimental results of Cu removal from germanium. Upper curve is for the case of CP4 etched surface, lower curve is for the "roughened" surface.

The surface of a specimen is polished with emery paper, washed with alcohol and de-ionized water, and then immersed into conc. HNO_3 for 1 hour. The roughened surface is washed and dried. The specimen is then heated at 650°C for 1.5 hours in Ar gas. The surface is again etched with CP-4.

As is shown in Fig. 1 (solid line), about 45% of Cu atoms are taken out from the specimen after this treatment. Repeating the treatment 4~5 times, almost all of the Cu atoms are removed. The results of Fig. 1 were obtained from the resistivity measurements, while Fig. 2 shows the recovery of the minority carrier lifetime along the repeated treatment.

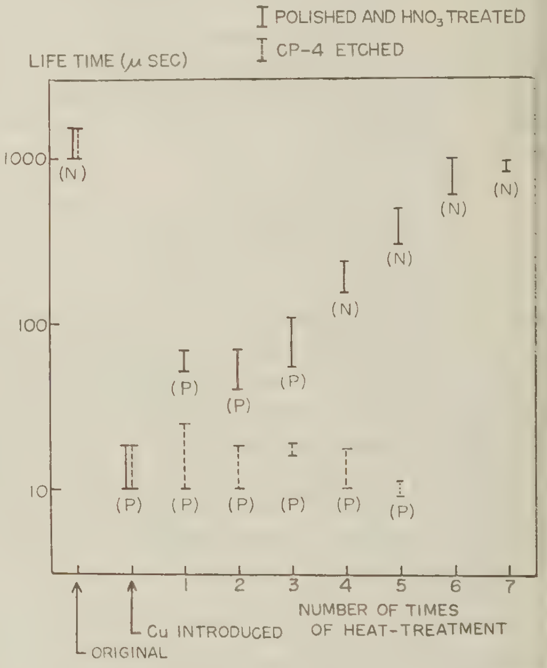

Fig. 2. Recovery of the minority carrier lifetime by the repeated heat-treatment (corresponding to Fig. 1).

As is shown, nearly the same value of the lifetime is restored after repeating the treatment six times.

The results of the heat treatment with normal CP4 etched surface are shown in Fig. 1 and 2 for comparison. The effect of the surface roughening method for the removal of Cu is quite evident.

If we take a quantity "relative distribution coefficient" into account as an analogy to the segregation phenomena, the removal effect can be calculated for the first approximation. The dotted line in Fig. 1 is the calculated curve.

The details will be presented elsewhere in the near future.⁽²⁾

On the Mechanism of Deformation Twin in fcc Crystal

By Akiya OOKAWA

Department of Physics and Chemistry, Gakushuin University, Mejiro, Tokyo.

(Received April 24, 1957)

With the pole mechanism suggested by Cottrell and Bilby[1], the deformation twin in bcc crystal is expected to grow easily in its width, while that in fcc crystal can not be expected to form any more than in a single atomic plane. It is reported[2], however, that single crystal of copper shows when cold worked at low temperature (4.2°K) an apparent twin with {111} as twinning plane at stresses 12–16 kg/mm². Here, we suggest a similar mechanism of deformation twin in fcc crystal, with reference to the Lomer-Cottrell barrier.

When a dislocation segment on a (111) plane dissociates according to the reaction

$$(a/2)[110] \rightleftarrows (a/3)[111] + (a/6)[11\bar{2}]$$

and the twin dislocation $(a/6)[11\bar{2}]$ sweeps once around the segment, a stacking fault on the (111) is formed but further repitition in the state is impossible (see Fig. 3 in *ref.* 1). As the perfect dislocation $(a/2)$ [110] after the rejoinment is movile on (1$\bar{1}$0), the dislocation segment, if happened to lie along [11$\bar{2}$], can glide out of the (111). If the segment displaces itself parallel to a neighbouring (111) plane, another stacking fault on the new (111) plane can be formed.

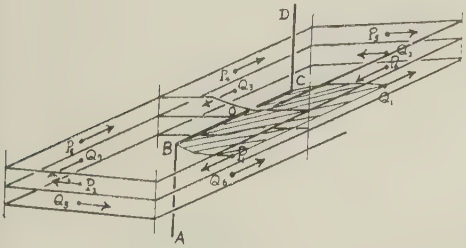

Fig. 1.

In the above treatment, two dislocation lines connected by the segment are tacitly assumed to emerge on the same side of the (111) plane. When the two dislocations emerge on different sides, the one on lower side and the other on upper side, the (111) planes look like a scheme in Fig. 1. It is characteristic to this state, that the sweeping dislocations BP_1 and CQ_1, both starting from the mother segment BC, rotate on different net planes consecutively. The one dislocation BP_1 sweeps in the sequence $BP_1 \rightarrow BP_2 \rightarrow BP_3 \rightarrow BP_4 \rightarrow BCP_5 \rightarrow CP_6 \rightarrow \cdots$, and afterwards the twin dislocation CP_6 rotates around the pole dislocation CD, resulting in growth of deformation twin on upper side of the reference plane. The growth on lower side is maintained by BQ_6 as consequence of CQ_1.

According to the above mechanism, neither the original segment is extended nor the two partial dislocations have elastic interaction after dissociation. The critical stress for twinning is, therefore, governed in main by the critical stress $\sigma_0 \sim \mu b/l$ needed to expand a dislocation segment of length l and the stress $\sigma_s \sim \varepsilon_s/b$ necessary to drag the twin dislocation trailing the stacking fault of energy ε_s. With $\varepsilon_s \sim 20$ erg/cm² for copper, we have $\sigma_s \sim 10^9$ dyne/cm², in the same order of magnitude as the experimental value. As the stress $\sigma_0 \sim 10^8$ dyne/cm² estimated for $l \sim 10^{-4}$ cm is much smaller than this value of σ_s, we can interpret the apparent twin in copper with the present mechanism, if provided the mother segment is sufficiently long.

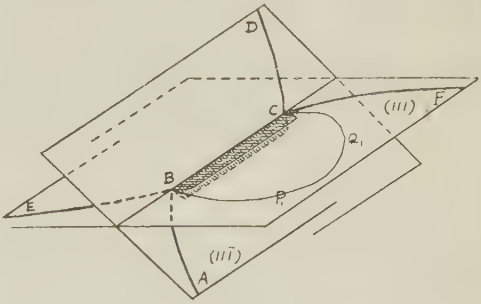

Fig. 2

A dislocation segment on (111) sufficiently long is realized in the Cottrell-Lome barrier[3], stabilized under dissociation

$$(a/2)[110] \rightleftarrows (a/6)[11\bar{2}] + (a/6)[110] + (a/6)[112].$$

When the twin dislocation $(a/6)[11\bar{2}]$ sweeps on (111), the dislocation lines AB and CD on the crossing (11$\bar{1}$) stand for the pole dislocations. In contrast to Fig. 1, however, the growth on either side is suppressed by the intrinsic fault on (11$\bar{1}$).

It is to be noted that at low temperature the induced deformation twin is expected stable, because the thermal energy does not suffice to activate the sessile dislocation $(a/6)[110]$ to dissociate; this is the mode prefered at high temperature[4].

Nuclear Magnetic Resonance in Irradiated Teflon

By Hazime Kusumoto*

Institute of Science and Technology
University of Tokyo, Tokyo

(Received March 27, 1957)

We have examined at room temperature the F^{19} magnetic resonance in Teflon (polytetrafluoroethylene, PTFE) irradiated with deuterons from the cyclotron of our institute. The Teflon was commercial thin film and was irradiated repeatedly in vacuum at room temperature so much that it was powdered easily. The another four sheets were irradiated in the same condition of irradiation for 20 sec., 1 min., 3 min. and 10 min. respectively. They seem to have no change apparently. These samples were very kindly furnished by Prof. K. Ōno and H. Abe of this institute.

Table I. The experimental values of line width and second moment of PTFE's and PTFE*-1.

	PTFE*-1	PTFE	A.N.*	J.A.S.S.*
Line width (gauss)				
ΔH (m.sl.)	2.8	0.7	0.7	2.6
ΔH (1/2)	4.1	2.8	2.9	—
Second Moment (gauss^2)	2.4	1.8	2.8	3.8

* These values of A.N.(2) and J.A.S.S.(1) were interpolated approximately in their data.

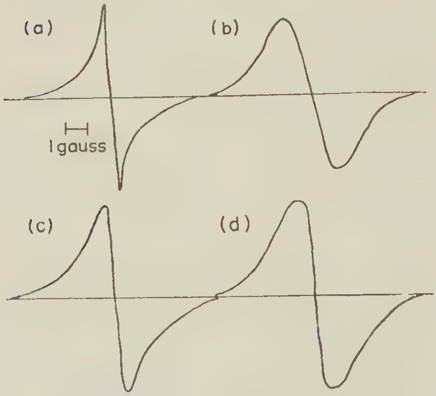

Fig. 1. F^{19} magnetic resonance in (a) PTFE, (b) PTFE*-1 (irradiated to be powdered), (c) PTFE*-2 (irradiated for three min.) and (d) PTFE*-3 (irradiated for ten min.).

In Fig. 1 there are reproduced the observed li shapes. The experimental values of line wid and second moment of the original PTFE an irradiated PTFE (PTFE*-1) are described in Tab I compared with such values obtained by anoth authors.

As shown in Fig. 1 the sharp central peak b came broad with increasing of irradiation ti and line shape would become similar to that PTFE*-1.

According to Charlesby3), the energy absorbed Teflon breaks it mainly at C-C bond to make smaller molecules. However, the experimental r sults suggest that the motion of F^{19} nuclei, name the segmental motion of the molecules, in PTF is more disturbed compared with the origin molecules. Therefore, it might be supposed th such structures that disturb segmental motion ha been produced in irradiated Teflon.

In irradiated Teflon: (1) at a broken C-C bon producing a free radical, oxygen atom might b trapped4),5) during aging in air after irradiati and/or double bond might be produced. Further more there would exist possibility for a broke chain to form some of ring5), (2) some of C- bonds must be broken releasing gases3) to leave free radical, which might produce double bon make a cross-linkage with a free radical produce in other molecule as at the case of polyethylen Unfortunately, since the irradiation dose and th quantity of released gas3) were not known, estimation of cross-linkage could not be done.

Though Teflon molecules become smaller b irradiation, these double bond, cross-linkage an rings produced sametime disturb the segmenta motion and cause broadening of line width. Further measurement on variation of line width an second moment vs. temperature has been done The results will be published later.

The author wishes to express his sincere thank to Prof. K. Oshima for his suggestions of thi work.

Some Comments on the Theory of Coercive Force of Fine Particles

By Tetuo OHOYAMA

Department of Physics, Faculty of Science, Tokyo Metropolitan University

(Received April 26, 1957)

It is well known that the coercive force H_c of ferromagnetic fine particles increases with decreasing diameter d of the particle, and that a theoretical explanation of this variation has been given by Kittel1).

Recently Néel2) raised a theoretical objection against it, but it seems not to be absolutely correct to conclude that Kittel's model must lead to a constant H_c independent of d, on the basis of Néel's discussion. The model on which Néel carried out his calculation (Fig. 2) differs somewhat from Kittel's model (Fig. 1). Moreover, Néel's expression for the magnetostatic energy has an ambiguity connected with the conditional convergency.

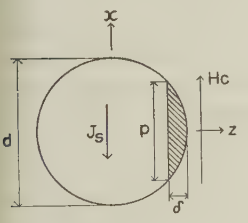

Fig. 1.

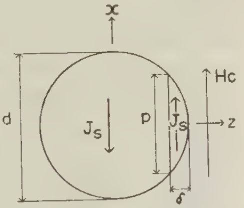

Fig. 2.

In Fig. 1, the spherical cap is a wall itself, but in Fig. 2, it is a domain of reversed magnetization bounded by an infinitely thin wall. In Fig. 1, δ has a definite meaning, the wall thickness, but in Fig. 2, its physical meaning is not very clear.

In both cases, the energy blance is given by the equation

$$\sigma(\pi p^2/4)=H_c(\bar{J}_x+J_s)v+(-\varDelta U)\,. \qquad (1)$$

Here σ is the surface energy density of a domain wall, $\bar{J}_x$ is the average of the x-component of the magnetization in the interior of the spherical cap. v is its volume. $-\varDelta U$ is the gain in magnetostatic energy due to the varied magnetization. $\bar{J}_x=J_s$ in Fig. 2.

Kittel put $\bar{J}_x=0$ and $-\varDelta U=(1/2)\cdot J_s^2\cdot(4\pi/3)(d/2)^3\cdot(\delta/2d)$ as a crude estimate in his model, coming to the expression $H_c/H_c^\infty=1-d/d_0$. As Néel pointed out, he would have come to an expression for H_c independent of d, if he had put $(\delta/2d)^2$ instead of $(\delta/2d)$.

The magnetostatic energy of a system shown in Fig. 2 has been calculated by Néel3) and can be written*, with an abbreviation $1-2\delta/d=u$,

$$U=\frac{\pi^2J_s^2d^3}{2}\times\left\{\frac{(u^3-3u)^2}{18}\right.$$
$$\left.+(1-u^2)^2\sum_{n=2}^{\infty}n(n+1)[\mathrm{P}_n^{-2}(u)]^2\right\}. \qquad (2)$$

According to Néel2), U can be written, if $\delta\ll d$, as**

$$U=(\pi^2d^3J_s^2/9)[1-12(\delta/d)^2+\cdots]\,, \qquad (3)$$

thus $-\varDelta U\propto d^3(\delta/d)^2$, leading to the d-independent H_c.

After some calculations we come, however, to infinitely large coefficients*** of $(\delta/d)^4, (\delta/d)^5, \cdots$, in the expansion of U in the power series in δ/d. It seems that we can not trace the energy curve as a function of δ/d, without numerical calculations.

This difficulty might be avoided by breaking off the series (2) after a finite number of terms. Then we can neglect the terms of higher order in δ/d unambiguously, if δ/d is sufficiently small. But if we reserve one more higher order term than Néel, we have, using geometrical identities $v=(1/2)\pi(d\delta^2-2\delta^3/3)$ and $p^2=4\delta(d-\delta)$,

$$H_c=\left(\frac{\sigma}{J_s\delta}-\frac{4\pi J_s}{3}\right)-\frac{\sigma}{3J_sd}\,,\quad(\delta\ll d)\,.$$

The last term on the right might be, in some cases, comparable to the quantity in the parenthesis****, and, with constant values of σ and δ, it makes H_c even decrease with decreasing d.

As Néel pointed out, H_c would become, to the first approximation, independent of d in the Kittel's model, if, and only if, $-\varDelta U\propto d^3(\delta/d)^2$. But Néel's calculation corresponds to an infinitely thin wall and another calculation seems to be necessary to decide the question that $-\varDelta U$ in the Kittel's model be proportional to $d^3(\delta/d)^2$.

Electron Transport in Metals

By Mikio Tsuji

General Education Department, Kyusyu University, Fukuoka, Japan

(Received May 13, 1957)

Barrie[1] has calculated the change produced in the conductivity and thermoelectric power of metals when one uses Bohm and Pines' $E_k \sim k$ curve[2] instead of the usual parabolic curve of free electrons. Barrie's calculation is confined to the case of high temperatures and pure metals, and there is a mistake in Barrie's paper. We have calculated the conductivity and thermoelectric power for the general case of arbitrary temperatures and arbitrary concentrations of impurities.

If the spherical energy surface is assumed, the energy of electron E_k may be expanded as follows,

$$E_k=\zeta+\alpha(k-k_0)+(1/2)\beta(k-k_0)^2, \qquad (1)$$

where k is the wave number vector of electrons, ζ the energy of Fermi level, and k_0 the wave number at the Fermi level. We derive Boltzmann's equation for the distribution function of electrons whose energy surface are given by Eq. (1). The lattice scattering term in the equation is identical to that given by Klemens[3], and in the impurity scattering term we expand the scattering cross section Q as $Q=Q_0\ \{1+\gamma_1(E-\zeta)+\gamma_2(E-\zeta)^2+\cdots\}$. We solve the Boltzmann equation by a variational method similar to that of Sondheimer[4], and obtain the electrical conductivity σ and thermoelectric power S as follows,

$$1/\sigma=\rho=\rho_0+\rho_r\ , \qquad \rho_0=A\frac{1}{\alpha^2}\left(\frac{T}{\Theta}\right)^5 J_5\left(\frac{\Theta}{T}\right)\ , \qquad \text{(2}$$

$$\rho_r=B(1/\alpha^2)\ , \qquad \text{(3}$$

$$S=-\frac{2\pi^2\beta}{3e\alpha^2}\kappa^2 T\frac{\left(1-\frac{\alpha^2}{2\beta}\gamma_1\right)+\frac{\rho_0}{\rho_r}\left\{\left(1+\frac{2\alpha}{\beta k_0}\right)-\frac{1}{2\pi^2}\left(1+\frac{\alpha}{2\beta k_0}\right)\frac{J_7}{J_5}+\frac{3}{\pi^2}\frac{k_0^2}{q_0^2}\left(\frac{\Theta}{T}\right)^2\right\}}{1+\frac{\rho_0}{\rho_r}\left\{1-\frac{J_7}{2\pi^2 J_5}+\frac{3}{\pi^2}\frac{k_0^2}{q_0^2}\left(\frac{\Theta}{T}\right)^2\right\}}\ , \qquad (4)$$

where A is a constant proportional to the interaction between electrons and lattice waves, q_0 the maximum wave number of phonons, Θ the Debye temperature, κ Boltzmann's constant, J_n Grüneisen's function and B a constant proportional to Q_0.

Eqs. (2) and (3) show the well known fact that the conductivity is proportional to $(dE/dk)^2$ at the Fermi surface. Eq. (4) is our new expression for the thermoelectric power.

In the case of high temperatures and pure metals, (2) and (4) reduce to

$$\sigma=\frac{4}{A}\frac{\Theta}{T}\alpha^2\ , \qquad (5)$$

$$S=-\frac{2\pi^2}{3e}\left(\frac{2}{\alpha k_0}+\frac{\beta}{\alpha^2}\right)\kappa^2 T\ . \qquad (6)$$

Eqs. (5) and (6) are different from the results of Barrie. (The error of Barrie is due to his Eq. (3), which should be replaced by $\tau=ck^3(m^*)^{-1}$.) We calculate the values of α and β in (1) from the $E \sim k$ relation obtained by Bohm and Pines, and use these values in (5) and (6); then we obtain the numerical results given in the first two rows of Table I.

In the Table σ_0 and S_0 are the values for the standard parabolic bands, and σ and S are the values for the band modified by the theory of Bohm and Pines. σ/σ_0 is decreased considerably from Barrie's results, but S/S_0 is only slightly different from Barrie's result. The values of σ/σ_0 do not depend on temperatures and impurity concentrations, but the values of S/S_0 depend on them.

Table I. Conductivity and thermoelectric power of alkali metals.

	Li	Na	K	Rb	Cs
σ/σ_0	1.43	1.23	1.14	1.12	1.08
$(S/S_0)_H$	0.82	0.91	0.97	0.99	1.02
$(S/S_0)_L$	0.80	0.91	1.04	1.11	1.14

At low temperatures (4) gives the following result for pure metals:

$$S=-\frac{2\pi^2\beta}{3e\alpha^2}\kappa^2 T\ . \qquad (7)$$

The values of S/S_0 calculated from (7) are shown in the last row of Table I. It is seen that the effect of modification of the band on S/S_0 is more appreciable at low temperatures than at high temperatures, but the effect is not so large. For impure metals at low temperatures, the values of S/S_0 are nearer to unity than those for pure metals.

Our conclusion is that, for any temperature and any concentration of impurity, the modification of the $E \sim k$ curve by the theory of Bohm and Pines dose not have very large influence on the electron transport phenomena of metals.

Eq. (4) shows that deviations of the band structure from the free electron model have very important effect on the thermoelectric power. In fact if $\beta<0$, the sign of thermoelectric power may become positive. The detailed calculations will be published in this journal.

A Method of Evaluating the Dissociation Constant in the Excited State of a Molecule

By Reikiti ITOH

Kobayasi Institute of Physical Research
Kokubunzi, Tokyo

(Received May 13, 1957)

If a molecule liberates a proton in the excited state as well as in the ground state, one can evaluate the dissociation constant of the molecule from the pK value of the molecule in the ground state and the absorption spectra of the molecule in the acid and alkali solution. It is naturally expected that the dissociation of proton is easier in the excited state than in the ground state. Then, the excited molecule, if it is meta stable, has the smaller pK value than that of ground state. For the sake of comparison of the dissociation constants of the two states in a given solvent at a given temperature, we consider the equilibrium

$$GH+E^- = G^- + EH\,,$$

where GH and EH correspond to the ground and the excited state of a molecule respectively. Hammet[1] and lately Longuet-Higgins[2] have discussed in detail how the equilibrium constant for such a reaction is related to the kinetic and potential energies of the reacting species. If we ignore the entropy difference between the states in the right and left hand sides of the reaction, the standard free energy change in the reaction can be expressed by the difference in resonance energy of the π-electrons between the species on the right hand side of the equation and those of the left. This assumption may be expressed by the equation

$$(\varepsilon_{EH}-\varepsilon_{GH})-(\varepsilon_{E}-\varepsilon_{G}) = -2.303\,RT(pK_e - pK_g),$$

where ε_A is the π-electron energy of the specy A and pK is the logarithmic equilibrium constant of the molecule for the proton dissociation, and suffixes g and e correspond to the ground and the excited state of the molecule respectively. Then, the left hand side of the equation can be replaced by

$$hc\,\tilde{\nu}_{\text{acid}} - hc\tilde{\nu}_{\text{alkali}} = hc\,\varDelta\tilde{\nu}\,,$$

where $\tilde{\nu}_{\text{acid}}$ and $\tilde{\nu}_{\text{alkali}}$ are the absorption wave numbers in the acidic and alkaline solution of the molecule respectively, and h and c are the Planck's constant and the light velocity. For example, we take β-Naphthol for which the pK data have been reported, i.e., $pK_g=9.49$[3] and $pK_e=2.82$[3] (at 25C°), and the absorption wave numbers are $\tilde{\nu}_{\text{acid}} = 31250$[4] cm^{-1} (solvent HCl, 1/100 N) and $\tilde{\nu}_{\text{alkali}} = 28570$[4] cm^{-1} (solvent NaOH, 1/100 N). From the difference of the absorption wave numbers between the two solutions, one can obtain 5.62 for the value of $pK_g - pK_e$, which is near the observed value, that is $9.49-2.82=6.67$. The small difference between the calculated and the observed value may be attributed to the effects of hydration and entropy change of the reaction.

The author thanks to Prof. I. Oshida for valuable discussion.

Electrical Resistance of CuAu$_3$ and Cu$_3$Au at Low Temperatures*

By Makoto HIRABAYASHI and Yoshio MUTÔ
The Research Institute for Iron, Steel and Other Metals, Sendai.

(Received May 16, 1957)

One of the present authors¹⁾ has previously reported that the electrical resistance of CuAu$_3$ is larger in the ordered state than in the disordered state near room temperature. The behaviour seems to have an opposite sense to that of usual ordered alloys, so that it is of interest to clarify the dependence of the residual resistance of CuAu$_3$ on the degree of order. Although Passaglia and Love²⁾ found no difference in the residual resistance between the quenched and annealed states of CuAu$_3$ in contrast with Cu$_3$Au or CuAu, it seems rather doubtful whether the annealing imposed on this alloy was sufficient to attain the highly ordered state. Thus, we measured the electrical resistivities of CuAu$_3$, CuAu, and Cu$_3$Au in quenched and annealed states from about 2°K to room temperature.

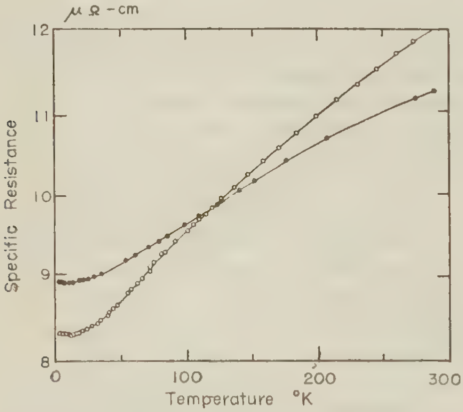

Fig. 1. Specific resistance-temperature curves for CuAu$_3$. Open and closed circles correspond to the highly ordered and disordered states, respectively. Specific resistance values were calculated by using dimensions measured at room temperature, taking no account of temperature change of the dimensions.

In Fig. 1 the specific resistance of CuAu$_3$ containing 75.06 atomic per cent gold, is plotted against temperature. The highly ordered state was obtained by slow cooling from about 200°C to room temperature in four months and the disordered state was obtained by quenching from 450°C to ice water. As shown in this figure, the resistivity-temperature curves for both states each other at about 120°K. It should be noticed, therefore, that the residual resistance is lower in the ordered state than in the disordered one, in the same way as in Cu$_3$Au and CuAu. Ratios of the residual resistance to the ice point resistance are 0.699 and 0.793 for the highly ordered and quenched states, respectively. The resistivity-temperature curves were obtained for various states after different heat-treatments, though not represented here, and it was established that in the partially ordered state the resistance becomes once larger than in the quenched state and again decreases as ordering proceeds. The initial increase might be due to the short-range order effect³⁾. The temperature-dependent portion of the resistance decreases approximately as T^5 below about 20°K for the ordered as well as disordered states. Above this temperature the temperature coefficient of resistance increases as ordering proceeds, similary to Cu$_3$Au and CuAu.

The results for Cu$_3$Au and CuAu almost agree with the work of Passaglia and Love. However, for Cu$_3$Au alloy, containing 25.07 atomic per cent gold, the so-called resistance minimum appeared at about 13°K in the resistance-temperature curves as depicted in Fig. 2. The temperature of the minimum point seems to be little affected by ordering. Such a minimum may probably occur from the presence of very small amounts of specific impurities, such as Fe, Mn, Mg and Si, which were spectroscopically detected. A detailed report will shortly be published elsewhere.

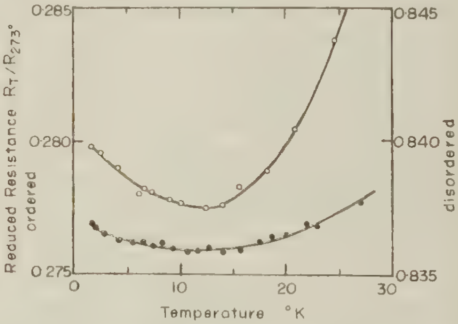

Fig. 2. Reduced resistance $R_T/R_{273K°}$-temperature curves for Cu$_3$Au. Open and closed circles correspond to the ordered and disordered states, respectively.

The authors wish to express their sincere thanks to Professor S. Ogawa and Professor T. Fukuroi, whose guidance and encouragement have made this work possible.

---

Barium Supplied Oxide Coated Cathodes

By Tetsuji Imai

Electrical Communication Laboratory,
Nippon Telegraph & Telephone Public
Corporation, Tokyo, Japan

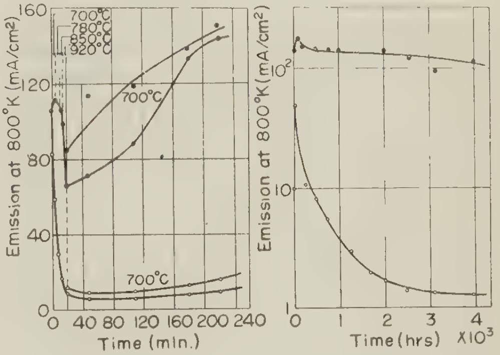
(Received April 22, 1957)

In the oxide coated cathodes, it is believed that stoichiometric excess Ba in the coating layer acts as an active center and its density influences remarkably upon the activity of the cathode. "Stoichiometric excess" allows the possibility of existence of two type of imperfect crystaline states of the cathode coating. The one type is the barium atoms situated in the interstitial positions and the other is the oxygen vacancies.

Though it is quite difficult to decide which is more probable, it is clear that the free Ba is important in any case. In this point of view, many studies have been made on cathode base metals so as to obtain high activity coating. The base metal with large reducing power, however, has the tendency to form the high resistive interface layer which gives rise to many wrong influences upon the vacuum tube characteristics. Therefore, a new attempt is proposed to supply the Ba atom directly into the oxide coating without any chemical reactions between the oxide coating and the base metal.

(1) Supply through the Ni sleeve: Sleeve is constructed duplicately with electrolytic pure Ni, and the Ba source is sealed in the gap between the inner sleeve and the outer one on which oxide emitter is coated. In present experiments Ba getter is utilized as the Ba source.

The emission characteristics of two cathodes which have the same structure except for the existence of Ba source are examined. In each cathode, a deactivation process is produced at first due to flashing of the cathode at high temperature, because in each cathode electrolytic pure Ni are used as the base metal. However, after this heat treatment, if the cathode temperature is decreased to the normal operating condition, the rapid increase of emission is brought about in the cathode occluding Ba source. These aspects are shown in Fig. 1 (a). Life test for these two cathodes are also undertaken at about 700°C quiescently, and the remarkable difference of the emission durability is observed between them as seen in Fig. 1 (b).



(a) (b)

Fig. 1. Vatiation of emission for the two type of cathodes. The closed points indicate the cathode in which Ba is supplied through a pure Ni sleeve and the open points indicate the one with no Ba source.

(a) Represents the inital stage of heat treatment, and

(b) represents the quiescent life test undertaken at about 700°C of cathode temperature.

(2) Supply through the porous metal: The effect of the Ba supply is examined for the cathode with L-cathode type Ni sleeve on which upper side porous metal (in this case porous pure Ni) is welded and with the Ba source which is sealed in the same manner as the previous case. In this case, we found that the activation is taken place from the begining at very lower temperature and the special high temperature treatment is not necessary for the activation process.

Thus the effect of the Ba supply is obvious and by the proper choice of the rate of Ba supply, low temperature activation and low temperature cathode operation may be possible and much more long life may be expected for the oxide coated cathode.

Note on Collective Energy Losses in Metals

By Takao Sato
Department of Physics
Tokyo Metropolitan University, Tokyo

(Received April 4, 1957)

On the theoretical treatments of the collective behavior of electrons in metals, thorough investigations have been done by Bohm and Pines[1], while the experimental evidences thereof have been furnished first by Ruthemann, then by many authors[2]. That is, when a fast charged particle excites such collective oscillations, we are dealing with energy transfer to a number of electrons moving cooperatively in consequence of their mutual interaction. The energy of a plasmon is in the neighborhood of $\hbar\omega_p=\hbar(4\pi ne^2/m)^{1/2}$ where n is the valence electron density and m is the free electron mass.

We now will consider the experimental evidence for plasmon excitation in metals. It was clear from the experimental results that two kinds of situations prevail in the characteristic loss spectrum of a thin metal film; e.g. A group which shows comparatively good agreement between theory (calculated on the assumption that the valence electrons are free) and experiment, and B group metals do not coincide with the frequency $\hbar\omega_p$, and also there has been frequently observed only a single broad loss line.

The interpretation to the A group was provided by Mott[3], who showed that if the valence electrons are weakly bound, and the core electrons are strongly bound (with respect to the free electron plasmon energy $\hbar\omega_p$), the solid state environment would not greatly affect the plasmon energy. One interpretation to the B group was provided by Wolff[4], showed that the coupling of the plasmons to the core electrons in noble metals and transition metals would be expected to broaden the plasma resonance and increase the plasmon energy substantially. He is then led to the conclusion that loss lines continue to broaden as one goes through the transition elements in order of increasing valency. The conclusion, however, is not in agreement with the experiment done by Marton and Leder[5].

It seems that the discrepancies for the B group metals are the consequence of the situation inherent of the transition metals, and are closely related to the substantial problems concerning to their electronic structure. The reason, why the disagreement prevails mainly in noble metals and transition metals, will be attributed to the fundamental problem; what their valency means or what electrons are which contribute to plasma oscillation. It is to be noted that in the A group metals we obtain good agreement between theory and experiment by assuming simply that the valence electrons and the number of electrons which contributed to plasma excitation are equal.

So far the valencies has been considered only formally for the A group elements this may have some substantial meaning. For the B group metals, however, we might consider that the formal valencies lose its meaning. The latter group forms a new scheme of metallic valencies proposed by Pauling[6], in which the significance of formal valency has been in dispute. According to Pauling's theory of new valency scheme, the valencies have the substantial meaning that they concern directly with bond in metals.

A comparison of $\hbar\omega_p$ (eV) with E_{obs} (eV) for metals. Z denotes the number of Pauling's valence.

	Cr	Mn	Fe	Co	Ni	Cu	Zn	Ga
Z	5.78	5.78	5.78	5.78	5.78	5.44	4.44	3.44
E_{obs}	24	22	21	21	23	20	23	—
$\hbar\omega_p$	25	25	26	26	27	25	20	15
	Mo	**Ma**	**Ru**	**Rh**	**Pd**	**Ag**	**Cd**	**In**
Z	5.78	5.78	5.78	5.78	5.78	5.44	4.44	3.44
E_{obs}	25	—	—	—	22	23	20	12
$\hbar\omega_p$	22	—	24	24	23	21	16	13
	W	**Re**	**Os**	**Ir**	**Pt**	**Au**	**Hg**	**Tl**
Z	5.78	5.78	5.78	5.78	5.78	5.44	4.44	3.44
E_{obs}	22	—	—	—	23	24	—	17
$\hbar\omega_p$	22	23	24	24	23	22	16	13

When one calculates $\hbar\omega_p$ for the B group on the basis of Pauling's new valency scheme, the obtained values come closer to the observed ones, as one sees in the table. Although the agreement is not perfect, of course, this seems to provide some indication to the problems of plasmon excitation in transition metals.

It is a great pleasure to thank Professor M. Sasaki for his helpful discussions and encouragements.

Absorption Band due to Colloidal Silver

By Ryosuke YOKOTA and Kazuo SHIMIZU
Matsuda Research Laboratory,
Tokyo Shibaura Electric Company,
Kawasaki-city, Japan

(Received May 14, 1957)

Photosensitive glass is one of the most remarkable progress in the field of glass in recent years[1]. But very little has been studied about this interesting and useful glass.

We have discovered a very sharp absorption band due to silver colloid in this glass.

From the pure chemicals we prepared the photosensitive glass containing silver and cerium whose concentrations are about 6.4×10^{16} cm^{-3} and 1.6×10^{18} cm^{-3} respectively.

The oxide composition of the base glass in weight per cent is: SiO_2 82.5, Li_2O 12.5, K_2O 2.5 and Al_2O_3 2.5.

The glass whose size is $15 \times 6 \times 1$ mm^3 was irradiated with the ultra-violet light emitted from the high pressure mercury arc lamp. By this exposure the latent image was formed.

The irradiated glass was quickly inserted into the electric furnace which was maintained at any temperature from 510 to 590°C within ±1°C, and was held for some time, say, about 20 minutes. Then it was quickly withdawn and cooled in air to room temperature. Yellow color was developed.

We have discovered a very sharp absorption band whose half-width is 22 mμ by the use of Beckman DU spectrophotometer. The increase of absorption is given in Fig. 1 in the full line. In this case the dosage of the effective spectral region of the irradiated light was about 2×10^3 erg/cm^2 and the time and temperature of development were 20 minutes and 560°C, respectively.

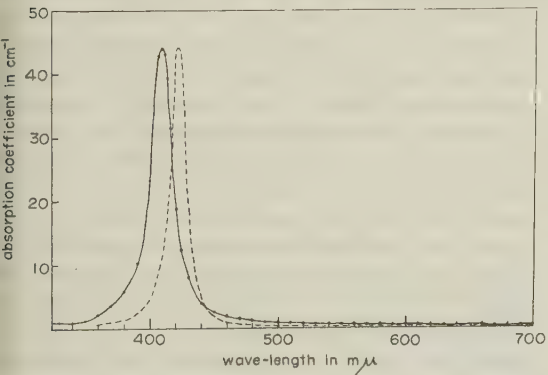

Fig. 1.

The shape and location of this band do not change by cooling down to 80°K, and by heating to 200°C, and by the irradiation of light lying in this band. The absorption bands produced by the ionizing radiation, for example, X-irradiation[2], have changed by the above treatments.

We prepared the glass which does not contain silver but the other compositions are the same. No band was developed in this glass by the same exposure and development.

Therefore this band is due to the silver colloid, especially that of diameter much less than the wave-length of the incident light, because no scattering of light was observed.

In this case the shape and location of this band can be calculated from the equation[3])

$$K=\frac{36\pi N_V V \dfrac{n^2\kappa}{n_u\lambda}}{\left[\left(\dfrac{n}{n_u}\right)^2+\left(\dfrac{n\kappa}{n_u}\right)^2\right]^2+4\left[\left(\dfrac{n}{n_u}\right)^2-\left(\dfrac{n\kappa}{n_u}\right)^2+1\right]}$$

Where K is absorption coefficient, N_V is the number of particles per unit volume; V is the volume of single particle; λ is the wave-length in air for which K is sought; n_u and n are the refractive indices of the glass and silver respectively and $n\kappa$ is the "absorption coefficient" of silver.

Our measured value of n_u for this glass was 1.513 at the wave-length of 420 mμ. The dispersion of n_u is so small that it can be neglected in this case.

It may be the most appropriate to employ in this calculation the optical constants of the silver measured by Schulz[4]) and by Schulz and Tangherlin,[5]) because they measured in an annealed state of the silver film evaporated on glass.

The calculated curve is given in Fig. 1 in the dotted line. In this case neither N_V nor V is known, the maximum value of K was set equal to the measured value.

A good agreement is obtained between the shapes and locations of the observed and calculated bands, although there is small difference of 12 mμ in their locations of peaks.

This small difference is supposed to originate in the circumstance that the colloidal silver in this glass has some different values of n and $n\kappa$ with those measnred by Schulz *et al.*

Effect of Heat Treatments on the Magnetic Properties of the $FeTiO_3$–Fe_2O_3 Solid Solution Series

By Yoshikazu Ishikawa
Institute of Science and Technology University of Tokyo, Tokyo
and Syun-iti Akimoto
Geophysical Institute Tokyo University, Tokyo

(Received April 30, 1957)

It has been recently reported that the complete solid solutions between ilmenite ($FeTiO_3$) and hematite (Fe_2O_3), $x TiFeO_3 \cdot (1-x) Fe_2O_3$ can be prepared in the whole range of $0 \leq x \leq 1$ when the mixture of pure Fe_2O_3 and $FeTiO_3$ in an appropriate ratio sealed in a quartz tube evacuated approximately to 10^{-3} mm mercury is quenched from above 1200°C[1]. Although their Curie point temperatures and lattice parameters vary continuously with their compositions, the intensity of magnetization changes discontinuously near $x=0.5$; that is, very strong ferromagnetic (30~70 gauss/gram at 80°K) for $x>0.6$, while feeble ferromagnetic (1~2 gauss/gram) for $x<0.55$[2].

In the course of comprehensive research on the magnetic properties of the $FeTiO_3$–Fe_2O_3 solid solution series, we have found that the intensity of magnetization of the specimens of which chemical composition is near 0.5 is remarkably affected by the heat treatments. Before heat treatments, the specimen of $x=0.5$ which was prepared by the quench method from above 1200°C had the intensity of magnetization of about 2 gauss/gram at room temperature. We have carried out the following heat treatments upon this specimen; that is, the specimen sealed again in an evacuated quartz tube was either quenched or slow-cooled naturally in the furnace from the appropriate high temperatures after being maintained at these temperatures for five hours. Remarkable change in the intensity of magnetization for a magnetic field of 9350 Oe was found after such heat treatments. In Fig. 1, the cross marks show the case of quenching from high temperatures, while the hollow circles show the case of slow-cooling. In this figure, the abscissa shows the temperatures in which the specimen was maintained for five hours.

X-ray analysis carried out by a Norelco diffractometer shows that hardly any changes can be seen in the diffraction patterns as long as the temperature of heat treatment does not exceed 1100°C. On the contrary, when the specimen is cooled slowly from 1100°C, the positions of the diffraction line on the Norelco chart are shifted in the appreciable quantity, corresponding to the decrease of x by 0.05. Consequently, the sharp decrease in the curve B of Fig. 1 when the temperature of heat treatment is 1100°C is due to change of the composition. The Curie point of the specimen which acquired the strong ferromagnetism by means of the above-mentioned procedure is higher than that of the feeble ferromagnetic one by 30°C, but their magnetic susceptibilities above Curie points coincide with each other at high temperatures.

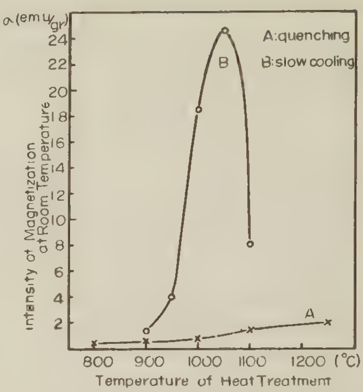

Fig. 1. Effect of heat treatments on the intensity of magnetization of $0.5\,TiFeO_3 \cdot 0.5\,Fe_2O_3$.

It may be very probable that the discontinuous change of the magnetization of the solid solutions with their compositions is closely related to the ordering of Ti and Fe ions, which is established in pure ilmenite[3] and is expected to be responsible for the strong ferrimagnetism. Such an effect of the heat treatments as described in this short note may also be related to an order-disorder transformation phenomenon. There are certain reasons, not described here, to infer that the order-disorder transformation temperature of this specimen is near 600°C. Hence, the fact that the strong ferromagnetism can be acquired only when the specimen was cooled slowly from above 1000°C may be interpreted as follows. It is necessary to maintain the specimen at the temperatures higher than 1000°C in order to create some short range order, without which ordering of Ti and Fe ions can not be attained even if the specimen is cooled slowly through the transformation temperature near 600°C. Furthermore, we have found that the intensity of magnetization of the original specimen can be increased three or four times even in the case of cooling from 600°C if the magnetic field is exerted in the cooling process. This phenomenon can be explained consistently if we assume that in the magnetic field the short range order can be created even at low temperatures.

Detailed investigation is now progressing and the understanding of the mechanism of this phenomenon may give us some information about the origin of ferromagnetism of this solid solution series.

Frequency Shift in Ammonia Absorption due to Foreign Gases

By Kiyokata Matsuura, Yoshikazu Sugiura and G. M. Hatoyama

Electrotechnical Laboratory, Nagatacho, Tokyo

(Received May 11, 1957)

We have already reported the frequency shift in ammonia (3,3) absorption line due to self-broadening[1]). We have also studied the frequency shift of the same line due to foreign gases present in the absorption cell.

The measurements were done with an absorption cell first filled with NH_3 to an amount corresponding to $2\Delta\nu_0 \approx 200$ to 300 kc, to which foreign gases were introduced, and the shift, line width and the pressure were measured similtaneously. The results are tabulated in Table I.

K. Tomita[2]) has calculated theoretically the shift due to impact between molecules, based on dipole-dipole interaction. He gives the value of $a=0.18$ for the shift due to self-broadening, which is some ten times larger than our observed value. Moreover, his calculations do not lead to any negative value of a. Some other types of interaction seem to be taken into account.

Table I. The shift due to foreign gases in ammonia

Gas	Molecular dipole (Debye unit)	$\Delta\nu/p$ (Mc/mmHg)	$a\times 10^2$ (Mc/Mc Width)
(NH_3)	1.47	27	1.8
H_2	0	3.0	− 0.6
A	0	2.0	− 0.6
O_2	0	2.3	− 0.7
N_2	0	4.5	− 1.8
CH_4	0	3.4	− 0.7
CO_2	0	6.6	− 3.8
C_3H_8	0	6.9	− 4.2
$C_6H_5CH_3$	0.5	8.5	− 2.6
H_2O	1.8	4.3	− 3.6
CH_3OH	1.7	9.0	− 3.9
C_2H_5OH	1.7	12.5	− 3.9
CH_3COCH_3	2.7	22	−12

Some Aspects of Wedge-shaped Domains in $BaTiO_3$ Crystal

By Terutaro NAKAMURA, Wataru, KINASE
and Yoshinori KATŌ*
Department of Physics, Faculty of Science,
University of Tokyo

(Received May 6, 1957)

Domain structure in barium titanate crystals has been investigated by a number of authors.[1] This communication is a record of observations of a domain structure in a barium titanate crystal, which has yielded some aspects hitherto not yet reported.

Our observation of a barium titanate crystal through a polarization microscope, at about 20°C, gave patterns shown in Fig. 1, at a position 45° rotated from the extinction positions. Fig. 1*a* shows the top view, while *b* the bottom. The fact that fringes were observable, and the locations of fringes, which were the same either viewed from the top side or the bottom, indicates that the domain arrangement must be as shown in Fig. 2. The crystal showed remarkable bending, favorable to the structure suggested (Fig. 2). Some irregularities of fringes in Fig. 1*b* (shown by an arrow) were useful for distinguishing between the "top" surface and the "bottom", in consistent with the sense of bending.[2] The thickeess of the sample was 0.15 mm.

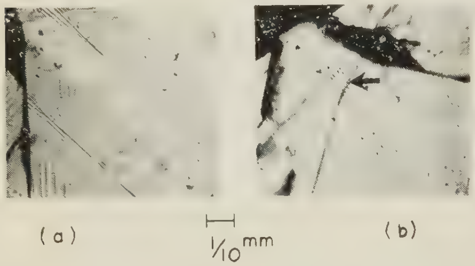

Fig. 1. (*a*) top and (*b*) bottom views at 20°C.

The process of the formation of this type of domain structure will be presumably as follows. At high temperatures, the crystal had been subject to mechanical or thermal stressess, which had caused bending of the plate-like crystal, in the course of the preparation of the specimen. Cooled through the 120°C Curie point, cubic crystal metamorphosed into tetragonal, and the domains assumed the arrangement shown in Fig. 2 so as to decrease the elastic energy.

Near a grain boundary, a number of stripes 45° to prismatic axes were observed, which were confirmed to be plate-like domains showing extinction at the positions parallel and perpendicular to prismatic axes. These plate-like domains were existent only in the regions of which c-axis is parallel to the crystal surface (part A in Fig. 2), and the plates of these domains were perpendicular to the crystal surface. These domains may have been created by mechanical stressess, which probably arised on the grain boundary.

Where "45°-stripe-domains" were existent, there it was observable that the fringe of the middle position was split into two and a new fringe was created between them, or that the fringe of the middle position became thicker. These effects may be understood as follows. The interference fringe of the middle position is not the zero-th order, but there is a minute distance between the crystal surface and the top of the prisms. Mechanical stressess may affect the distance and cause the splitting of the fringes.

Cooled down to 0°C through the transition point 5°C, the patterns which differ markedly from Fig. 1 were observed, as shown in Fig 3, photographed at 3°C. The prismatic domains split up into fine domains, the arrangement of which is supposed to be as shown in Fig. 4. Warmed back up to about 20°C, the previous patterns never reappeared and the bending was removed. This may be because in the orthorhombic phase the mechanical stressess had been relaxed.

The authors wish to thank Prof. H. Takahasi for his helpful discussions. They are also indebted

Paramagnetic Resonance of Silicocarbon

By Yoshikazu Sugiura and George Mitio Hatoyama

Electrotechnical Laboratory, Tokyo

(Received June 8, 1957)

When silicone resins are heated in vacuum to over 900°C, they become semiconductors[1]. We call them silicocarbon. The conductivity seems to arise from the carbon atoms present in the resin. Actually, resins with higher carbon content show conductivity at lower treatment temperatures.

At moderate treatment temperatures, hydrogen will come out of the resin leaving broken bonds in the carbon atoms. At higher temperatures, the carbon atoms will be rearranged so that the wave functions for these broken bonds may overlap. Such phenomena might be observed by resonance absorption experiments.

Dow Corning Silicone No. 2104 was used as samples. This material contains roughly 4 carbon atoms per one silicon atom. The resin was treated at temperatures between 600 and 1000°C and the microwave resonance absorption was observed at 1.25 cm. The number of unpaired electrons as a function of the treatment temperature is plotted as Curve A, Fig. 1. Probable errors in relative values are shown in the figure by bars. The number is deduced from the area of the absorption curve compared with that for $ZnAl_2O_4$ with a known amount of Mn^{++}. The absolute number may be in error by a factor of less than 2. Specific resistivity of the samples at room temperature is also shown in the figure as Curve C. It can be seen that the number of unpaired electrons first increases with the treatment temperature and then decreases at temperature range where the conduction becomes appreciable. The general feature is similar to those obtained by Ingram and others[2)3)] with carbohydrates.

The width between the maximum slope of the absorption is plotted as Curve B in the figure. It is seen that the width decreases suddenly as the number of unpaired electrons approaches its maximum. This is also similar to the results obtained by Combrisson and Uebersfeld[3)] with carbohydrates, and hence it seems that the exchange narrowing is happening.

The g-value was measered in reference with DPPH, giving a value 2.0027 ± 0.0005 for a sample treated at 1100°C. No appreciable change in g-value with the treatment temperature was observed.

On the Neutrons from the N^{14} (d, n) O^{15} Reaction-II

By Itaru NONAKA*, Susumu MORITA, Nawoyuki KAWAI,
Toshiyuki ISHIMATSU, Kenji TAKESHITA,
Yutaka NAKAJIMA and Nawoyuki TAKANO

Department of Physics, Faculty of Science, Kyushu University,
Fukuoka, Japan

(Received May 1, 1957)

The angular distribution of the neutrons from the $N^{14}(d, n)O^{15}$ reaction leading to O^{15} ground state was investigated in the angular range from 0 to 165 degrees (lab. system) by the photographic method. The energy of the bombarding deuterons was 1.96 MeV, and the Q-value was found to be $Q_0=(5.13\pm0.05)$ MeV.

The angular distribution shows a maximum at about 30 degrees (c. m. s.) and decreases considerably beyond this maximum, in accordance with what is characteristic to the stripping process corresponding to $l_p=1$. In the backward direction, the intensity of neutrons increases remarkably and reaches the value almost three times as large as that of the forward maximum. The absolute cross section of this reaction was estimated to be $\sigma(0°)=(2.4\pm0.7)$ mb/sterad. and $\sigma=(38\pm7)$ mb.

§ 1. Introduction

It is important to measure the angular distribution of particles emitted through the deuteron induced reaction in order to obtain the information concerning the mechanism of the nuclear reaction and the structure of nucleus. Many measarements of this sort have been performed so far on various nuclei and their theoretical interpretation have also been reported.

In our previous work[1], we measured the angular distribution of the neutron from the $N^{14}(d, n)$ O^{15} reaction leading to O^{15} ground state at angles ranging from 0 to 105 degrees (lab. system). The energy of bombarding deuterons was 1.85 MeV and the result was interpreted satisfactorily by Butler's theory. That is, the angular distribution had a maximum at about 20 degrees (c.m.s.), showing the contribution from the stripping process corresponding to $l_p=1$, in agreement with the results of other authors.

Most of the measurements of the neutron angular distributions in (d, n) reactions have so far been restricted to the relatively narrow angular ranges in the forward direction. The backward angular distribution, however, may be as useful as the forward in the analysis of nuclear reaction. Accordingly, we have tried to extend the measured angular range of our previous work on $N^{14}(d, n)O^{15}$ reaction to the more backward direction. In addition, the absolute value of the cross section of this reaction was estimated taking the ratio of the neutron yield of this reaction to that of the $D(d, n)$ reaction.

§ 2. Experimental Arrangements and Procedures

The experimental arrangements were similar to the previous ones except at a few points. As is shown in Fig. 1, the target chamber filled with nitrogen gas was made of glass cylinder of 3 cm in diameter and 4 cm in length and the bottom plate of silver of 1 mm thickness. The entrance to the chamber was of an aperture of 0.8 cm in diameter and sealed with a nickel foil of 1.6 mg/cm² thick. Any portion of the target chamber exposed to the direct deuteron beam was covered with silver plates to minimize the neutron background. The deuterium gas of 4.3 cm Hg in partial pressure was mixed to the nitrogen gas of 23.2 cm Hg in the target chamber, and the neutrons emitted from these two substances were detected simultaneously. Thus, it was possible to estimate the absolute cross section of the $N^{14}(d, n)O^{15}$ reaction comparing the neutron yield of this reaction with that of the D (d, n) He^3 reaction.[2] Commercial nitrogen gas was used as the target gas. The mass-spectrometric analysis* of the target showed traces of argon and oxygen besides nitrogen and deuterium,

---

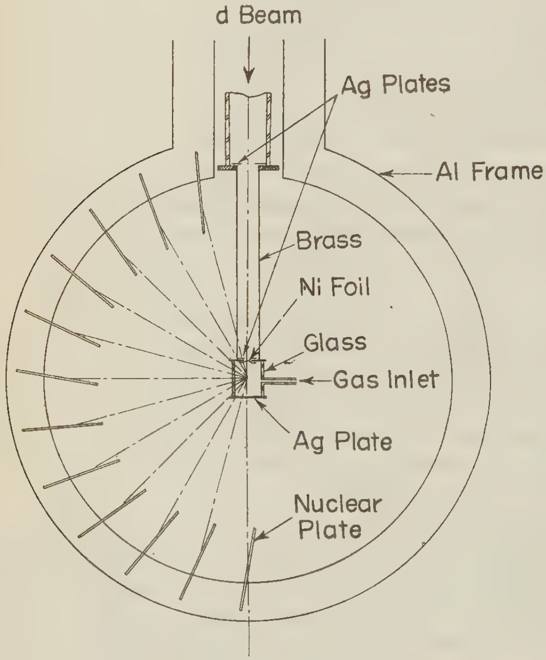

Fig. 1. Arrangements of the target chamber and photographic plates.

but these impurities would not affect the neutron spectrum.

Deuterons were accerelated to (2.31±0.01) MeV by means of the Van de Graaff accelerator at Kyushu University, whose voltage was calibrated with the resonances of F^{19} $(p, \alpha)\, O^{16**}\, (\gamma)\, O^{16}$ reaction. The mean energy of the beam in the target chamber was estimated to be 1.96 MeV, considering the energy loss of 190 keV in the nickel foil and that of 320 keV in target gas. These values of energy loss were caluculated from the data by Allison and Warshaw[3].

The slit system allows the whole deuteron beam to pass through the entrance aperture into the target chamber, so it was possible to use the target chamber as a collector cup for the deuteron beam, and the chamber was connected to a current integrator and microammeter in series. The intensity of the magnetically analyzed deuteron beam had been 1μA in average during the bombardment of about three hours. The background run, without the target gas, was carried out in such a way that the total integrated beam currents were equal to the true run.

Sakura NR-MI nuclear plates, 200 micron emulsion thickness, were used to detect the neutrons. The shrinkage factor of this emulsion was measured to be 2.0±0.1. Each plate was wrapped in a thin black paper after being covered with an aluminium foil. As is shown in Fig. 1, these plates were placed on an circular aluminium frame centered to the target chamber at intervals of 15 degrees in the angular range from 0 to 165 degrees with respect to the incident deuteron beam. The glancing angle of each plates was chosen to be 10 degrees.

The center of each scanned area was 3 cm distant from the inner edge of the plate and 19 cm from the center of the target chamber. The observed tracks were treated by the precedures described in the previous work. The range-energy relation for the NR-MI emulsion was determined with the energy of neutrons emitted from D (d, n) He^3 reaction and observed ranges in the emulsion of their recoil protons. As shown in Fig. 2, this rang-energy relation gives three percent smaller energy than that given by the previously calculated relation to the recoil

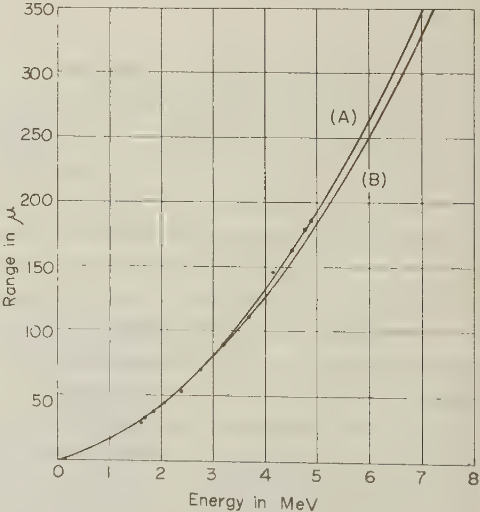

Fig. 2. Proton range-energy relation for Sakura NR-M1 emulsion. Curve (A) was determined with the energy of neutrons emitted from D (d, n) He reaction, and Curve (B) was calculated by Webb' method[1].

---

* This mass-spectrometric analysis was performed by Mr. M. Yokota. The authors wish to express their thanks to him for his kind assistance.

protons of the same range in the energy region up to 5 MeV.

When neutrons emerging from the target pass through the matter of the target chamber, some of the neutrons were scattered out of the neutron beam. As the thickness of the matter passed through by neutrons was different in each observing angle, the proportion of the lost neutrons was also different. The correction for these scattered out neutrons was also different. The correction for these scattered out neutrons were carried out as follows. The attenuation of neutron intensity in the materials which were present between the target and plates was estimated by considering their total cross sections for the neutron. The correction was found to become maximum at 165 degrees and amounted to 9 per cent for the D (d, n)-neutron and 10 per cent for the $N^{14}(d, n)$-neutron which leaves the residual nucleus in its ground state. These corrections, however, would be somewhat overestimated, because all the scattered neutrons were assumed to be lost entirely. But the errors introduced by this assumption would be negligible.

§ 3. Results and Discussions

Some of the typical energy spectra of neutrons are shown in Fig. 3, (A), (B) and (C), which were obtained at angles of 15, 90 and 165 degrees (lab. system), respectively. In each spectrum, the group of neutrons with higher energy are from the $N^{14}(d, n)O^{15}$ reactions leading to the ground state of O^{15} nucleus, and those with intermediate energy from $D(d, n)He^3$ reaction. Moreover, those with lower energy below 2 MeV consist of the neutrons emitted from the $C^{12}(d, n)N^{13}$ reactions due to carbon contamination and probably from the $N^{14}(d, n)O^{15}$ reaction leading to the first excited state of O^{15} nucleus.

The positions of the neutron groups from the $N^{14}(d, n)O^{15}$ reactions leading to the ground state in O^{15} nucleus, gave the Q-value of this reaction of $Q_0 = (5.13 \pm 0.05)$ MeV. The discrepancy between this value and our previous one (5.21±0.07) MeV is attributed to the different range-energy relations used.

In order to estimate the intensity of the neutrons of higher energy group from the $N^{14}(d, n)O^{15}$ reaction, the slope of the lower energy side of the spectrum was extrapolated to zero intensity and this extrapolated energy was assumed to be the lower end of this group. For examples, these values were found to be 5.60, 5.10 and 4.70 MeV as are shown by arrows in Fig. 3 (A), (B) and (C) respectively. It was found that in almost all spectra these energy values were smaller than those corresponding to the peaks by the amount of 20 per cent of the latter. The same procedures were also applied to the neutrons from the D (d, n) reaction. As is shown in Fig. 3, however, a part of the neutron spectrum from the D (d, n) reaction overlapped with that from the $N^{14}(d, n)$ reaction at smaller angles, and with that due to the carbon contamination at larger angles. The corrections for these overlappings of the groups were estimated simply assuming that

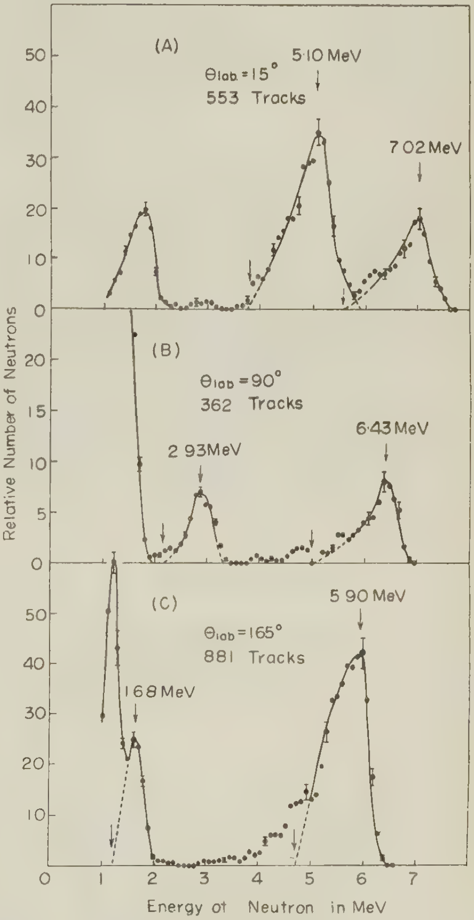

Fig. 3. Energy spectra of neutrons for $E_d = 1.96$ MeV, obtained by eliminating the background. (A), (B) and (C) were obtained at angles of 15, 90 and 165 degrees (lab. system), respectively.

all the neutron groups concerned have the same shapes irrespective of their positions and reactions they refer to. For instance, this correction for the intensity of the neutrons emitted at 15 degrees from D(d, n) reaction amounts to 7 per cent (see Fig. 3 (A)).

The angular distribution of neutrons was obtained from the intensity thus determined at each angle. The angular distribution of neutrons from the D(d, n)He^3 reaction is shown in Fig. 4, where indicated errors are the statistical ones. As is expected from kinematics, it is almost symmetrical about a plane perpendicular to the direction of the incident beam in the center-of-mass system. But the yield of neutrons in the backward directions seems to be some what smaller than that in the forward directions. The origin of this deviation cannot be attributed to the misalignment of experimental arrangement. For this deviation from the symmetry about 90 degrees, the following interpretations would be possible. Firstly, some of deuterium gas in the target chamber may have been absorbed onto the silver plate at the bottom of the chamber, and the neutrons from this deuterium contamination may have been detected in addition to that due to the target gas. Secondly, at the backward directions, the resolution between two groups referred to the D(d, n) and C$^{12}(d, n)$ reactions is very poor, as can be seen in Fig. 3 (C). Then the systematic errors may have been introduced into the estimation of the intensities of neutrons emitted in the D(d, n) reaction at the larger angles. In Fig. 4, the measure of ordinate was determined by comparing the observed intensities of neutrons at three forward angles to the known values of the differential cross section.

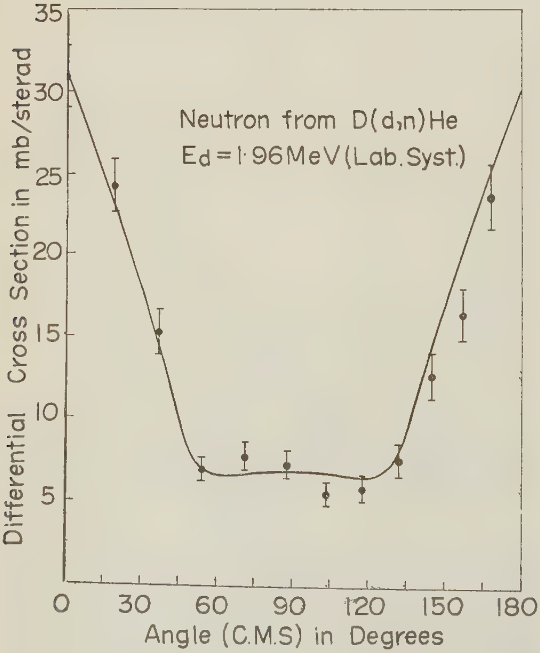

Fig. 4. Angular distribution of neutrons from D(d, n)He^3 reaction for $E_d=1.96$ MeV.

The angular distribution of neutrons from the N$^{14}(d, n)$O^{15} reaction leading to the ground state in O^{15} nucleus is shown in Fig. 5 where the indicated errors are the statistical ones. The forward distribution having a peak at about 30 degrees can be well fitted to the stripping theory using Bhatia's curve with $R=7.0\times10^{-13}$ cm and $l_p=1$. The absolute values of the differential and total cross sections of the N$^{14}(d, n)$O^{15} reaction leading to the ground state in O^{15} nucleus are evaluated from the mixing ratio of nitrogen and

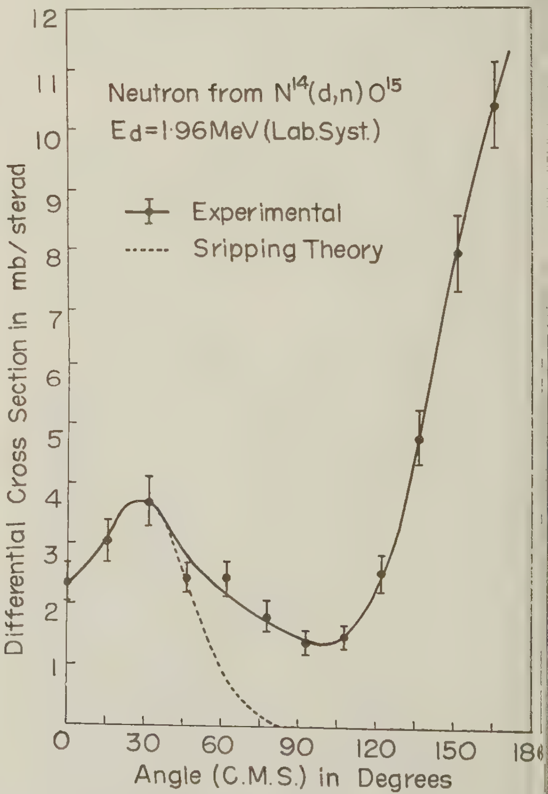

Fig. 5. Angular distribution of neutrons from N$^{14}(d, n)$O^{15} reaction leading to the ground state in O^{15} nucleus, for $E_d=1.96$ MeV. The dotted curve shows the Bhatia's curve with $R=7.0$ $\times10^{-13}$ cm and $l_p=1$.

deuterium gases, referring to the known value of cross section of the D(d, n)He^3 reaction, and found to be $\sigma(0^0)=(2.4\pm0.7)$ mb/sterad. and $\sigma=(38\pm7)$ mb, respectively. The measure of ordinate in Fig. 5, thus determined, is expected to have an uncertainty of 20 per cent. The unexpected behavior of the angular distribution is the large increase in the backward direction and the intensity of neutrons at 165 degrees comes up to almost three times as large as that of the forward maximum at 30 degrees. It is suspected that the considerable part of the reactions induced by deuterons of 1.96 MeV would be due to the process of compound nucleus formation. And the interference between the compound nucleus formation and the stripping processes may contribute appreciably. In conclusion, it seems interesting to investigate the angular distribution of neutrons at various energies of the bombarding deuterons, and also it would be much useful for the theoretical interpretation to know the variance of angular distribution with the bombarding energy.

The authors with to express their cordial thanks to Mr. Y. Wakabayashi of the Chemical Research Laboratory of Konishi-Roku Photographic Industry for his kind preparation of nuclear plates. Thanks are also due to Miss Hirakura and Miss J. Yoshida for their skilful scanning of the nuclear plates. This work has been supported by the Scientific Research Expenditure of the Ministry of Education.

Cosmic Ray Nuclear Interactions in Nitrogen Gas

By Saburo MIYAKE, Kensaku HINOTANI,
Itsuo KATSUMATA and Tatsunosuke KANEKO
Institute of Polytechnics, Osaka City University, Osaka

(Received February 26, 1957)

The natural rate of occurence of nuclear interactions of cosmic ray N-component in which more than 5 Mev are given to charged secondary particles have been measured in the nitrogen filled high pressure cloud chamber at Mt. Norikura (2840 m above sea level and 25°N geomagnetic latitude). From the rate of occurence of number interactions, the vertical intensity of N-component was estimated at $(2.4\pm40\%)\cdot10^{-3}\cdot E^{-1.4}\mathrm{cm}^{-2}\mathrm{s}^{-1}$ $\mathrm{sr}^{-1}\mathrm{Mev}^{-1}$ for the energy range from 10 Mev to 100 Mev by assuming the geometrical cross section. These events may be considered to be the source of the cosmic ray N-component with an energy less than that sufficient to produce nuclear interactions in the atmosphere, and it was shown that the spectrum of secondary particles was in accord with that of the latter. The absolute intensity of N-component was also consistent with that expected from the data of other energy regions in our previous paper. A possible scheme of the nuclear cascade was discussed in relation to the size distribution of the observed stars.

§ 1. Introduction

In this paper an experiment of the nuclear interactions in nitrogen gas is described and the intensity of cosmic ray N-component in the atmosphere is also estimated, assuming the geometrical cross section.

In the previous paper[1)], the energy spectrum of cosmic ray neutrons of energy range from 1 ev to 10 Gev and the general aspects of nuclear cascade in atmosphere have been discussed. However, a greater part of the spectral curve still remains unmeasured. Nuclear interactions with light nuclei such as nitrogen have not been studied to enable the understanding of the process of nuclear cascade in cosmic ray phenomena. The present paper will show one of the examples of experimental analysis for such problems.

The experimental method employed is to observe the cosmic ray nuclear interactions in a randomly operated high pressure cloud chamber filled with nitrogen gas.

The comparison of stars in ordinary emulsion with those occuring in nitrogen gas may allow an unambiguous interpretation of each observed events, namely, the observed events in emulsion can be extraporated to low energy events and discussed for light and heavy nuclear elements separately, using the data presented in this paper. In the case of emulsion, low energy events may be overlooked, because of the insufficient scanning efficiency.

Because photographic emulsions consist of a variety of elements, it is often impossible to ascribe with certainty an individual event observed in the ordinary emulsion to the disintegration of the nucleus of a particular element. The knowledge of the star characteristics, which vary with the atomic number of the nucleus and the energy of the incident particles, is also of importance in the interpretation of the existing data on stars in emulsions, as well as in understanding the nuclear interaction processes themselves.

§ 2. Experimental Procedure

The high pressure cloud chamber[2)] (50 cm in dia and 20 cm in depth) filled with nitrogen gas up to 55 atm was used. Usually this chamber is used at 100–150 atm but for the present purpose the pressure was decreased to be able to observe low energy secondaries. At this decreased pressure the range of proton of 5 Mev was about 5 mm. The experimental arrangement and procedure are the same with those as described in the previous paper, except the pressure and the gas of the chamber. The stopping power is shown in Fig. 1. The sensitive volume and the sensitive time were determined to be 12.5 liters and 5.2 sec, respectively by similar methods described in the previous paper.

To correct the effect of the surrounding materials, twice the geometrical mean free path was used as the absorption mean free

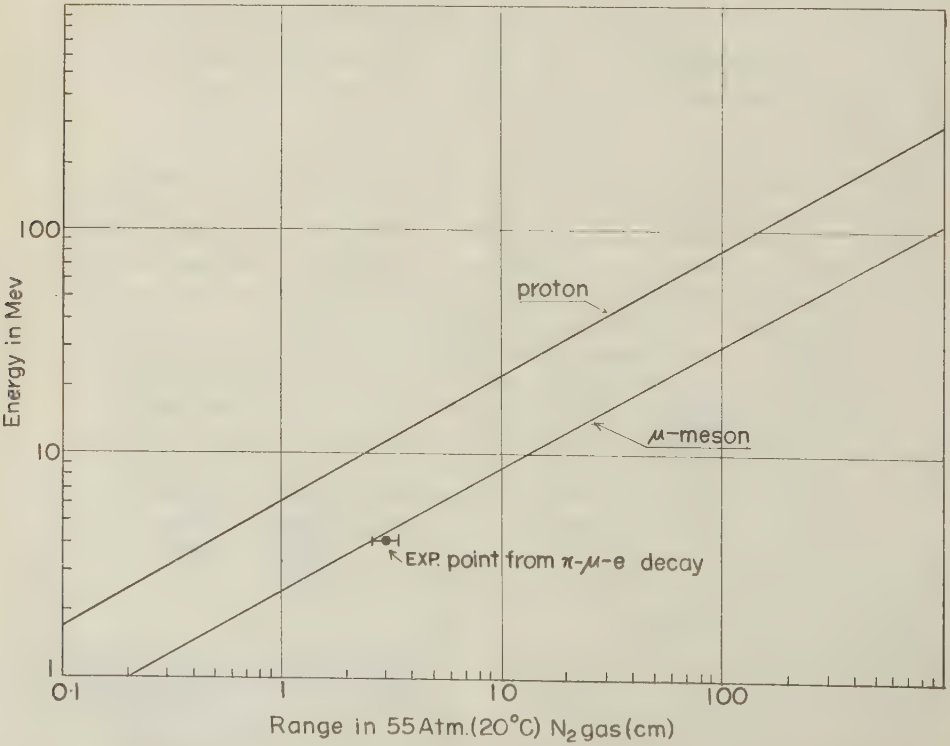

Fig. 1. Range-Energy relations for proton and μ meson in 55 atm (20°C) nitrogen gas.

path for the star producing component. The frequency of one prong stars which have long secondary tracks was corrected for the geometry of the instrument. All these corrections are also similar to those in the previous paper.

The purity of the nitrogen gas was 99.5% and the events by impurity nuclei such as alcohol vapor are negligible. The total sensitive time in this case is given by the product of the chamber sensitive time and the number of photographs taken. The chamber sensitive time is estimated from the width distribution of tracks using the diffusion constant of ions in nitrogen gas.

The observation covered by the total sensitive time may be considered to be equivalent to that of all cosmic ray nuclear events in the atmospheric air of about 690 liters at the mountain altitude during about 1.2 hours.

§ 3. Experimental Results

Throughout the experiment, 805 cloud chamber photographs were taken and 560 nuclear interactions in total were observed. The events which have at least one charged secondary particles and the particles have energies greater than 5 Mev were taken as the nuclear interactions. In Table I the results are listed according to the total number of charged particles observed in each interaction, whether they are primary or secondary. All tracks longer than 5 mm were counted, because of the unclear direction and of the insufficient detection efficiency for shorter ones. Under these conditions the protons with an energy less than 5 Mev and the alpha particles less than 20 Mev are likely to be missed, but the number of such prongs can be estimated from the energy distribution of secondaries, as described in later section. The effects due to radioactive contaminations can be excluded, because of the shorter track of only about 1 mm.

Fig. 2 shows some of the photographic records of the nuclear interactions occuring in the gas of the cloud chamber.

The integral rate of occurence of all nuclear interactions in the gas at 2840 m elevation and 25°N geomagnetic latitude, computed from the corrected data of Table I, was $1.78\cdot10^{-4}g^{-1}s^{-1}$.

1) *Size distribution*

The differential star size distribution corrected is shown in Fig. 3 where the rate of stars with m prongs observed per target nucleus is plotted semi-logarithmically against

Table I. Frequencies of events for each group, classified according to prong number and charged or neutral primaries. The corrected number for 1-prong stars are indicated in parenthesis.

Prong No.	1	2	3	4	5	6	7	8	total
Neutral primaries	332 (362)	126	42	17	8	1	1	1	528 (558)
Charged primaries	8	19	4	1	0	0	0	0	32
Total*	332 (362)	134	61	21	9	1	1	1	560 (590)

* In the third row, the total number of events in which the all charged particles are counted as secondaries regardless of characteristics of the prongs are indicated.

m. Statistical probable errors are indicated in the graph, as well as limits for the best straight line fit from which were found constant of a distribution of the form

$$M(m)=M_0\exp(-\alpha m) \qquad (1)$$

where α is 0.85 ± 0.12. Since the target nuclei are of single element, the distribution should be explained by the energy spectrum of the primaries and the character of the nuclear disintegration.

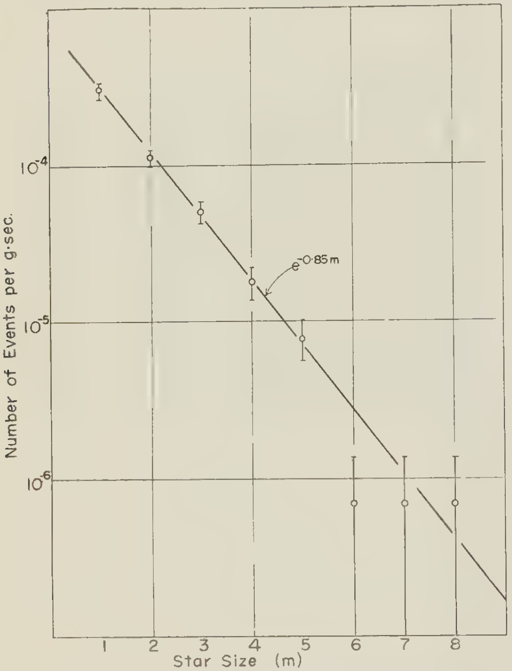

Fig. 3. Differential star size distribution: number of events per g. sec. plotted against star size.

The real size distribution can be computed as follows: The probability of the observation that n prong stars were observed as m prong stars is

$$P(n,m)=\frac{n!}{m!(n-m)!}p^m(1-p)^{n-m} \qquad (2)$$

where p is the probability that the length of each prong is longer than 2 mm. (As above mentioned, single tracks shorter than 5 mm were not counted, but the tracks longer than 2 mm in the multi-prong stars could be clearly distinguished.) If the real size distribution is expressed by the form of

$$N(n)=N_0\exp(-\lambda n) \qquad (3)$$

where λ is a constant. The observed size distribution, $M(m)$, is related to the real size distribution, $N(n)$, by the following equation:

$$M(m)=\sum_n P(n,m)N(n) \qquad (4)$$

From Eq. (1), (2) and (3), one can show easily following relations:

$$\lambda=\ln(pe^{\alpha}+(1-p)) \qquad (5)$$

$$N_0=(M_0\alpha/\lambda)(1-(1-p)e^{-\lambda}) \qquad (6)$$

where p is found to be about 0.9 by the estimation of number of undetected particles from energy distribution assuming that the distribution is expressed in the form of $(E-V)/T^2\exp-(E-V)/T$ even in the low energy region. From Eq. (5) one can show approximately $\lambda=\alpha p$. Then, the real size distribution is

$$N(n)=N_0\exp(-0.76\,n)\,. \qquad (7)$$

The similar star size distribution for light nuclei has been obtained from the data of photographic emulsion excluding the contribution of stars of heavy nuclei. In this case, α is about 0.6 at mountain altitude and about 0.4 at balloon height. These data are plotted in Fig. 10.

In the case of emulsion, in which 1 and 2 prong stars are not recorded, the frequency of the stars with 3 and 4 prongs are somewhat lower than those expected from the exponential relation Eq. (1), which was derived from the star frequencies of prong number larger than 4. This is probably due to the insufficient scanning efficiency for small size stars. The determination of the constant α in Eq. (1) is not so accurate for light nuclei in emulsion, but it does not contradict the present data.

There are small periodic increase of frequencies, in the present data, at 1, 3 and 5 prongs as compared with those at 2, 4 and 6 (the mean value of the increase is about 15%). This may be explained by the stability of the residual nuclei, namely, the nuclei with even atomic number are more stable than those with odd atomic number. But the quantitative explanation based on the shell model of light nucleus is difficult.

2) *Angular distribution*

The zenith angles of the trajectories of the charged particles involved in each nuclear interaction occuring in the gas were measured as follows. The cloud chamber photographs were projected onto a screen as the images have real size at the center of the cloud chamber and we get the angles from stereoscopic analysis of two photographs.

Fig. 4 shows the zenith angle distributions in which the distributions of tracks having ionization less than about twice minimum (lightly ionizing particles), medium ionization and those greater than about several times of the minimum (heavily ionizing particles) have been plotted separately. Since the direction of motion of the more lightly ionizing particles, some of which may be initiating particles, could not be determined, they were regarded, for the purpose of above measurement, as emanating from the points of origin of the nuclear interactions.

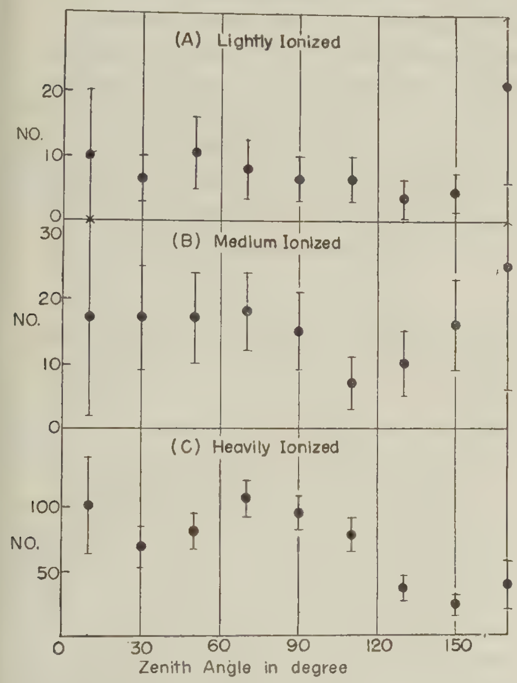

Fig. 4. Zenith angle distributions (A) Lightly ionized particles (B) Medium ionized particles (C) Heavily ionized particles

The heavily ionizing particles show a preference for the downward (zenith angles less than 90°) over the upward hemisphere and the lightly ionizing particles show more sharp downward pattern.

For the events with only one charged particle of range longer than 5 mm, whose both ends can be observed in the gas, the angular distribution is shown in Fig. 5 apart the other events. Since the most of their ends cannot be distinguished whether they were starting points or terminating ones, the zenith angles are obtained by assuming that the all tracks have downward direction (less than 90°).

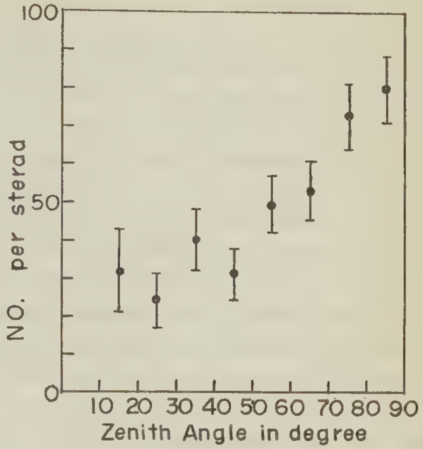

Fig. 5. Zenith angle distribution for one prong stars.

In the each angular distribution of the 1 and 2 prong stars, a maximum can be seen at about 80°−90°. It may be explained as follows. The perpendicular direction to the chamber axis favors the incident particles due to the minimum thickness of surrounding material of the chamber which they have to pass. And the secondary particles are inclined to be emitted in somewhat large angle to the incident particles by the Pauli's exclusion principle in Fermi's gas model of nucleus. Because the spirit of the model, representing all nucleons are free, clearly requires that the momentum of the two collision partners after the collision lie in an unoccupied region of the momentum space and so evidently a small momentum transfer to the struck nucleon is forbidden unless the nucleon initially lies very near the edge of the sphere in momentum space of radius P_F (Fermi momentum). This tendency is also in azimuthal angle distribution, namely, the secondaries are dominant in forward and backward direction of the chamber.

For the stars with more than 3 prongs, the angular distribution of black tracks show a preference for the downward over the upward hemisphere. It may be explained as follows. As the mean energy of the incident particles is thought to be greater than that of 1 and 2 prong stars, the directions which the direct knock-on secondaries are emitted are advantageous to the direction of incident particles. Slow particles may also posess such tendency by the Doppler effect of the bomberded and moving target nucleus.

In Fig. 5, some of the particles which show upward direction may be incident charged primaries. In the observed energy region, the intensity of the incident proton is so small and the obtained data are also so insufficient that the intensity of the proton cannot be discussed. Even in the energy range of emulsion stars (200 Mev to 1000 Mev), the intensity is only one fourth of neutrons.

3) *Energy distribution of secondary particles*

From the emulsion work, among the secondary charged particles there are protons, alpha particles and a group of deuterons and tritons with the proportions of 4, 2 and 1 respectively[4]. In this experiment the tracks were not distinguished whether they were protons or other particles, but the contribution of α particles to the total number of secondaries is not expected to be so large. Because most of the recorded tracks are longer than 5 mm and the lowest energy is about 20 Mev for α particles.

Assuming that the secondary charged particles are protons only, the energy distribution of the secondaries is obtained from the range of the tracks. The distribution is shown in Fig. 6 for the each group of prong number normalizing as area enclosed by the curve is equal to each other. It seems that the energy distributions have similar character.

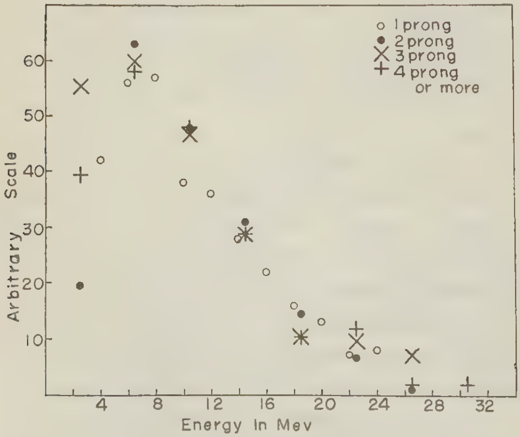

Fig. 6. Energy distribution for the each group of prong number normalizing as total number is equal.

Fig. 7 shows the approximate expression of the energy distribution in the form of $(E-V)/T^2 \exp(-(E-V)/T)$ where V is a Coulomb potential barrier of the nitrogen nucleus and T is a mean temperature of compound nucleus. This is well known expression as the spectrum of protons evaporated from the compound nucleus of the heavy element. The fundamental idea of the above expression may not be applied to the light nuclei as nitrogen, but it shows good approximation for the energy spectrum of secondaries of the stars of the light element. The mean temperature obtained from the gradient of the

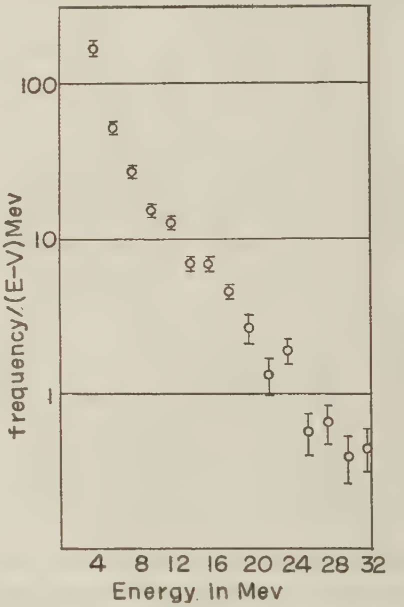

Fig. 7. Energy distribution expressed in the form of $(E\text{-}V)/T^2 \exp(-(E\text{-}V)/T.)$

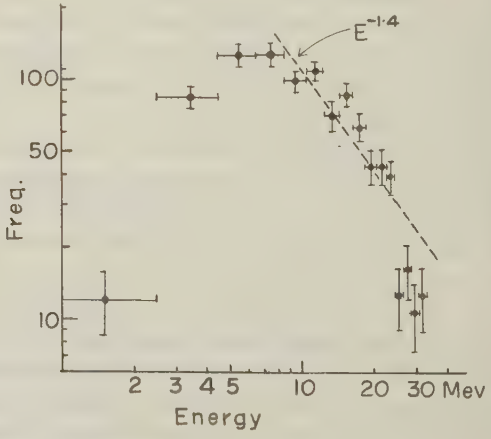

Fig. 8. Corrected differential energy spectrum of charged secondaries.

curve in Fig. 7 in the energy region from 5 to 10 Mev is about 2.7 Mev and is in accord with that obtained from the energy distribution of cosmic ray neutrons of such energy region[1)].

Fig. 8 shows the differential energy spectrum of the charged secondaries in logarithmic scale. The straight lines drawn through the points indicate that it is reasonable to represent the data over limited energy regions by the formula $F(E)=\text{const.}\,E^{-m}$ where m is 1.4 in this experiment. This is qualitative agreement with the results of emulsion work in which the distribution of the secondary protons are expressed as $k/(E+50)^2$ in the energy range from 50 to 1000 Mev.

4) *Energy distribution of primary particles*

The energy distribution of the primary particles, which initiating the nuclear interactions in the nitrogen gas, were obtained as follows. To estimate the absolute intensity of the star producing component, it is assumed that the cross section for nuclear interaction is geometric. The energy of the primary particle is obtained by the assumption that multiplicity and the energy distribution of the neutral secondaries are equal to those of the charged secondaries and each secondary particle is emitted independently. Finally, the energies for the thin, gray and black tracks which went out of the chamber are thought to be able to estimate from the energy spectrum of secondaries.

According to the above assumptions, the frequency of the stars which have n secondaries, including the neutral particles, is expressed approximately as follows:

$$K(n+1)\exp(-\alpha n)\Big(=\sum_{n_p+n_n=n} k\exp(-\alpha n_p)\exp(-\alpha n_n)\Big) \qquad (8)$$

In this expression, the factor $(n+1)$ is derived from the fact that the probability, that a event with n_p secondary protons and n_n secondary neutrons occures, is thought to be independent upon n_p and n_n. However, the probability has maximum value at $n_p=n_n$, because the residual nucleus is most stable at $n_p=n_n$, and the difference of the probabilities of occurence of $n-p$ and $n-n$ or $p-p$ interactions supports also such tendency in the process of the nuclear cascade. So, from the practical point of view the factor $(n+1)$ in Eq. (8) is thought to be too large. The energy spectrum of incident particles which produce the stars with n secondaries is thought to be equal to the visible energy spectrum dissipated for charged secondaries in each star which has equal number of prongs. The total energy dissipated for charged secondaries in each star is a sum of the following energies; the observed energies of black tracks which stopped in the chamber, the estimated energies of 70 and 350 Mev for gray-black and thin tracks, respectively, which went out of the chamber, and $n-1$ times the binding energy of nucleons in target nucleus. The variety of the estimated value does not give large change of the curve because it moves the curve to the direction of E^{-1} in the graph (45°).

In Fig. 9, the curves show the energy spectra of primaries for 1 prong stars, 2 prong stars, 3 prong stars and stars of more than 4 prongs and total sum of their intensities in the scale of $1/2\pi$ of total flux as they show the vertical intensities if their angular distributions are isotropic. Then the ratio of intensity to the estimated vertical flux which is described in the previous paper shows the angular distribution. If the ratio is m, the angular distribution of N-component at the

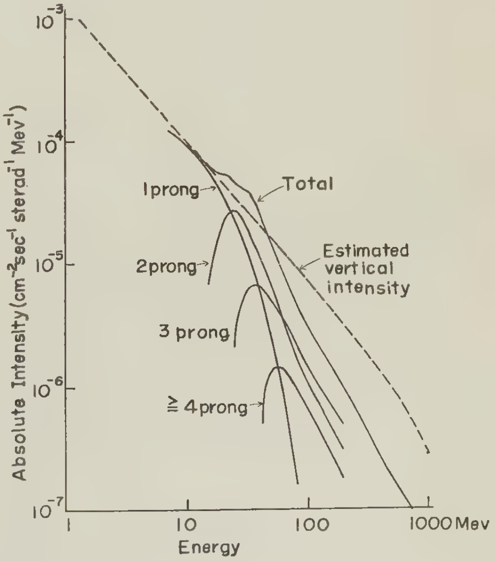

Fig. 9. Energy spectra of primary for 1 prong stars, 2 prong stars, 3 prong stars, stars of more than 4 prongs and total sum of their intensities in the scale of $1/2\pi$ of total flux. The dotted line indicates the energy spectrum of of cosmic ray neutrons given in reference 1).

energy region is thought to be $\cos^{m+1}\theta$. It is concluded from the figure that the angular distribution is isotropic at energy region lower than about 10 Mev and it changes to $\cos^5\theta$ according as the energy increases to 1 Gev.

There is no experiments to give the energy spectrum and absolute intensity of N-component in cosmic ray of these energy range. Then the present data were compared with another data of both side (higher and lower) of the energy range, and they agreed with each other within the limits of their errors, but at high energy region the accuracy of the present data is not good.

§ 4. Discussion and Conclusion

In this experiment, the tracks which displaced from the chamber wall to the illuminated region by the sweeping electric field are thought to be one of the stars occuring in the chamber wall. But such tracks have been probably counted as 1 prong stars. The ratio of such the tracks to the total 1 prong stars is estimated as below as 5%. In the case of 2 prong stars, the tracks which scattered by the nitrogen nucleus may be counted as 2 prong stars. The estimated number of such the events is below about 5% of 2 prong stars. These corrections have not so influence on the size distribution.

Brown[5)] finds for ion-cloud chamber stars, the size distribution varying uniformly down to the smallest stars, and also finds for stars of $n \geq 2$ a variation with atomic weight less rapid than $A^{2/3}$. The data differ from the present ones only in the part of smaller prongs than 3. The difference will be due to the bias of the selection in ion-cloud chamber. And the present result, though lightly ionizing particles are included in Table I, is also qualitatively in agreement with the conclusion from sandwich emulsion work[3)] that has analyzed nuclear interactions (stars) generated in the oxygen and smaller nuclei of the emulsion which have less than 6 heavily ionizing prongs.

In the observed events, various processes were mixing, namely, meson-producing collision and their secondary collision in the nucleus, a knock-on process or nuclear cascade in which particles of moderate energy are ejected, and a final process in which any particles, associated with these interaction, whose energies have degraded until they cannot escape from the nucleus, contribute to the excitation of the whole nucleus and its evaporation of low energy particles.

Insight into the operation of all above three types of interaction may be expected from investigation of how various characteristics of nuclear disintegrations depend on the primary energies.

Since we are dealing in the cosmic radiation with a particles whose De Broglie wave length is less than that of the nuclei involved, a semi-classical approach to the theoretical consideration of the origin of these fast protons can be expected to be fairly satisfactory.

In this approach, a high energy nucleon is considered as a particle which interact independently with a single nucleon in the nucleus having the same cross section as a free nucleon-nucleon interaction. Each particle from such a collision can in turn collide with other nucleon or escape from the nucleus. Then any nucleon has insufficient energy to escape, it is considered as contributing to the excitation of the whole nucleus and the subsequent evaporation.

Goldberger[6)] has calculated by the Monte Carlo method, effect of the exclusion principle for the nucleon-nucleon collision resulting when 90 Mev neutrons are incident on such a Fermi gas of nucleons and finds a reduction of the effective cross section in the ratio of 1 to $1-7E_f/5E_i$, where E_f is the Fermi energy and E_i is the energy of the incident neutron. A similar calculation was carried out at 400 Mev by Bernardini et al[7)]. The mean free path in the nuclear matter is a function of energy only, and is a constant of $4 \cdot 10^{-13}$ cm in the present energy region[8)].

About the nuclear cascade, in the energy region that is sufficient for growth of nuclear cascade and has not enough probability to produce the mesons, the number of secondary particles will be expressed as Furry function at first approximation.

If we take the mean free path of $4 \cdot 10^{-13}$ cm[8)] in nuclear matter, and treat as one dimentional problem in the average thickness of nucleus. It is sufficient in this discussion to assume that the nucleus is sphere, and average path length in nucleus is not much differ from average thickness of nucleus. The thickness is $0 \cdot 4 \cdot A^{1/3}$ in units of mean free path and the probability, $W(n)$, which a star has n secondary particles, is calculated as:

$$W(n)=k\exp(n\cdot\ln(1-e^{-0.4A^{1/3}})) \qquad (9)$$

Eq. (1) is compared with this expression and α is obtained as follows:

$$-\alpha=\ln(1-\exp(-0.4A^{1/3})) \qquad (10)$$

The data for size distribution obtained by sandwich emulsion technique at balloon height and other emulsion data are shown in Fig. 10 and the curve by Eq. (10) is also shown and best fit curve for the data of moutain altitude is calculated from the deformed Furry function considering the absorption of secondary particles in the nucleus. This result is as follows:

$$-\alpha=\ln(1-\exp(-aA^{1/3}))-\ln b \qquad (11)$$

where a is $0.4b$ and b is chosen as 1.2 to match the curve to experimental points of mountain altitude.

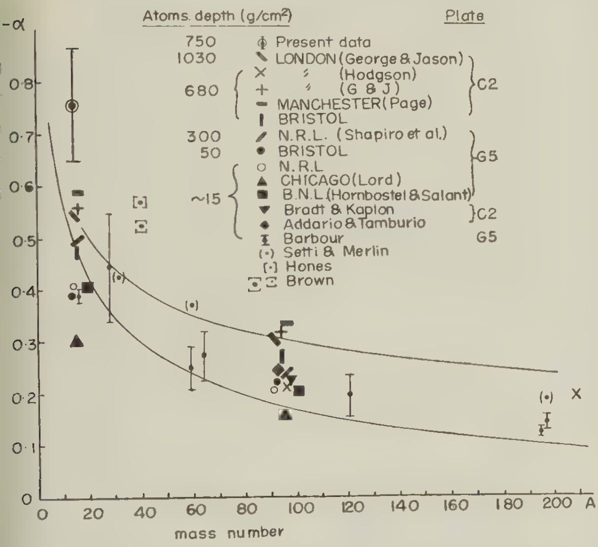

Fig. 10. Exponent, α, of size distribution is plotted as a function of mass number. The curves indicate the calculated value from Eq. (8) and (9). The experimental points except the present data are reproduced from reference 3).

In general, the effect of the difference in the incident energy spectrum at balloon and mountain altitude is clearly reflected in the graph. In other chamber experiment, in which the light nuclei are bomberded by 90 Mev neutrons, α was 1.2[9].

It is not strange that the calculated curve shows good approximation for the experimental points, because, since the gray-black track group includes protons of energies than 25 Mev it can contain relatively few evaporation particles. For light nuclei, however, the separation is not clear cut. The present data also show that the black track group has salient anisotropy of angular distribution and this fact indicate that the origin of the considerable parts of the group are not in an evaporation process but a knock-on process. Even in the evaporation prongs, their number will be proportional to excitation energy which is thought to be proportional to the frequency of inelastic collisions in the target nucleus. Then, it can be said that the size distribution is related mainly to a knock-on process.

Above explanation would in any case be dubious for nuclei as well as $A=14$, since no allowance is made for the alpha particle model or nucleon pair structure of the light elements or for the depletion of the nucleus during the cascade, which represents a significant change in the case of small nuclei. And the explanation is only qulitative one for the general stars which treated in Fig. 10.

In this experiment, the total interaction cross section is assumed to be geometric and it contradicts to the mean free path of $4\cdot10^{-13}$ cm in nuclear matter. This discrepancy means that there are many cases (about 30% of total) in which the incident particles pass through the nucleus with no interaction. It is also caused to crude approximation of the independent particle model which does not cover all interactions. Other model of interaction should be considered for low energy excitation of target nucleus, but detailed discussion is not reasonable from such crude conclusion in this paper which give us out-line of the interaction character.

The authors express their sincere thanks to Prof. Y. Watase for his continuous interest. This study has been supported in part by a Grant in Aid for Fundamental Scientific Research from the Ministry of Education and from Cosmic Ray Observatory of Tokyo University.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 8, AUGUST, 1957

On the Range Spectrum of μ-Mesons at Sea-Level at Geomagnetic Latitude 24°N

By Shūji FUKUI,
Department of Physics, Osaka University, Osaka
Takashi KITAMURA and Yōjirō MURATA
Institute of Polytechnics, Osaka City University, Osaka

(Received March 4, 1957)

Differential intensities of μ-mesons at sea-level at 24°N have been measured for the residual range equivalent to from 44 to 430 g/cm^2 of the air using a delayed coincidence method. It was found that the obtained range spectrum was nearly flat for present ranges and was 20 per cent lower than Rossi's curve which should be valid at geomagnetic latitude greater than 45°. The effect of the lateral displacement as well as the angular deflection of particles in the absorber was taken into account for the scattering correction. Mesons locally produced in the absorber was found to be at most a few per cent of all mesons that stop and decay in the apparatus. This fact suggests that the discrepancy between μ-meson spectra by the absorption method and by the magnetic cloud chamber method can not be accounted for only by the local π-meson production.

§1. Introduction

We have reported the differential momentum spectrum of μ-mesons at sea-level at geomagnetic latitude 24°N obtained by means of a magnetic cloud chamber in the preceding paper[1)] (hereafter referred to as *I*). The momentum spectrum of μ-mesons described in *I* showed some contradiction with what derived from the production spectrum theoretically obtained by Olbert[2)] in the low momentum part, and it appeared to disagree with the frequency of stopped μ-mesons in the emulsion at sea-level measured by Kaneko *et al*[3)]. It has been pointed out[4)] that, in general, all absorption methods give results somewhat higher than those obtained by magnetic cloud chamber methods. As a possible interpretation for this discrepancy, we have suggested in *I* the local π-meson production by the N-component in the thick absorber used in t absorption method.

In the present experiment, the intensities μ-mesons at sea-level have been measure over ranges 44 to 430 g/cm^2 air equivalent b the delayed coincidence method which is th most usable for identifying low energy mesons. At the same time, the contributio of locally produced π-mesons to μ-meso intensity has been examined with the hodoscope tray arranged under the absorber.

§2. Apparatus

The experimental arrangement is schematically shown in Fig. 1. GM counter trays and be define the incident beam. Each consist of 8 counters of 4 cm diameter and has th effective area of 33×44 cm^2. The distanc between them is 100 cm. The effective soli angle area of the counter telescope is estimated to be 193 sr cm^2 for the $\cos^2\theta$ zenith angle dependence of the flux.

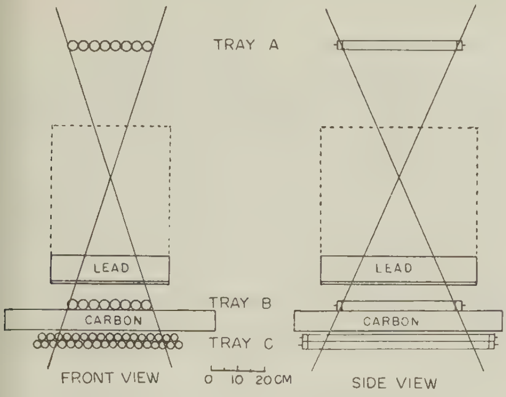

Fig. 1. Experimental arrangement.

A lead absorber between counter trays A and B, which determined the range of the incident particle, was placed on a 1 cm iron plate and its thickness was varied from 5 to 60 cm. If, as has usually been the case, the absorber covers little more than solid angle defined by telescope tray, the effect of scattering out predominates over that of scattering in. Then, in order to reduce a difference between both effects, it is desirable to use a sufficiently wide absorber.

The absorber S, in which slow μ-mesons come to rest and succeedingly decay into electrons, is the graphite slab of 8 cm (13.4 g/cm^2) in thickness.

The block diagram of the circuits employed in this experiment is shown in Fig. 2.

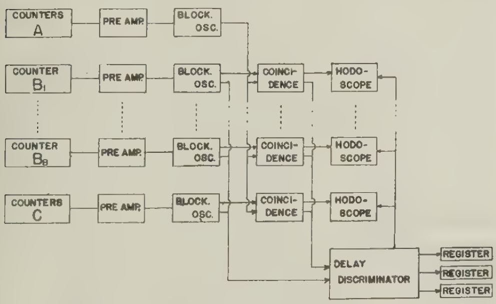

Fig. 2. Block diagram of the circuit.

Counters in tray A are joined at an input of the pre-amplifier stage and then connected to a blocking oscillator. Pulses from each of counters in tray B, through the individual pre-amplifier, trigger each corresponding blocking oscillator. Each of counters in tray B is individually in coincidence with tay A through a diode-coincidence circuit which has a resolving time of 0.6μs. Counters in tray C are connected to one blocking oscillator similarly to tray A.

Delayed coincidences $AB+(B \text{ or } C)_d$, i.e., events in which a coincidence AB was followed by a pulse from counters in tray B or C with a delay of 1.9 to 9.2 μs were recorded by a 3-channel delay discriminator. Each channel of the delay eiscriminator corresponds to delay of 1.9 to 4.4 μs, 4.4 to 6.7 μs and 6.7 μs and 6.7 to 9.2 μs, respectively.

If the blocking oscillator for tray C is triggered by a prompt pulse, tray C is insensitive for the detection of a decay electron because of the dead time of the blocking oscillator. Thus, μ-mesons which came to rest in the carbon absorber S after passing through trays A and B were detected, if their decay electrons traversed any one of counters in tray B or C during the selected time interval.

Each counter in tray B and counters in tray C were hodoscoped. The neon tube of the hodoscope panel was lighted by a prompt coincidence pulse between the corresponding counter and counters in tray A, whenever a delayed coincidence occurred. The probability that a neon tube of the hodoscope is lighted by chance is extremely small, i.e., $\sim 10^{-4}$ per delayed coincidence.

Rates of coincidence AB were recorded simultaneously to normalize rates of stopped μ-mesons.

This experiment was performed under a thin wooden roof (1 g/cm^2 of air equivalent).

§ 3. Experimental Results

a) *Delayed coincidence rate*

The measurements were performed with six different thicknesses of the lead absorber, i.e., 5, 10, 15, 30, 40 and 60 cm. Delayed coincidences accompanied by AC prompt coincidences, $ABC+(B)_d$, are considered almost to be accidental delayed coincidences due to random pairs of the threefold coincidence ABC and the single pulse from counters in tray B. These events are excluded in calculating the μ-meson intensity. Background rates unaccompanied by AC were obtained from measurements without the carbon absorber S for each thickness of the lead absorber. The background may be attributed to the following causes, i) the decay of mesons which stop in materials between trays *B* and *C*, ii) delayed discharges of counters of tray *C* and iii) accidental delayed coincidences unaccompanied by coincidence *AC* due to the inefficiency of tray *C*.

Measured rates of stopped mesons are listed in Table I. These values were obtained by subtracting background counts from rates of delayed coincidences with the absorber *S*.

Table I. Measured rates of stopped mesons. These values were obtained by subtracting rates of background from rates of delayed coincidence with the carbon absorber *S*.

Absorber thickness	Number of hours	Rate per hour
5 cm Pb	63.9	4.13±0.31
10	64.1	4.75±0.32
15	54.4	4.47±0.34
30	75.3	5.18±0.34
40	67.4	5.18±0.32
60	64.8	4.02±0.29

b) *Decay life time of mesons*

All observed rates were subdivided into three channels of delay discriminator. Results are shown in Fig. 3. The mean life time of μ-mesons was obtained to be 2.22±0.20 μs from our measurements. This is in fair agreement with values of the mean life time of μ-mesons in carbon obtained by other workers[5].

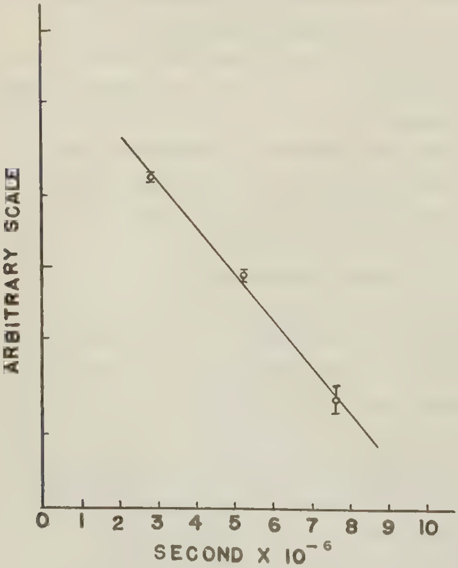

Fig. 3. Differential time distribution of delayed coincidence counts. The straight line corresponds to a mean life time of 2.22 μs. Errors are standard statistical ones.

§ 4. Corrections

It is necessary to consider various corrections that must be performed on the results.

a) *The extension of the range*

A slow meson is in a zig-zag motion through matter because of the multiple Coulomb scattering. Consequently, its actual path length *R* becomes longer than the thickness *T* of the absorber. The relation between *R* and *T* is given by the following expression, according to Koenig[6],

$$R(p_0/mc)-T(p_0/mc)=\int_0^{p_0/mc}\frac{\theta_m'}{2}\frac{dR}{d(p/mc)}d(p/mc)\,, \qquad (1$$

where the r.m.s. angle of scattering θ_m is a function of momentum p of the meson and p_0 is its initial momentum. We obtained values of *R* for thicknesses of the absorber employed in this experiment from this expression. The first and the second colums of Table II show thicknesses of the absorber and corresponding ranges *R* in air equivalent for the meson stopped in the corbon absorber, respectively.

b) *Barometer effect*

The intensity of μ-mesons at sea-level is affected by the variation of the atmospheric pressure through changes of the absorption and the decay probability of μ-mesons in the atmosphere. Therefore, counting rates of delayed coincidence must be corrected for this effect. Assuming a simple barometric regression, we figured out the barometer effect for each momentum of μ-mesons corresponding to the absorber thickness on a basis of the calculation of Trefall[7]. Values of atmospheric pressure during the experiment were offered from the Osaka Meteorological Observatory. Correction factors for the barometer effect are given in the third column of Table II.

c) *The effect of scattering in absorber on the measurement of the flux of mesons*

In such an arrangement that an absorber is placed between the counters of a telescope, the effective solid angle is in general distorted in a complicated way by the effect of Coulomb scattering in the absober, because some of mesons originally in the solid angle of the arrangement are scattered out, while some originally out of the solid angle are scattered in. This effect is remarkable for slow mesons. The absorption method always concerns with mesons which are near the ends of their ranges. Therefore, the correction for the effect of the multiple Coulomb scattering is significant, but is difficult to evaluate accurately. So far, in almost all experiments of the range spectrum, no careful consideration was paied for the effect of scattering of particles. Recently, Brini *et al.*[8] suggested the method to calculate this scattering effect by the Monte Carlo method. However, the effect of lateral displacement of particles was not taken into account in their method. The effect of the lateral displacement becomes important especially in the case of a thick absorber and a smaller area of an absorber than that of a counter tray. Eyges[9] gives the distribution function of the angular and lateral displacement due to the multiple Coulomb scattering including the energy loss of particles through the material. The effect of Coulomb scattering was computed using the distribution function of Eyges (cf. Appendix). In the course of computation we assumed the value of 70 MeV/c as the momentum of meson emerging from the lead absorber. The fourth column of Table II indicates the decreasing rates, C, of the effective solid angle due to the scattering effect, i.e., the ratio of the number of mesons coming off counter tray A which fall into counter tray B, by considering the scattering, to the number of the same mesons (from tray A) falling into tray B without considering the scattering. If, neglecting the term of the lateral displacement, our method to compute the scattering correction is directly applied to the arrangement of Brini *et al.*, our result is in agreement with their value for the scattering correction.

Table II. Some quantities pertinent to corrections for the barometer effect and the multiple Coulomb scattering effect. R is the range obtained from eq. (1) for mesons which come to rest in the carbon absorber. B is the correction percentage for the barometer effect evaluated on the basis of the calculation of Trefall. C is the decreasing rate of the effective solid angle due to the scattering effect.

Absorber thickness	R (in air eq.)	B	C
5 cm Pb+1 cm Fe	44 g cm^{-2}	$+0.48\times10^{-2}$	0.948
10 cm Pb+1 cm Fe	80 〃	+4.21 〃	0.912
15 cm Pb+1 cm Fe	112 〃	+2.90 〃	0.890
30 cm Pb+1 cm Fe	220 〃	+0.19 〃	0.833
40 cm Pb+1 cm Fe	295 〃	+1.74 〃	0.792
60 cm Pb+1 cm Fe	430 〃	+4.48 〃	0.710

Table III. The corrected rates of stopped mesons and the corresponding absolute differential intensities normalized to the value of $4.45\times10^{-6}\,\mathrm{g^{-1}\,s^{-1}\,sr^{-1}}$ at the range of 166 g/cm² air-equivalent.

Range (g cm^{-2} air eq.)	Corrected rate per hour	Absolute differential intensity ($\mathrm{g^{-1}\,s^{-1}\,sr^{-1}}\times10^{-6}$)
44	4.38±0.33	3.41±0.35
80	5.42±0.30	4.23±0.35
112	5.17±0.33	4.03±0.37
220	6.23±0.31	4.85±0.45
295	6.66±0.35	5.16±0.41
430	5.91±0.36	4.60±0.41

Rates of stopped mesons corrected for effects described above are shown in the second column of Table III.

§ 5. Normalization

In order to determine the absolute intensity of μ-mesons from the obtained rates of delayed coincidence, it is necessary to estimate the detection efficiency of counter trays for the decay electron. However, the accuracy of this estimation is very questionable mainly on account of the uncertainty concerning the range distribution of the decay electrons. Thus, the AB rates were used to normalize the stopped meson rates. The AB rates were concurrently recorded with the delayed coincidence rates at various thicknesses of the lead absorber. In the fifth column of Table IV are listed the AB coincidence rates corrected for accidental coincidences and for the barometer effect.

Table IV. Rates of two-fold coincidence AB.

Absorber thickness* (cm Pb)	Duration (minute)	Uncorrected number	Correction factor for barometer effect (%)	Rate** per minute
5	2120	195208	+1.37	92.93±0.22
10	1406	124419	+1.43	89.36±0.26
15	6510	556021	+0.10	85.08±0.10
30	3221	260024	+1.00	79.51±0.16
40	1892	143609	+1.01	76.26±0.21
60	1726	119726	+0.56	69.35±0.21

* Lead absorbers were put on an iron plate of 1 cm thickness.

** These rates were corrected for rates of accidental coincidence, too.

For the absorber thinner than 10 cm lead, a part of electron and nucleon components may contribute to the incident flux. On the other hand, the accuracy of the correction for the scattering decreases with increasing thickness of the absorber. From these reasons, the difference between the AB rates at the 15 cm and the 30 cm lead absorbers was used to determine the absolute differential intensity at the average range between them. After making the correction for the scattering, the AB rates are reduced to values of $(7.35\pm0.20)\times10^{-3}\,\text{cm}^{-2}\,s^{-1}\,sr^{-1}$ and $(6.87\pm0.25)\times10^{-3}\,\text{cm}^{-2}\,s^{-1}\,sr^{-1}$ for the integral vertical intensities of mesons penetrating the 15 cm and the 30 cm lead absorbers, respectively. The above value for the 15 cm lead is in agreement with other worker's values; namely, $(7.2\pm0.1)\times10^{-3}\,\text{cm}^{-2}\,s^{-1}\,sr^{-1}$ at 25°N by Kitamura and Minakawa[10], and $(7.3\pm0.1)\times10^{-3}\,\text{cm}^{-2}\,s^{-1}\,sr^{-1}$*) at 19°N (for 10 cm lead) by Gokhale and Balasubrahmanyan[11].

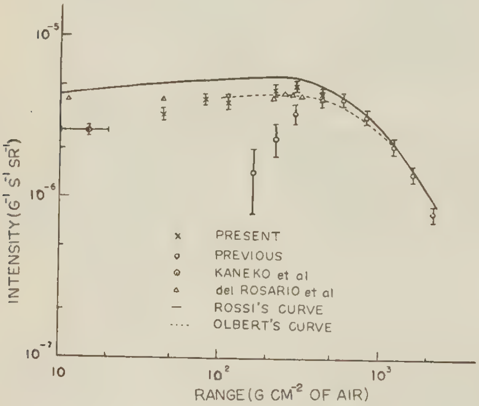

Fig. 4. Differential range spectra of μ-mesons at sea-level.

Obtained rates of delayed coincidence indicate that the differential vertical intensity of low energy μ-mesons is a slowly varying function of the range. Then, we obtained the absolute differential vertical intensity as follows,

$$\frac{I_v(15\text{ cm lead})-I_v(30\text{ cm lead})}{\text{Range between 30 and 15 cm lead}}=(4.45\pm0.12)\times10^{-3}\,\text{cm}^{-2}\,s^{-1}\,sr^{-1}$$

for mesons with range of 22.5 cm lead (=166 g/cm² air equivalent), where the symbol $I_v(T\,\text{cm lead})$ indicates the absolute vertical intensity of mesons penetrating a T cm lead absorber. Making use of this value as the normalization point, the absolute value of differential vertical intensities of μ-mesons at various ranges are given in the third column of Table III. The resultant differential range spectrum of μ-mesons is shown in Fig. 4.

§ 6. Local π-meson Production

The N-component (protons and π-mesons) which exists among cosmic rays at sea-level may undergo nuclear interactions in the lead absorber, giving rise to secondary π-mesons which stop in the carbon absorber and subsequently decay into electrons through π-μ-e process. Because of the very short mean life time of π-mesons, such π-mesons locally produced, ion addition to μ-mesons from the atmosphere, are capable of causing delayed coincidences. Thus, these events are recorded as those due to μ-mesons with the range corresponding to the thickness of the lead absorber. The π-meson production are frequently accompanied by other ionizing particles. Therefore, events of this kind cause simultaneous discharge in two or more counters in tray B. But electromagnetic interactions (electronic cascade showers and eletron productions by knock on processes) by μ-mesons can not be phenomenologically distinguished from penetrating showers only by the hodoscope picture in the present experiment. The rate of the former should be computed by an analytical consideration. In what follows we shall discuss about the contribution of π-mesons locally produced to the number of μ-mesons stopped in the carbon absorber.

---

* This value was reduced to sea-level by them from the value of $(7.55\pm0.10)\times10^{-3}\,\text{cm}^{-2}\,s^{-1}\,sr^{-1}$ at 124 m above sea-level.

The obtained data of hodoscope pictures are summarized in Tables V-a and V-b. Whole events were classified as "*Group I*" and "*Group II*" according to whether the event was accompanied by the prompt coincidence AC or not, respectively.

a) "*Group I*"

The majority of events which belong to this group are most likely due to accidental delayed coincidences caused by pairs of particles penetrating the whole absorber and other delayed particles. The mean energy of the penetrating particles is estimated to be about 2 GeV.

With a cloud chamber containing five 1.27 cm lead plates, Brown *et al.*12) observed an average number of 0.069 knock-on electrons (per meson) emerging from heavy materials and found that the distribution of the projected angle α between the trajectory of the incident meson and that of the knock-on electron emerging from the lead is represented by $\cos^n\alpha$, most likely, with $n=2.5$.

In the present experiment, we obtained a value of 0.044±0.005 for a ratio of the number of the ($B=2$) events, in which any two of counters in tray B were struck simultaneously, to the total number of events. If the angular distribution of knock-on electrons obtained by Brown *et al.* is applied to the geometry of our experimental arrangement, it is expected that 55 per cent of knock-on electrons emerging from the lead absorber strike another counter in tray B than that traversed by the primary meson. If one assumes that the ($B=2$) events are due to productions of knock-on electrons, the average number of secondary electron is estimated to be 0.080±0.009 per meson from this experiment. In the cloud chamber experiment of Brown *et al.*, 0.02 "back scattered" electrons (per meson) emerging from the surface through which the mesons enter the lead plate were observed. Making allowance for the existence of "back scattered" electrons from the absorber S in our case, the above value for the average number of secondary electrons is in fair agreement with the result of Brown *et al.*

Moreover, a ratio of the number of ($B=2s$) events to that of ($B=2a$) events was 0.27±0.07, as is seen in Table V-a. The ($B=2s$) indicates an event in which two counters in tray B separated by more than one counters were struck and the ($B=2a$) an event in which any two adjacent counters in tray B were struck. This value should be compared with a value of 0.32 which is figured out for a ($B=2s$)-to-($B=2a$) ratio by applying the angular distribution of secondary electrons obtained by Brown *et al.* to the geometry of our experimental ar-

Table V–a. Number of events accompanied by prompt coincidences AC, versus number of counters struck in tray B.

Type of coincidence	Absorber S	Number of counters struck in tray B			
		$B=1$	$B=2$		$B=3$
			$B=2a$*	$B=2s$**	
$AB+(B)_a$***	absent	297	11	2	1
$ABC+(B)_a$	absent	712	26	8	3
$ABC+(B)_a$	present	737	27	7	9
total:		1746	64	17	13
			81		

* Events in which any two adjacent counters in tray B were struck.

** Events in which two counters in tray B separated by more than one counters were struck.

*** This measurement was carried out without tray C.

rangement.

From the above discussions, it is concluded that almost all ($B=2$) events in "*Group I*" can be attributed to secondary electron production by knock-on processes in the lead absorber.

The ($B \geq 3$) events, in which three or more counters in tray B were simultaneously discharged, are probably accounted for in terms of double knock-ons, soft and hard showers.

b) "*Group II*"

The probability for a μ-meson of kinetic energy E to produce a secondary electron of energy between E' and $E'+dE'$ by a knock-on process is given by the follwing expression[13]:

$$\phi(E, E')dE' = \frac{2Cm_ec^2}{\beta^2}\frac{dE'}{E'^2}\left[1-\beta^2\frac{E'}{E'_m} + \frac{1}{2}\left(\frac{E'}{E+mc^2}\right)^2\right], \qquad (2)$$

where E'_m is the maximum transferable energy to a secondary electron and C is a constant which depends on the material. Let $g(E)$ represent the differential energy spectrum o μ-mesons. For the average number $n(E_c')$, o the knock-on electrons with energies large than E_c' produced by a cosmic ray μ-meso with energy larger than $\mathcal{E}$, one obtains

$$n(E_c') = \int_{\varepsilon}^{\infty}\int_{E_c'}^{E_m'} \phi(E, E')g(E)\, dE'dE \Big/ \int_{\varepsilon}^{\infty} g(E)dE\, . \quad (3$$

If $E_c' \ll E_m'$ for μ-mesons with kineti energies more than 76 MeV, which is th minimum energy required for μ-meson t penetrate the carbon of 13.4 g/cm² thickness eq. (3) may be written approximately a follows:

$$n(E_c') \simeq 2Cm_ec^2/E_c'\, . \qquad (4$$

Since C is 0.06 for lead, substituting th value of 0.08 obtained in "*Group I*" fo $n(E_c')$, one gets a value of 0.8 MeV for E_c' fo from eq. (4). This estimate suggests that th knock-on electron detected in our apparatu must have at least the kinetic energy o 0.8 MeV.

Table V–b. Number of events unaccompanied by prompt coincidences AC, versus number of counters struck in tray B.

Type of coincidence	Absorber S	Number of counters struck in tray B			
		$B=1$	$B=2$		$B=3$
			$B=2a$*	$B=2s$**	
$AB+(B \text{ or } C)_d$	present	2060	63	1	3

* Events in which any two adjacent counters in tray B were struck.

** Events in which two counters in tray B separated by more than one counters were struck.

*** This measurement was carried out without tray C.

In "*Group II*", the fraction of the ($B=2$) events was 0.030±0.004 of the total events. The probability for a μ-meson which comes to rest in S to produce a knock-on electron of energy larger than 0.8 MeV is considerably small. Moreover, only one ($B=2s$) event was observed among 64 ($B=2$) events of "*Group II*". From these evidences, it is suggested that ($B=2$) events in this group are attributed rather to large angle deflections which slow mesons undergo in passing through the lead absorber, than to production of knock-on electrons. For instance, in the case of 15 cm lead absorber, the r.m.s. angle of deflection of μ-mesons which come to rest at the center of S is estimated to be 29° and hence the probability that the mesons traverse obliquely two adjacent counters in tray B is 0.031.

c) *Local π-meson production*

12 ($B \geq 3$) events were obtained during th run with S (cf. Tables V-a and V-b). It i expected that ($B \geq 3$) events include doubl knock-ons, soft showers and hard shower (local and extensive), but our apparatus is n able to distinguish between them. Even if on assumes that all of ($B \geq 3$) events were du to local hard showers originating in the lea absorber, the number of those which coul trigger the apparatus was at most only 0. per cent of the number of stopped mesons.

In order to find the fraction of mesons tha are produced locally, it is necessary to es timate the relative efficiency for our apparatu to detect them. Because counters struck b shower particles become inactive for a decay electron, the detection efficiency for a stopped meson in the local shower is less than that for a single stopped meson. If N counters in tray B are struck by shower particles, the efficiency is approximately $\frac{1}{2}\{1+(8-N)/7\}$ for "*without AC*" and $\frac{1}{2}(8-N)/7$ for "*with AC*", respectively.

Moreover, owing to the nuclear copture for the negative π-mesons by carbon nuclei, the detection efficiency for π-mesons is about one half of that for μ-mesons.

Thus, from the obtained distribution on N (the number of discharging counters in tray B) we estimated the detection efficiency for π-mesons locally produced to be on the average about 1/6 of that for μ-mesons from the atmosphere. After this correction, it was found that mesons locally produced were at most 3.5 per cent of mesons stopped in the carbon absorber. Although, in ($B=2$) events, there may partly exist events due to local showers, their fraction is expected to be appreciably small from the previous discussion. Then, the fraction of mesons locally produced is consistent with one expected in I from Olbert's production spectrum.

§7. Discussion

As shown in Fig. 4, the present differential range spectrum is nearly flat in the interval of ranges from 44 to 430 g/cm^2 of air equivalent, and can consistently be extended to the data of Kaneko *et al*. Our data are about 20 per cent lower than Rossi's curve based on many experimental results measured at geomagnetic latitude greater than 45°. Some of recent measurements on intensities of low energy μ-mesons at high geomagnetic latitude have given values slightly higher than Rossi's curve, so that it can not be concluded that the variation of intensities of low energy mesons due to the geomagnetic effect between 24°N and 50°N is equal to 20 per cent.

Open circles in Fig. 4 show the range spectrum converted from the momentum spectrum (measured by a magnetic cloud chamber) described in I by making use of the theoretical momentum-range relation. (Hereafter, we shall call this range spectrum *the converted spectrum*.) It is seen in the figure that the present spectrum is consistently connected with *the converted spectrum* for ranges greater than 430 g/cm^2 of air equivalent, but there is a noticeable discrepancy for ranges lower than 430 g/cm^2. However, the present range spectrum is in good agreement with the range spectrum of μ-mesons at sea-level derived from Olbert's production spectrum at 24°. The low range part of Olbert's production spectrum has been based on results of altitude and latitude dependence of slow μ-meson intensity measured by the delayed coincidence and anticoincidence methods of detection.

Recent results[4)8)15)] by delayed coincidence method have indicated that the range spectrum of low energy μ-mesons is nearly flat, and have not been inconsistent with ones derived from Olbert's production spectra for each corresponding latitude.

Very recently, Nagoya University group has obtained a momentum spectrum of cosmic rays penetrating 15 cm lead at Mt. Norikura (2840 m altitude, 25°N geomagnetic latitude) by means of a magnetic cloud chamber. The resulting spectrum falls below that derived from Olbert's production spectrum at momenta lower than 1·5 GeV/c and decreasing momentum, while the latter still increases.

When we calculate the momentum spectrum at sea-level from that at Mt. Norikura under the consideration of the momentum loss due to ionization and the spontaneous decay of μ-mesons in traversing the atmosphere between the two places, we obtain a spectrum which agrees with our previous momentum spectrum.

These results provide evidence that there exists a consistency between the sea-level and altitude spectra obtained by the same kind of the method of detection.

The possible explanation for higher values in the differential range method is that π-mesons locally produced contribute to the number of μ-mesons from the atmosphere. Besides, since the effect of scattering becomes large for increasing thickness of a lead absorber, an insufficient correction for this effect tends to result in a flat spectrum. But these effects were found, as already discussed, to be too small to remove the discrepancy mentioned above, even though, in the present experiment, our paticular attention was given on these subjects.

The other approach to remove the discrepancy between the "present" and "previous" spectra is a modification of the range-momentum relation of μ-mesons. If, under the assumption that the range and momentum spectra are correct respectively, one calculates the momentum loss of μ-mesons in air as a function of momentum from both spectra, the momentum loss of μ-mesons should be a few times as large as the theoretical curve cited in Rossi's book[17)] at low momentum region. This conclusion yields an improbable result that the mass of μ-mesons should be considerably heavier than that is accepted at present. On the other hand, various theoretical range-energy relation have been exprerimentally confirmed within an error of a few per cent[18)].

We have, at present, no other explanation to remove the discrepancy between the "range" and "momentum" spectra of μ-mesons at low momentum region.

This research was conducted under the direction of Prof. Y. Watase, without whose constant guidance and encouragement this project would be impossible. The writers express their thanks to Prof. W. L. Kraushaar of the Massachusetts Institute of Technology, with whom authers have enjoyed the discussion and the collaboration during his stay in this laboratory as a Fullbrighter, for the design and the construction of electronic circuits. Thanks are also due to Prof. M. Oda and Prof. Y. Yamaguchi, who have made many helpful criticisms and suggestions. This study was supported in part by a Grant in Aid for Fundamental Scientific Research (Institutional Research) from the Ministry of Education.

Appendix

Let us consider one of projections of the motion of a particle on two vertical planes parallel with each side of the rectangular counter-tray (cf. Fig. 5), and let a, b and d be the length of one side of tray, the distance between two trays and the distance between the lower surface of the absorber and tray B. Consider that a particle enters toward a point P at an angle ω with the vertical direction and emerges from the absorber at a point T, suffering the multiple scattering. Let $F(t, y, \theta)d\theta dy$ represent the scattering probability for the particle to travel at an angle in $d\theta$ at θ with the original direction and to undergo a latera displacement in dy at y after traversal of th absorber of a thickness t. Taking into accoun energy loss of the particle in the substance Eyges[9)] gives the following expression for th scattering probability,

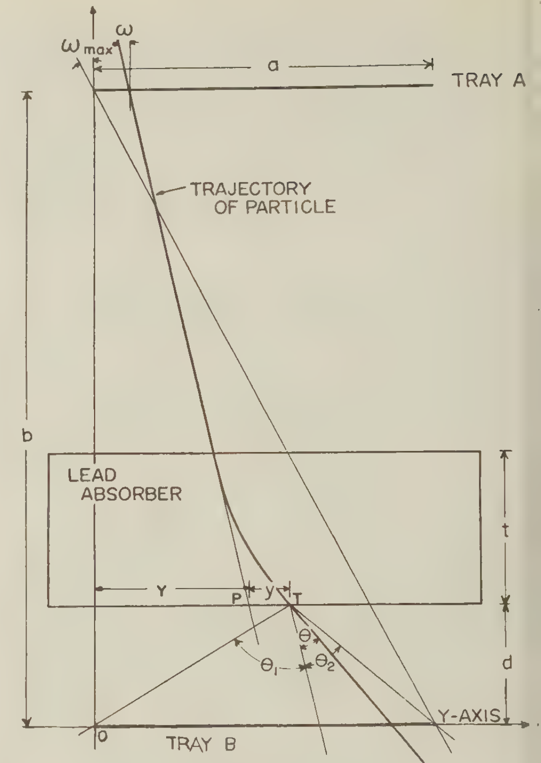

Fig. 5. Illustrating the computation of the scattering effect of the meson flux in the absorber.

$$F(t, y, \theta)=\frac{1}{2\pi[B(t)]^{1/2}}$$
$$\times\exp\left[-\frac{\theta^2 A_2-2y\theta A_1+y^2 A_0}{4B(t)}\right], \quad \text{(A-1}$$

where

$$\left.\begin{aligned} &A_0=\int_0^t\frac{d\eta}{w^2(\eta)}, \qquad A_1=\int_0^t\frac{(t-\eta)d\eta}{w^2(\eta)}, \\ &A_2=\int_0^t\frac{(t-\eta)^2 d\eta}{w^2(\eta)}, \quad B(t)=A_0A_2-A_1^2, \\ &w(\eta)=\frac{2p\beta}{E_s} \quad \text{and} \quad E_s=21\,\text{MeV}. \end{aligned}\right\} \quad \text{(A-2}$$

We got the values of A_0, A_1 and A_2 by th numerical integration using the range-momen tum relation of μ-mesons. Henceforce, w assume $\cos\omega\simeq 1$ to simplify the calculatio For our geometry, an error introduced b this assumption is negligible.

In Fig. 5, let us take the Y-axis of a sys tem of coordinates, whose origin O is at an edge of the tray B, in the horizontal direction. We shall denote by $\phi(Y, \omega)$ the probability that a particle toward the point $P(0, Y)$ passes through tray B after traversing the absorber. The expression for $\phi(Y, \omega)$ is given by

$$\phi(Y, \omega)=\int_{-\infty}^{\infty} dy \int_{\theta_1}^{\theta_2} F(t, y, \theta)\, d\theta\,, \qquad \text{(A-3)}$$

where

$$\theta_1=\tan^{-1}\frac{-(Y+y)}{d}-\omega$$

and

$$\theta_2=\tan^{-1}\frac{a-(Y+y)}{d}-\omega\,.$$

Put

$$D\equiv\sqrt{2A_2} \quad\text{and}\quad q(\theta, y)\equiv\sqrt{\frac{A_2}{2B}}\left(\theta-\frac{A_1}{A_2}y\right).$$

Eq. (A-3) becomes

$$\phi(Y, \omega)=\frac{1}{\sqrt{2\pi}D}\int_{-\infty}^{\infty}\int_{q_1}^{q_2} e^{-(y^2/2D^2+q^2/2)}\, dydq\,. \qquad \text{(A-4)}$$

where

$$q_1=q(\theta_1, y) \quad\text{and}\quad q_2=q(\theta_2, y)\,.$$

In eq. (A-4), the integral concerning q can be easily obtained from the table of the error function. After the numerical integration over y in eq. (A-4), we can obtain the value of $\phi(Y, \omega)$.

Let Φ be the relative number of particles which can pass through both trays A and B, to particles which are originally in the aperture defined by trays A and B. The expression for Φ is

$$\Phi=\int_0^{\pi/2}\int_{Y_0}^{Y_0+a}\phi(Y, \omega)\, dY d\omega \Big/ \int_0^{\omega_{\max}}(Y_1-Y_0)\, d\omega \qquad \text{(A-5)}$$

where $Y_0=(b-d)\tan\omega$ and $Y_1=b-d\tan\omega$.

The integral concerning Y must be limited within the region occupied by the absorber. Total triggering efficiency for the two fold coincidence AB is given by the product of two Φ's for each projection.

Radial Distribution Function of Fluids II

By Kazuo HIROIKE

Department of Physics, Tokyo Institute of Technology

(Received April 6, 1957)

It is shown that the radial distribution function of fluid can be derived from the expression for the free energy in the form of a "functional derivative" with respect to the pair interaction potential. Three examples are treated on the line of the theory: (1) the simple chain approximation of classical fluid, (2) the second quantization and (3) the lowest state of the spinless bosons derived by Bogolyubov and Zubarev. A procedure, which differs from the usual one, is given in the derivation of the expressions by which the pressure and the internal energy are expressed in terms of the radial distribution function.

§1. Introduction

In a previous paper[1)] the consistency of several approximate radial distribution functions of fluid was examined in the sense that the pressure and the internal energy derived from them should satisfy the relation

$$\frac{\partial}{\partial T}(p/T)=\frac{\partial}{\partial V}(E/T^2)\,,$$

where T, p, V and E denote the temperature, the pressure, the volume and the internal energy of fluid respectively. It was found that the original form of Green's linear theory is the only one among them that satisfies the above relation. Although this theory was further improved without breaking the above relation, it was still a poor approximation from the quantitative point of view.

This situation shows that it is difficult to calculate the thermodynamical quantities without inconsistency when use is made of any approximate distribution function, because the Helmholtz free energy cannot be derived in a consistent way from the expressions of p and E unless they satisfy the relation above mentioned. In the present paper, attempts on the line considered in the previous paper are abandoned and, on the contrary, it is attempted to derive a relation which should hold between the free energy and the radial distribution function and which can be used to derive the approximate distribution function from an approximate expression for the free energy.

The Hamiltonian of a system composed of N molecules is assumed to be expressed in the form:

$$H=K+\frac{1}{2}\sum_{i\neq j}^{N}\phi_{ij} \qquad (1)$$

where K stands for the kinetic energy and $\phi_{ij}\equiv\phi(\boldsymbol{r}_i-\boldsymbol{r}_j)$ is the potential energy of interaction between two molecules at the positions $\boldsymbol{r}_i$ and $\boldsymbol{r}_j$ respectively, which is assumed to be the function of the distance $r_{ij}\equiv|\boldsymbol{r}_i-\boldsymbol{r}_j|$ alone. The average of any quantity X, which is expressed as an operator in quantum mechanics, over a canonical ensemble will be denoted by

$$\langle X\rangle=\mathrm{T}_r Xe^{-H/\kappa T}/Z\,, \qquad (2)$$

where

$$Z=\mathrm{T}_r\, e^{-H/\kappa T} \qquad (3)$$

and κ is the Boltzmann constant and $\mathrm{T}_r\ X$ means the trace of an operator X. In classical statistical mechanics, the trace should be replaced by the integration over the phase space. The Helmholtz free energy A of the system is given by

$$A=-\kappa T\log Z\,. \qquad (4)$$

The radial distribution function $g(r)$ and the structure factor $S(k)$ are defined respectively by

$$g(|\boldsymbol{r}-\boldsymbol{r}'|)=\left(\frac{V}{N}\right)^2\left\langle\sum_{i\neq j}^{N}\delta(\boldsymbol{r}-\boldsymbol{r}_i)\delta(\boldsymbol{r}'-\boldsymbol{r}_j)\right\rangle \qquad (5)$$

and

$$S(k)=1+\frac{N}{V}\int_V[g(r)-1]e^{i\boldsymbol{k}\boldsymbol{r}}\,d\boldsymbol{r} \qquad (6)$$

or, conversely,

$$g(r)=1+\frac{1}{(2\pi)^3}\frac{V}{N}\int[S(k)-1]e^{-i\boldsymbol{k}\boldsymbol{r}}\,d\boldsymbol{k}, \qquad (6')$$

where $\delta(\boldsymbol{r})$ is Dirac's δ-function and r and k are the absolute values of the vectors $\boldsymbol{r}$ and $\boldsymbol{k}$ respectively. The fact that $g(r)$ or $S(k)$ depends on the absolute value r or k alone is due to the circumstance that the interaction energy between two molecules is assumed to be dependent only on their distance. The functions $g(r)$ and $S(k)$ have the properties

$$\lim_{r\to\infty} g(r)=1 \quad \text{and} \quad \lim_{k\to\infty} S(k)=1\ .$$

§ 2. The Relation between the Free Energy and the Radial Distribution Function

The variation of the free energy, corresponding to a variation $\varDelta\phi$ of the interaction potential, will be denoted by $\varDelta A$. $\varDelta A$ can be written as follows:

$$\varDelta A=F[\varDelta\phi(\boldsymbol{r}')]+O(\varDelta\phi)^2\ . \tag{7}$$

The first term on the right-hand side of this equation is a functional of the function $\varDelta\phi$ and is linear with respect to $\varDelta\phi$. Actually this functional has the form

$$F[f(\boldsymbol{r}')]=\left\langle \frac{1}{2}\sum_{i\neq j}^{N} f(r_{ij}) \right\rangle \tag{8}$$

and Eq. (7) becomes, when explicitly written,

$$\varDelta A=\left\langle \frac{1}{2}\sum_{i\neq j}^{N} \varDelta\phi_{ij} \right\rangle+O(\varDelta\phi)^2\ . \tag{7'}$$

Whenever a functional of the form given by Eq. (8) appears it will be related with a variation of the free energy A.

The quantity $\left\langle \frac{1}{2}\sum_{i\neq j}^{N} e^{i\boldsymbol{k}(\boldsymbol{r}_i-\boldsymbol{r}_j)} \right\rangle$ can be transformed with the helf of Eq. (5) as

$$\left\langle \frac{1}{2}\sum_{i\neq j}^{N} e^{i\boldsymbol{k}(\boldsymbol{r}_i-\boldsymbol{r}_j)} \right\rangle$$

$$=\frac{1}{2}\iint_{VV} e^{i\boldsymbol{k}(\boldsymbol{r}-\boldsymbol{r}')} \left\langle \sum_{i\neq j}^{N} \delta(\boldsymbol{r}-\boldsymbol{r}_i)\delta(\boldsymbol{r}'-\boldsymbol{r}_j) \right\rangle d\boldsymbol{r}d\boldsymbol{r}'$$

$$=\frac{1}{2}\left(\frac{N}{V}\right)^2\iint_{VV} g(|\boldsymbol{r}-\boldsymbol{r}'|)e^{i\boldsymbol{k}(\boldsymbol{r}-\boldsymbol{r}')}d\boldsymbol{r}d\boldsymbol{r}'$$

$$=\frac{N}{2}\left\{\frac{N}{V}\int_V [g(r)-1]e^{i\boldsymbol{k}\boldsymbol{r}}\, d\boldsymbol{r}+\frac{N}{V}\int_V e^{i\boldsymbol{k}\boldsymbol{r}} d\boldsymbol{r}\right\}\ .$$

Hence from Eq. (6):

$$\left\langle \frac{1}{2}\sum_{i\neq j}^{N} e^{i\boldsymbol{k}(\boldsymbol{r}_i-\boldsymbol{r}_j)} \right\rangle$$

$$=\frac{N}{2}\left[S(k)-1+(2\pi)^3\frac{N}{V}\delta(\boldsymbol{k})\right]. \tag{9}$$

On the other hand $\left\langle \frac{1}{2}\sum_{i\neq j}^{N} e^{i\boldsymbol{k}(\boldsymbol{r}_i-\boldsymbol{r}_j)} \right\rangle$ can also be written be written by Eq. (8) in an alternative form:

$$\left\langle \frac{1}{2}\sum_{i\neq j}^{N} e^{i\boldsymbol{k}(\boldsymbol{r}_i-\boldsymbol{r}_j)} \right\rangle=F[e^{i\boldsymbol{k}\boldsymbol{r}'}]\ .$$

Comparison of this equation with Eq. (9) leads to

$$S(k)=1-(2\pi)^3\frac{N}{V}\delta(\boldsymbol{k})+\frac{2}{N}F[e^{i\boldsymbol{k}\boldsymbol{r}'}]\ .$$

When this expression is inserted in Eq. (6′) and the linear property of F is noticed, the expression for $g(r)$ is obtained as

$$g(r)=\frac{2V}{N^2}F[\delta(\boldsymbol{r}-\boldsymbol{r}')]\ ,$$

where the functional F operates on the variable $\boldsymbol{r}'$. This relation can be obtained directly from Eq. (5).

It is seen from these equations together with Eqs. (7) and (8) that the functions $g(r)$ and $S(k)$ can be related to the variation of the free energy A. Thus the expressions for $g(r)$ and $S(k)$ can be written symbolically as

$$g(r)=\frac{2V}{N^2}\left(\frac{\delta A}{\delta\phi}\right)_r, \tag{10}$$

$$S(k)=1-(2\pi)^3\frac{N}{V}\delta(\boldsymbol{k})+\frac{2}{N}\left(\frac{\delta A}{\delta\phi}\right)_k, \tag{11}$$

where

$$\left.\begin{aligned} \left(\frac{\delta A}{\delta\phi}\right)_r &\equiv F[\delta(\boldsymbol{r}-\boldsymbol{r}')] \\ \text{and}\qquad & \\ \left(\frac{\delta A}{\delta\phi}\right)_k &\equiv F[e^{i\boldsymbol{k}\boldsymbol{r}'}]\ . \end{aligned}\right\} \tag{12}$$

The functional $\left(\frac{\delta A}{\delta\phi}\right)_r$ or $\left(\frac{\delta A}{\delta\phi}\right)_k$ is similar to but somewhat different from the usual functional derivative. However, the terminology "functional derivative" will be used hereafter because of the lack of a suitable one. This terminology will be further generalized to quantities other than the free energy. The functional derivative of a quantity B, which is a functional of ϕ, will be defined in a similar way as above. Namely, when ϕ is varied by $\varDelta\phi$, the corresponding first order variation, with respect to $\varDelta\phi$, of B is denoted be $G[\varDelta\phi(\boldsymbol{r}')]$, which is a linear functional of $\varDelta\phi$. Then

$$\left.\begin{aligned} \left(\frac{\delta B}{\delta\phi}\right)_r &\equiv G[\delta(\boldsymbol{r}-\boldsymbol{r}')] \\ \text{or}\qquad & \\ \left(\frac{\delta B}{\delta\phi}\right)_k &\equiv G[e^{i\boldsymbol{k}\boldsymbol{r}'}]\ . \end{aligned}\right\} \tag{13}$$

If B depends also on another functional C of ϕ, it is seen from the above definition that the following relation is valid:

$$\left.\begin{array}{l}\left(\dfrac{\delta B}{\delta\phi}\right)_r=\left(\dfrac{\delta B}{\delta\phi}\right)_{r,\,C=\text{const.}}+\dfrac{\partial B}{\partial C}\left(\dfrac{\delta C}{\delta\phi}\right)_r\\ \text{or}\\ \left(\dfrac{\delta B}{\delta\phi}\right)_k=\left(\dfrac{\delta B}{\delta\phi}\right)_{k,\,C=\text{const.}}+\dfrac{\partial B}{\partial C}\left(\dfrac{\delta C}{\delta\phi}\right)_k,\end{array}\right\}\qquad(14)$$

Equation (10) is the relation which is to hold between the free energy and the radial distribution function, and it has been the object of this section to derive the relation. The function $g(r)$ measures the correlation between the positions of two molecules. Such a correlation arises from the presence of the interaction potential ϕ apart from the symmetry effect of the wave functions. Therefore it will be plausible to express $g(r)$ in the form of a functional derivative of the free energy with respect to ϕ. The relation under consideration is still valid in the case where $\phi(r)$ has no spherical symmetry and where many-body forces exist. In such cases the distribution function must be considered not only as a function of r but also of the direction of the vector $\boldsymbol{r}$.

There also exist similar formulas as Eqs. (10) and (11) when a grand canonical ensemble is considered. In this case the thermodynamic potential is pV and the following formulas can be derived:

$$g(r)=-\frac{2V}{N^2}\left(\frac{\delta(pV)}{\delta\phi}\right)_r\qquad(15)$$

and

$$S(k)=1-(2\pi)^3\frac{N}{V}\delta(k)-\frac{2}{N}\left(\frac{\delta(pV)}{\delta\phi}\right)_k,\qquad(16)$$

where N is to be interpreted as the average number of molecules over a grand canonical ensemble.

§ 3. Examples

The relations derived in the preceding section can be used to obtain the approximate distribution function if an approximate expression for the free energy is known, while these relations are valid between the exact free energy and the exact distribution function. Several examples will be shown in the following.

1. *Simple chain approximation to the free energy*

In a classical statistical mechanics the free energy A of fluid can be expressed as follows[2)]:

$$\frac{A}{N\kappa T}=\log\left(\frac{h^2}{2\pi m\kappa T}\right)^{3/2}\frac{\rho}{e}-\sum_{n=1}\frac{1}{n+1}\beta_n\rho^n,\qquad(17)$$

where ρ is the number density N/V and β_n's are the irreducible integrals. The irreducible integrals β_n's are composed of terms of various types, among which there are terms expressed symbolically as . When only such terms are used in place of β_n in the right-hand side of Eq. (17), an approximate expression A_0 for the free energy is obtained. (See Appendix I). This approximation will be named the simple chain approximation to the free energy. It gives the free energy the following expression:

$$\begin{aligned}\frac{A_0}{N\kappa T}&=\log\left(\frac{h^2}{2\pi m\kappa T}\right)^{3/2}\frac{\rho}{e}\\&\quad-\frac{\rho}{2}\left[(2\pi)^{3/2}\beta(0)-\pi\int_{-\infty}^{\infty}u^2\beta^2(u)du\right]\\&\quad+\frac{1}{\rho}\frac{1}{8\pi^2}\int_{-\infty}^{\infty}u^2\log[1-(2\pi)^{3/2}\rho\beta(u)]du\\&\quad+\frac{1}{2\sqrt{2\pi}}\int_{-\infty}^{\infty}u^2\beta(u)du,\end{aligned}\qquad(18)$$

where

$$u\beta(u)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}r[e^{-\phi(r)/\kappa T}-1]\sin ur\,dr\qquad(19)$$

and $\phi(r)$ is assumed to be an even function.

The functional derivative of A_0 is given from Eq. (18), with the help of Eq. (14), by

$$\begin{aligned}\frac{1}{N\kappa T}\left(\frac{\delta A_0}{\delta\phi}\right)_r&=-\frac{\rho}{2}(2\pi)^{3/2}\left(\frac{\delta\beta(0)}{\delta\phi}\right)_r-\frac{(2\pi)^{5/2}}{2}\rho^2\\&\quad\times\int_{-\infty}^{\infty}\frac{u^2\beta^2(u)}{1-(2\pi)^{3/2}\rho\beta(u)}\left(\frac{\delta\beta(u)}{\delta\phi}\right)_r du\,.\end{aligned}\qquad(20)$$

In order to calculate $\left(\dfrac{\delta\beta(u)}{\delta\phi}\right)_r$ or $\left(\dfrac{\delta\beta(0)}{\delta\phi}\right)_r$, it is convenient to write the right-hand side of Eq. (19) as

$$u\beta(u)=\frac{1}{(2\pi)^{3/2}}\int[e^{-\phi(r')/\kappa T}-1]\frac{\sin ur'}{r'}d\boldsymbol{r}'\,.$$

Then from definition (13)

$$\begin{aligned}&u\left(\frac{\delta\beta(u)}{\delta\phi}\right)_r\\&=-\frac{1}{(2\pi)^{3/2}}\frac{1}{\kappa T}\int e^{-\phi(r')/\kappa T}\delta(\boldsymbol{r}-\boldsymbol{r}')\frac{\sin ur'}{r'}d\boldsymbol{r}'\end{aligned}$$

$$=-\frac{1}{(2\pi)^{3/2}}\frac{e^{-\phi(r)/\kappa T}}{\kappa T}\frac{\sin ur}{r}$$

and

$$\left(\frac{\delta\beta(0)}{\delta\phi}\right)_r=-\frac{1}{(2\pi)^{3/2}}\frac{e^{-\phi(r)/\kappa T}}{\kappa T}\,.$$

When these expressions for $\left(\frac{\delta\beta(u)}{\delta\phi}\right)_r$ and $\left(\frac{\delta\beta(0)}{\delta\phi}\right)_r$ are inserted in Eq. (20) and use is made of Eq. (10), the following expression for $g(\boldsymbol{r})$ is obtained:

$$g(\boldsymbol{r})=e^{-\phi(r)/\kappa T}\times\left[1+2\pi\rho\int_{-\infty}^{\infty}\frac{u^2\beta^2(u)}{1-(2\pi)^{3/2}\rho\beta(u)}\frac{\sin ur}{ur}du\right]. \tag{21}$$

The above expression is identical to one which is obtained by putting $\varepsilon=1$ in Green's theory[3]. It is also identical to one[4,5] obtained by the procedure that only the terms expressed symbolically as  are taken in the exact expression for $g(r)$ which is a power series in ρ similar to Eq. (17). Such a procedure has been named the simple chain approximation by Rushbrooke[5], which will be called here the simple chain approximation to the distribution function in order to be distinguished from the approximation adopted in the derivation of Eq. (18). The fact that Eq. (21) is derived from Eq. (18) shows that both approximations are equivalent to each other. It can be shown that the netted-chain approximation, proposed by Rushbrooke and Scoins[6], to the distribution function is not the same as the netted-chain approximation to the free energy. This case will be treated in later occasion.

2. *The second quantization*

The Hamiltonian in the formalism of the second quantization $\boldsymbol{H}$, corresponding to Eq. (1), is written as

$$\boldsymbol{H}=\int\Psi^*(x)H(x)\Psi(x)dx+\frac{1}{2}\iint\Psi^*(x)\Psi^*(x')\phi(\boldsymbol{r}-\boldsymbol{r}')\Psi(x')\Psi(x)dxdx'\,, \tag{22}$$

where $H(x)$ is the kinetic energy which corresponds to K in Eq. (1), $\Psi(x)$ is a quantized wave function, $\Psi^*(x)$ the Hermitian adjoint of $\Psi(x)$ and $x\,(x')$ stands for both the configurational coordinates and the spin coordinates. The quantized wave functions satisfy the following commutation rules

$$\Psi(x')\Psi^*(x)-\varepsilon\Psi^*(x)\Psi(x')=\delta(x-x')\,,$$
$$\Psi(x')\Psi(x)-\varepsilon\Psi(x)\Psi(x')=0\,,$$
$$\Psi^*(x')\Psi^*(x)-\varepsilon\Psi^*(x)\Psi^*(x')=0\,,$$

where ε is taken to be either $+1$ or -1 according to the bosons or the fermions.

The grand partition function is

$$e^{pV/\kappa T}=\mathrm{T}_r\,e^{[\mu N-H]/\kappa T}\,, \tag{23}$$

where μ denotes the chemical potential. In the present subsection the average over the grand canonical ensemble will be denoted by $\langle\cdots\rangle$. Then, with the help of Eqs. (13), (22) and (23), $\left(\frac{\delta(pV)}{\delta\phi}\right)_r$ is calculated in the following manner:

$$\frac{1}{\kappa T}\left(\frac{\delta(pV)}{\delta\phi}\right)_r=-\frac{1}{2\kappa T}\left\langle\iint\Psi^*(x_1)\Psi^*(x_2)\delta(\boldsymbol{r}-\boldsymbol{r}_1+\boldsymbol{r}_2)\Psi(x_2)\Psi(x_1)dx_1dx_2\right\rangle$$

and hence from Eq. (15)

$$g(\boldsymbol{r})=\frac{V}{\langle N\rangle^2}\left\langle\iint\Psi^*(x_1)\Psi^*(x_2)\delta(\boldsymbol{r}-\boldsymbol{r}_1+\boldsymbol{r}_2)\Psi(x_2)\Psi(x_1)dx_1dx_2\right\rangle\,. \tag{24}$$

Equation (24) is the exact expression for $g(r)$ in the case that the Hamiltonian is given by Eq. (22). If the spinless bosons are considered, Eq. (24) is reduced to

$$g(\boldsymbol{r})=\frac{V}{\langle N\rangle^2}\left\langle\int\Psi^*(\boldsymbol{r}+\boldsymbol{r}')\Psi^*(\boldsymbol{r}')\Psi(\boldsymbol{r}')\Psi(\boldsymbol{r}+\boldsymbol{r}')\,d\boldsymbol{r}'\right\rangle\,, \tag{25}$$

which is usually known expression. Equation (25) can be transformed further into

$$g(r)=1+\frac{1}{\langle N\rangle^2}\sum_{\boldsymbol{k}_1}\sum_{\boldsymbol{k}_2\neq0}\langle N_{\boldsymbol{k}_1}N_{\boldsymbol{k}_2+\boldsymbol{k}_2}\rangle e^{i\boldsymbol{k}_2\boldsymbol{r}}+\frac{1}{\langle N\rangle^2}\sum_{\boldsymbol{k}_1}\sum_{\boldsymbol{k}_2\neq0}\sum_{\boldsymbol{k}_3\neq\boldsymbol{k}_1+\boldsymbol{k}_2}\langle a_{k_1}{}^*a_{k_3}{}^*a_{k_3-k_2}a_{k_1+k_2}\rangle e^{i\boldsymbol{k}_2\boldsymbol{r}}\,, \tag{25'}$$

where terms of the order of $\langle N\rangle^{-1}$ are omitted and N_k, a_k and $a_k{}^*$ are defined as follows:

$$\Psi(\boldsymbol{r})=\sum_k a_k\frac{1}{\sqrt{V}}e^{i\boldsymbol{kr}}\,,$$

$$\Psi^*(\boldsymbol{r})=\sum_k a_k{}^*\frac{1}{\sqrt{V}}e^{-i\boldsymbol{kr}}\,,$$

$$N_k=a_k{}^*a_k\,.$$

3. *The lowest state of the spinless bosons derived by Bogolyubov and Zubarev*

Bogolyubov and Zubarev[7] have derived approximate expressions for the energy E_0 and th wave function φ_0 for the lowest state of a system composed of spinless bosons, whic are

$$E_0=\frac{N^2}{2V}\nu(0)+\frac{1}{2}\sum_{k\neq0}\left(E(k)-\frac{\hbar^2k^2}{2m}-\frac{N}{V}\nu(k)\right), \qquad (26$$

$$\varphi_0=\exp\left\{-\frac{1}{4}\sum_{k\neq0}\left(\frac{1}{\lambda_k{}^2}-1\right)\rho_k\rho_{-k}\right\}, \qquad (27$$

where $\nu(k)$, $E(k)$ and ρ_k are defined by

$$\left.\begin{aligned}\nu(k)&=\int\phi(r)e^{-i\boldsymbol{kr}}d\boldsymbol{r}\,,\\ E(k)&=\sqrt{\frac{N}{V}\nu(k)\frac{\hbar^2k^2}{m}+\left(\frac{\hbar^2k^2}{2m}\right)^2}\,,\\ \lambda^2{}_k&=\frac{\hbar^2k^2}{2m}\Big/E(k)\,,\\ \rho_k&=\frac{1}{\sqrt{N}}\sum_{j=1}^{N}e^{-i\boldsymbol{kr}_j}\,,\end{aligned}\right\} \qquad (28$$

At temperature $T=0$, the free energy is the same with the energy and hence $g(r)$ an $S(k)$ in the lowest state are given from Eqs. (10) and (11) by

$$g(r)=\frac{2V}{N^2}\left(\frac{\delta E_0}{\delta\phi}\right)_r \qquad (29$$

and

$$S(k)=1-(2\pi)^3\frac{N}{V}\delta(\boldsymbol{k})+\frac{2}{N}\left(\frac{\delta E_0}{\delta\phi}\right)_k, \qquad (29'$$

of which the former expression is found in the paper of Bogolyubov and Zubarev*. Wit the help of

$$\left(\frac{\delta\nu(k')}{\delta\phi}\right)_k=\int e^{i\boldsymbol{kr}}e^{-i\boldsymbol{k'r'}}d\boldsymbol{r}=(2\pi)^3\delta(\boldsymbol{k}-\boldsymbol{k}')$$

and

$$\left(\frac{\delta E(k')}{\delta\phi}\right)_k=\frac{1}{2}\frac{N}{V}\frac{\hbar^2k'^2}{m}\frac{1}{E(k')}\left(\frac{\delta\nu(k')}{\delta\phi}\right)_k=\frac{(2\pi)^3}{2}\frac{N}{V}\frac{\hbar^2k^2}{m}\frac{1}{E(k)}\delta(\boldsymbol{k}-\boldsymbol{k}')\,,$$

Eq. (29′) is reduced to

$$S(k)=\frac{\hbar^2k^2}{2m}\Big/E(k)=\lambda_k{}^2 \qquad (30$$

and by Eq. (6′) $g(r)$ is obtained as

$$g(r)=1+\frac{V}{N}\frac{1}{(2\pi)^3}\int(\lambda_k{}^2-1)e^{-i\boldsymbol{kr}}d\boldsymbol{k}\,, \qquad (30'$$

---

* The starting point of the present investigation was an attempt to clarify the meaning of this expression

hich can be also obtained from the direct alculation of $(\delta E_0/\delta\phi)_r$.

As pointed out by Bogolyubov and Zubarev, q. (30) is identical to the relation derived by eynman[8] provided that $E(k)$ is interpreted o be a spectrum of excitation.

Comparison of the definition of ρ_k with Eq 9) leads to

$$S(k)=\langle\rho_k\rho_{-k}\rangle \quad \text{for} \quad k\neq 0\,. \tag{31}$$

Vhile Eq. (31) is valid for more general cases, ts right-hand side should be considered in ur case to be

$$\langle\rho_k\rho_{-k}\rangle=\frac{\int_V\cdots\int_V \rho_k\rho_{-k}\varphi_0{}^2 d\boldsymbol{r}_1\cdots d\boldsymbol{r}_N}{\int_V\cdots\int_V \varphi_0{}^2 d\boldsymbol{r}_1\cdots dd\boldsymbol{r}_N}\,. \tag{32}$$

f $\langle\rho_k\rho_{-k}\rangle$ is calculated by means of

$$\langle\rho_k\rho_{-k}\rangle=\frac{\int_{-\infty}^{\infty}\cdots\int(\sigma_k{}^2+\tau_k{}^2)\varphi_0{}^2\prod_{k'}d\sigma_{k'}d\tau_{k'}}{\int_{-\infty}^{\infty}\cdots\int\varphi_0{}^2\prod_{k'}d\sigma_{k'}d\tau_{k'}}\,,$$

where σ_k and τ_k are the real numbers defined y

$$\rho_k=\sigma_k+i\tau_k\,,\quad \sigma_{-k}=\sigma_k \text{ and } \tau_{-k}=-\tau_k\,,$$

a false result follows from Eq. (31), *i.e.*,

$$S(k)=\frac{\lambda_k{}^2}{1-\lambda_k{}^2}\,. \tag{33}$$

A calculation of Eq. (32) leading to Eq. (30) will be shown in Appendix II.

§4. The Expressions for the Pressure and the Internal Energy

In classical fluid the pressure p and the nternal energy E can be witten in terms of (r) by the following well-known expressions[9]:

$$\frac{p}{\rho\kappa T}=1-\frac{\rho}{6\kappa T}\int_0^\infty g(r)\frac{d\phi(r)}{dr}4\pi r^3 dr \tag{34}$$

nd

$$\frac{E}{(3/2)N\kappa T}=1+\frac{\rho}{3\kappa T}\int_0^\infty g(r)\phi(r)4\pi r^2 dr\,. \tag{35}$$

The above expressions are usually derived by making use of definition (5) of $g(r)$. Even if $g(r)$ is defined by Eq. (10), the same expressions ought to be derived as far as an exact theory is concerned, since then Eq. (10) is equivalent to Eq. (5). Therefore, as far as an exact theory is concerned, the following derivation is an alternative to the usual one of Eqs. (34) and (35). In addition to this, it has the advantage of being usable also in an approximate expression to the free energy. For the sake of completeness the quantum statistical mechanics will be considered.

The expression for the free energy will be assumed to have the following form:

$$\frac{A}{N\kappa T}=\log\frac{\lambda^3}{V}+a\left[\frac{\phi(Lx')}{\kappa T},\,\beta,\,\lambda^*\right], \tag{36}$$

where $V=L^3$, $\lambda^2=h^2/2\pi m\kappa T$, $\lambda^*=\lambda/L$ and Lx' is the position vector $\boldsymbol{r}'$ of a molecule and β is the parameter determined so as to minimize A under the condition of $T=$const. and $V=$const. and further functional a does not depend on T and V except for the form shown explicitly. With the help of Eqs. (10) and (14), $g(r)$ is written in terms of a as

$$\begin{aligned} g(r)&=\frac{2V\kappa T}{N}\left(\frac{\delta a}{\delta\phi}\right)_r+\frac{2V\kappa T}{N}\frac{\partial a}{\partial\beta}\left(\frac{\delta\beta}{\delta\phi}\right)_r \\ &=\frac{2V\kappa T}{N}\left(\frac{\delta a}{\delta\phi}\right)_r\,, \end{aligned} \tag{37}$$

where use has been made of the property of β to minimize A and $(\delta a/\delta\phi)_r$ should be interpreted as the functional derivative with respect to ϕ under the condition of $\beta=$const. It is more convenient for the present purpose to go back to the notation corresponding to $F[\delta(\boldsymbol{r}-\boldsymbol{r}')]$ in Eq. (12). Thus $g(r)$ is expressed as

$$g(r)=\frac{2V\kappa T}{N}f[\delta(\boldsymbol{r}-\boldsymbol{r}')]\,, \tag{37'}$$

where functional f is defined by the variation $\varDelta a$ in the similar way as F by $\varDelta A$ and it depends also on T, V, β and λ^*, though it is not shown explicitly. The essential point is that f is a linear functional with respect to the argument shown explicitly.

Now

$$\begin{aligned} \frac{p}{\rho\kappa T}&=-V\frac{\partial}{\partial V}\left(\frac{A}{N\kappa T}\right)=1-\frac{L}{3}\frac{\partial a}{\partial L} \\ &=1+\frac{\lambda^*}{3}\frac{\partial a}{\partial\lambda^*}-\frac{L}{3}\lim_{\varDelta L\to 0}\frac{a\left[\frac{1}{\kappa T}\left\{\phi(Lx')+x'\frac{\partial\phi}{\partial r'}\varDelta L\right\},\beta,\lambda^*\right]-a\left[\frac{\phi(Lx')}{\kappa T},\beta,\lambda^*\right]}{\varDelta L}\,. \end{aligned} \tag{38}$$

The third term in the last line of Eq. (38) can be transformed, by the use of the definition of f and Eq. (37′), in the following manner:

$$-\frac{L}{3}f\left[x'\frac{\partial\phi}{\partial\boldsymbol{r}'}\right]=-\frac{1}{3}f\left[\boldsymbol{r}'\frac{\partial\phi}{\partial\boldsymbol{r}'}\right]=-\frac{1}{3}f\left[\int_V\delta(\boldsymbol{r}-\boldsymbol{r}')\boldsymbol{r}\frac{\partial\phi}{\partial\boldsymbol{r}}d\boldsymbol{r}\right]$$

$$=-\frac{1}{3}\int_V f[\delta(\boldsymbol{r}-\boldsymbol{r}')]\boldsymbol{r}\frac{\delta\phi}{\partial\boldsymbol{r}}d\boldsymbol{r}$$

$$=-\frac{N}{6V\kappa T}\int_V g(r)\boldsymbol{r}\frac{\partial\phi}{\partial\boldsymbol{r}}d\boldsymbol{r}$$

$$=-\frac{\rho}{6\kappa T}\int_0^\infty g(r)\frac{d\phi}{dr}4\pi r^3dr\,.$$

Hence Eq. (38) becomes

$$\frac{p}{\rho\kappa T}=1+\frac{\lambda^*}{3}\frac{\partial a}{\partial\lambda^*}-\frac{\rho}{6\kappa T}\int_0^\infty g(r)\frac{d\phi}{dr}4\pi r^3dr\,. \qquad (39$$

In an analogous way the expression for E is obtained as

$$\frac{E}{(3/2)N\kappa T}=1+\frac{\lambda^*}{3}\frac{\partial a}{\partial\lambda^*}+\frac{\rho}{3\kappa T}\int_0^\infty g(r)\phi(r)4\pi r^2dr\,. \qquad (40$$

Equations (39) and (40) agree with Eqs. (34) and (35) respectively in the classical case, wher the second terms of the right-hand sides of Eqs. (39) and (40) are missing.

It might be supposed that the special form of the free energy assumed in (Eq. (36) limit the validity of) Eq. (39) or (40). However, the expression for the free energy will generall be written in the form given by Eq. (36) so far as it is calculated, even if approximately from the knowledge of $\phi(r)$. As an example we shall consider Eq. (18). It is rewritten as

$$\frac{A_0}{N\kappa T}=\log\frac{\lambda^3}{V}+\log\frac{N}{e}-\frac{N}{2}\left[(2\pi)^{3/2}\bar{\beta}(0)-\pi\int_{-\infty}^{\infty}y^2\bar{\beta}^2(y)dy\right]$$

$$+\frac{1}{N}\frac{1}{8\pi^2}\int_{-\infty}^{\infty}y^2\log[1-(2\pi)^{3/2}N\bar{\beta}(y)]dy+\frac{1}{2\sqrt{2\pi}}\int_{-\infty}^{\infty}y^2\bar{\beta}(y)dy\,,$$

where

$$y\bar{\beta}(y)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}x[e^{-\phi(Lx)/\kappa T}-1]\sin xy\,dx\,.$$

Obviously the above expression has the form given by Eq. (36). It can be shown that even Eq. (26) has the form under consideration, provided that a proper limit is taken.

§ 5. Discussion

Formula (10) can be used to obtain the approximate distribution function when the approximate expression for the free energy is known. The function thus derived is consistent with the approximation used in the derivation of the free energy. However, this function is not necessarily equal to the one derived from Eq. (5) based on the same approximation. Such an example is given by the third example considered in § 3. Equation (29′) is equivalent to Eq. (10), while Eq. (31) is equivalent to Eq. (5). In order to obtain Eq. (30) from the calculation of the right-hanc side of Eq. (31) or Eq. (32), a further appro ximate procedure must be introduced. A detailed calculation is shown in Appendix II In such cases, it can be said that the distri bution function based on Eq. (10) is preferabl to one based on Eq. (5), since the former i consistent with the approximation used in th derivation of the free energy.

Generally speaking, an approximate proce dure can be introduced more properly in th derivation of the free energy than in th derivation of the distribution function. It i often difficult for the true character of th approximation used in the latter case to b revealed and this approximation often leads t the results having the self-inconsistency a discussed in the previous paper.

An interesting application of Eq. (10) is ound in the cell theory of liquid state, where t is difficult to apply Eq. (5) and more intuiive procedures are usually adopted in order o derive the distribution function. This is lue to the fact that Eq. (10) is applicable irespective of underlying models upon which he theory is based.

Formula (10) has the drawback that it is not applicable to the case where the expression of the free energy is not known as the functional of interaction potential. Especially t becomes powerless in the case of quantum ideal gases, where the interaction potential ϕ does not exist and $g(r)$ differs from unity due to the symmetry effect alone. Ideal gases must be considered as the limiting case where ϕ tends to zero if it is tried to apply Eq. (10). However, such a method cannot be carried out unless the theory of quantum fluid is given.

The author would like to express his appreciation to Professor A. Harasima for his continual encouragement and helpful discussions throughout this work.

Appendix I

Expression (18) for the approximate free energy will be derived here. The following procedure is analogous to one which was used by Montroll and Mayer[4] in calculation of $g(r)$. The free energy A of classical fluid is given by Eq. (17), *i. e.*,

$$\frac{A}{N\kappa T}=\log\left(\frac{h^2}{2\pi m\kappa T}\right)^{3/2}\frac{\rho}{e}-\sum_{n=1}\frac{1}{n+1}\beta_n\rho^n\,. \tag{I-1}$$

The irreducible integrals β_n's are defined by[2]

$$\beta_n=\frac{1}{n!\,V}\iint\cdots\int\sum_{\substack{\text{All products which are more}\\ \text{than singly connected}}}\prod_{n+1\geq i>j\geq 1}\alpha_{ij}\,d\boldsymbol{r}_1 d\boldsymbol{r}_2\cdots d\boldsymbol{r}_{n+1}$$

where

$$\alpha_{ij}=\alpha(r_{ij})=e^{-\phi(r_{ij})/\kappa T}-1\,.$$

Among many terms composing β_n, only the terms of the following type will be considered:

$$\frac{1}{n!\,V}\iint\cdots\int\alpha_{12}\alpha_{23}\cdots\alpha_{n+1,\,1}\,d\boldsymbol{r}_1 d\boldsymbol{r}_2\cdots d\boldsymbol{r}_{n+1}\,.$$

There exist $n!/2$ such terms in β_n. Then approximate irreducible integral β_{n0} which involves only terms as shown above, is

$$\beta_{n0}=\frac{n!}{2}\frac{1}{n!\,V}\iint\cdots$$
$$\times\int\alpha_{12}\alpha_{23}\cdots\alpha_{n+1,1}d\boldsymbol{r}_1 d\boldsymbol{r}_2\cdots d\boldsymbol{r}_{n+1}$$
$$=\frac{1}{2}\iint\cdots\int\alpha_{12}\alpha_{23}\cdots\alpha_{n+1,1}d\boldsymbol{r}_1 d\boldsymbol{r}_2\cdots d\boldsymbol{r}_n\,,$$

which can be calculated by the use of $\beta(u)$ defined by Eq. (19) as follows:

$$\beta_{n0}=\frac{1}{2}(2\pi)^{(3n-1)/2}\int_{-\infty}^{\infty}u^2\beta^{n+1}(u)du\,,\ \text{for } n\geqq 2\,. \tag{I-3}$$

The above procedure is not valid for $n=1$. The correct expression should be used for β_{10}:

$$\beta_{10}=\beta_1=2\pi\int_{-\infty}^{\infty}r^2\alpha(r)dr=(2\pi)^{3/2}\beta(0)\,. \tag{I-3′}$$

The simple chain approximation to the free energy is to use β_{n0} instead of β_n in the right-hand side of Eq. (I−1). Then the summation with respect to n can be carried out as follows:

$$\sum_{n=1}\frac{1}{n+1}\beta_{n0}\rho^n=\frac{1}{\rho}\int_0^{\rho}\left[\sum_{n=1}\beta_{n0}\,x^n\right]dx$$

$$=\frac{1}{\rho}\int_0^{\rho}\left[\frac{1}{2}\frac{1}{\sqrt{2\pi}}\sum_{n=1}\int_{-\infty}^{\infty}u^2\beta(u)\{(2\pi)^{3/2}x\beta(u)\}^n du+\left\{(2\pi)^{3/2}\beta(0)-\pi\int_{-\infty}^{\infty}u^2\beta^2(u)\,du\right\}x\right]dx$$

$$=\frac{1}{\rho}\int_0^{\rho}\left[\frac{1}{2\sqrt{2\pi}}\int_{-\infty}^{\infty}\frac{u^2\beta^2(u)(2\pi)^{3/2}x}{1-(2\pi)^{3/2}x\beta(u)}du+\left\{(2\pi)^{3/2}\beta(0)-\pi\int_{-\infty}^{\infty}u^2\beta^2(u)du\right\}x\right]dx$$

$$=-\frac{1}{\rho}\frac{1}{8\pi^2}\int_{-\infty}^{\infty}u^2\log\left[1-(2\pi)^{3/2}\rho\beta(u)\right]du-\frac{1}{2\sqrt{2\pi}}\int_{-\infty}^{\infty}u^2\beta(u)du$$
$$+\frac{\rho}{2}\left[(2\pi)^{3/2}\beta(0)-\pi\int_{-\infty}^{\infty}u^2\beta^2(u)du\right].$$

Hence the approximate expression A_0 for the free energy is obtained as follows:

$$\frac{A_0}{N\kappa T}=\log\left(\frac{h^2}{2\pi m\kappa T}\right)^{3/2}\frac{\rho}{e}-\frac{\rho}{2}\left[(2\pi)^{3/2}\beta(0)-\pi\int_{-\infty}^{\infty}u^2\beta^2(u)du\right]$$
$$+\frac{1}{\rho}\frac{1}{8\pi^2}\int_{-\infty}^{\infty}u^2\log\left[1-(2\pi)^{3/2}\rho\beta(u)\right]du+\frac{1}{2\sqrt{2\pi}}\int_{-\infty}^{\infty}u^2\beta(u)du\,, \tag{I-4}$$

which is the one given by Eq. (18).

Appendix II

Equation (30) for $S(k)$ will be derived here from Eq. (32). The method of our calculatio is taken from Zubarev's paper[10]. Our object is to calculate

$$\langle\rho_k\rho_{-k}\rangle=\frac{\int\cdots\int\rho_k\rho_{-k}\varphi_0^2\,d\boldsymbol{r}_1\cdots d\boldsymbol{r}_N}{\int\cdots\int\varphi_0^2 d\boldsymbol{r}_1\cdots d\boldsymbol{r}_N}\,. \qquad \text{(II-1}$$

For brevity we shall write the wave function given by Eq. (27) as

$$\varphi_0=\exp\{-\tfrac{1}{2}\sum_k{}'\,a_k\,\rho_k\rho_{-k}\}\,, \qquad \text{(II-2}$$

where

$$a_k=\frac{1}{\lambda_k^2}-1 \qquad \text{(II-3}$$

and $\sum_k{}'$ means that the summation is carried out over the semi-infinite region of $\boldsymbol{k}$ in whic z-component $\boldsymbol{k}_z$ is positive.

The denominator of Eq. (II-1) can be written as follows:

$$\int\cdots\int\varphi_0^2 d\boldsymbol{r}_1\cdots d\boldsymbol{r}_N=\int_{-\infty}^{+\infty}\cdots\int_{-\infty}^{+\infty}\exp\Big\{-\sum_k{}'\,a_k\rho_k\rho_{-k}\Big\}\times D(\cdots,\rho_k,\cdots)\prod_k{}'\,d\sigma_k d\tau_k\,, \qquad \text{(II-4)}$$

where

$$D(\cdots,\rho_k,\cdots)=\int\cdots\int\prod_k{}'\,\delta\Big(\sigma_k-\frac{1}{\sqrt{N}}\sum_j\cos\boldsymbol{k}\boldsymbol{r}_j\Big)\,\delta\Big(\tau_k-\frac{1}{\sqrt{N}}\sum_j\sin\boldsymbol{k}\boldsymbol{r}_j\Big)d\boldsymbol{r}_1\cdots d\boldsymbol{r}_N \qquad \text{(II-5)}$$

and

$$\rho_k=\sigma_k+i\tau_k,\ \sigma_{-k}=\sigma_k,\ \tau_{-k}=-\tau_k$$

and $\prod_k{}'$ is the product of which meaning is similar to $\sum_k{}'$. The function $D(\cdots,\rho_k,\cdots)$ is a kind of Jacobian for the transformation from $(\boldsymbol{r}_1,\cdots,\boldsymbol{r}_N)$ to $(\cdots,\rho_k,\cdots)$. Use of the Fourier representation of δ-function leads to

$$D(\cdots,\rho_k,\cdots)=\int_{-\infty}^{+\infty}\cdots\int_{-\infty}^{+\infty}e^{i\pi\sum_k\omega_k\rho_k}\Big\{\int\exp\Big[-\frac{i\pi}{\sqrt{N}}\sum_k\omega_k e^{i\boldsymbol{k}\boldsymbol{r}}\Big]d\boldsymbol{r}\Big\}^N\prod_k{}'\,d\alpha_k d\beta_k\,. \qquad \text{(11-6)}$$

where

$$\omega_k=\alpha_k-i\beta_k,\ \alpha_{-k}=\alpha_k,\ \text{and}\ \beta_{-k}=-\beta_k\,.$$

When the expansion

$$\frac{1}{V}\int\exp\Big\{-\frac{i\pi}{\sqrt{N}}\sum_k\omega_k e^{i\boldsymbol{k}\boldsymbol{r}}\Big\}d\boldsymbol{r}=1-\frac{\pi^2}{2N}\sum_k\omega_k\omega_{-k}+\frac{1}{3!}\Big(\frac{-i\pi}{\sqrt{N}}\Big)^3\sum_{k_1+k_2+k_3=0}\omega_{k_1}\omega_{k_2}\omega_{k_3}+\cdots,$$

is used in the integrand of Eq. (II-6), $D(\cdots,\rho_k,\cdots)$ is expressed as:

$$D(\cdots,\rho_k,\cdots)=\Big\{1-\frac{1}{3!}\frac{1}{\sqrt{N}}\sum_{k_1+k_2+k_3=0}\frac{\partial^3}{\partial\rho_{k_1}\partial\rho_{k_2}\partial\rho_{k_3}}+\cdots\Big\}D_0(\cdots;\rho_k,\cdots)\,, \qquad \text{(II-7)}$$

where

$$D_0(\cdots,\rho_k,\cdots)=V^N\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\exp\Big\{i\pi\sum_k\omega_k\rho_k-\frac{\pi^2}{2}\sum_k\omega_k\omega_{-k}\Big\}\prod_k{}'\,d\alpha_k d\beta_k \qquad \text{(II-8)}$$

The integration of the right-hand side of Eq. (II–8) can easily be carried out:

$$D_0(\cdots,\rho_k,\cdots)=V^N\exp\Big\{-\sum_k{}'(\rho_k\rho_{-k}+\log\pi)\Big\}\,. \tag{11–9}$$

As the first approximation we use $D_0(\cdots,\rho_k,\cdots)$ in place of $D(\cdots,\rho_k,\cdots)$ in Eq. (II–4). Then

$$\begin{aligned}\int\cdots\int\varphi_0{}^2d\boldsymbol{r}_1\cdots d\boldsymbol{r}_N &\approx\int_{-\infty}^{+\infty}\cdots\int_{-\infty}^{+\infty}\exp\Big\{-\sum_k{}'a_k\rho_k\rho_{-k}\Big\}D_0(\cdots,\rho_k,\cdots)\prod_k{}'\,d\sigma_kd\tau_k\\ &=V^N\prod_k{}'\left[\frac{1}{\pi}\int_{-\infty}^{+\infty}\cdots\int_{-\infty}^{+\infty}\exp\{-(a_k+1)(\sigma_k{}^2+\tau_k{}^2)\}d\sigma_kd\tau_k\right]\\ &=V^N\prod_k{}'\frac{1}{a_k+1}=V^N\prod_k{}'\lambda_k{}^2\,.\end{aligned} \tag{II–10}$$

In the same way, the numerator of Eq. (II–1) is calculated as

$$\int\cdots\int\rho_k\rho_{-k}\varphi_0{}^2d\boldsymbol{r}_1\cdots d\boldsymbol{r}_N\approx V^N\lambda_k{}^2\prod_{k'}{}'\lambda_{k'}{}^2\,. \tag{II–11}$$

Therefore we finally obtain, as the first approximation to $\langle\rho_k\rho_{-k}\rangle$,

$$\langle\rho_k\rho_{-k}\rangle\approx\lambda_k{}^2 \tag{II–12}$$

which is identical to Eq. (30) for $S(k)$.

Submicroscopic Topography of Oxidized Surface of Stibnite and Etched Surface of Zincblende

By Masaru WATANABE

Japan Electron Optics Laboratory Co., Ltd.
Kamirenjaku, Mitaka, Tokyo, Japan

(Received December 8, 1956)

Submicroscopic topographies of oxidized stibnite and of etched zincblende were examined by electron microscopes. Crystallites of antimony oxide formed on stibnite have a roof-like shape bounded by two well-developed and four less developed {111} faces. This is in agreement with the conclusion drawn previously from electron diffraction study (Miyake, Sc. Pap. I. P. C. R. **34** (1938), 565). The direct observation by electron microscope gives some further information on the growth of the oxide. Zincblende surfaces etched by hydrochloric acid has a shape which is slightly different from the negative triakis tetrahedron inferred from electron diffraction study (Uyeda et al., Proc. Phys.-Math. Soc. Japan **24** (1941) 1049). In the diffraction patterns from this surface, structures of reflexion spots finer than those previously reported were observed and analysed by the theory of the dynamical refraction effect.

§ 1. Introduction

When crystallites have a well-defined external shape, the electron diffraction spots show fine structures. By observing such fine structures submicroscopic topography of crystal surfaces were studied before the advent of the electron microscopy[1]. The results obtained in this way seem to be convincing, but they are after all indirect. Therefore, it is of interest to re-examine by electron microscopy the surfaces which were previously studied by electron diffraction. In the present paper the following two surfaces are examined.

(i) Oxidized surface of stibnite (Sb_2S_3)

Miyake[2] concluded that crystallites of antimony oxide, Sb_2O_3, which were formed on cleavage faces of stibnite grew into characteristic roof-like protrusions elongated along [001]-axis of stibnite and bounded by octahedral planes as illustrated in Fig. 1.

(ii) Etched surface of zincblende (ZnS)

Uyeda et al[3]. concluded that when cleavage face (110) of zincblende is etched b hydrochloric acid it consisted of minute face of the negative triakis tetrahedron[4], a for composed of {211} faces (Fig. 2). When, how ever, the same surface was etched by nitri acid it consisted of minute faces of positiv and negative triakis tetrahedrons.

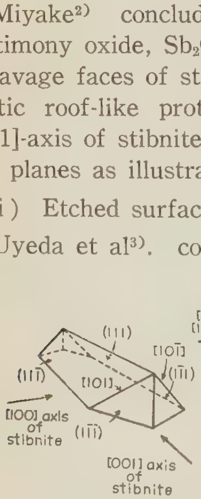

Fig. 1.

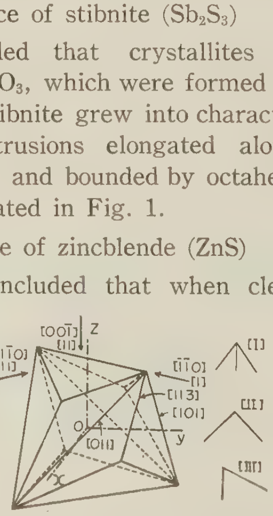

Fig. 2

In the present paper it will be shown a first that the antimony oxide grows in th form exactly as concluded by Miyake and the the zincblende surface etched by hydrochlori acid is made up of faces slightly differen from those of negative triakis tetrahedron In a later part of this paper structures o diffraction pattern finer than that observed b Uyeda et al. will be discussed in detail.

§ 2. Experimentals

(i) *Specimen Preparation*

The specimens were prepared following th methods adopted by the original observers.

a) Oxidized surfaces of stibnite

Small pieces of stibnite, about 1×1 sq. cm in area and 1~2 mm. in thickness, were clef off from larger crystals and oxidized for fron 1 to 60 min. in an open electric furnace a temperatures about 280°C.

b) Etched surfaces of zincblende

Small pieces of zincblende, about 1×1 sq cm. in area and 1~3 mm. in thickness, wer cleft off from a crystal block, and etched b hydrochloric acid at about 80°C and by nitric acid at room temperatures.

ii) *Method of Observation*

The surfaces prepared were studied with EM-5 electron microscope by the transmission method utilizing a replica technique and by the reflexion method as well. Each specimen was ascertained before electron microscopy that it gave electron diffraction patterns of the characteristic fine structures as described by the original observers.

iii) *Replica Technique*

Specimens of stibnite became so fragile by heating that it was difficult to apply the conventional replica techniques. Among other alternatives, metallic collodion negative replica[5] backed by reinforcing ethocel film gave the best result. Chromium-shadow was cast from the direction of [100]-axis of stibnite.

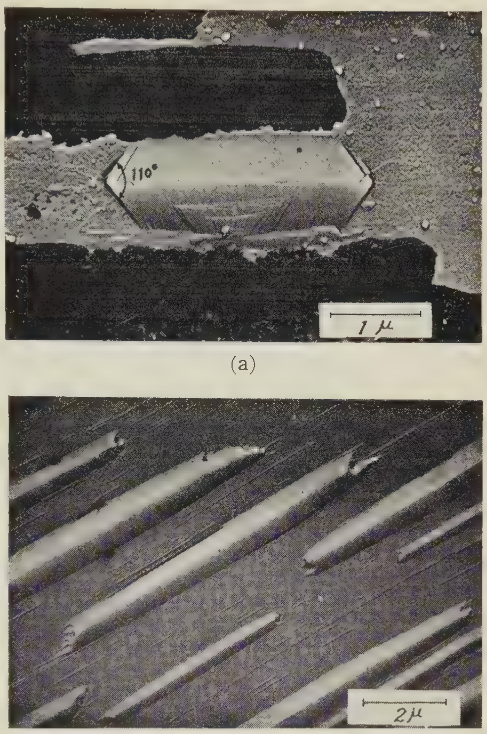
For zincblende specimens, a composite metallic film replica was prepared as follows: A mould of the specimen surface was made of a polystyrene plate of thickness about 2 mm., which was heated up to 150°～160°C with compressed to the specimen surface, and then the mould was chromium-shadowed from the direction of [$1\bar{1}0$]-axis of zincblende. Finally, an aluminum film was deposited on it. The composite metallic film was separated from polystyrene by immersing in benzene.

§ 3. Results

i) *Antimony Oxide formed on Stibnite*

Photos. 1a and 1b show two transimission electron micrographs of the surface. Photos. 2a and 2b reproduce reflexion micrographs obtained with incidences of electrons nearly perpendicular and parallel to [001]-axis of stibnite, respectively.

In Photos. 1a and 1b, it can be found that a number of parallel roof-like oxide protrusions stand out in relief from the substrate*. The angle between the two edges at the ends of the protrusion (Photo. 1a) is about 110° as illustrated in Photo. 1a and this agrees well with the calculated angle 109° 28′ between the projections of [101]- and [$10\bar{1}$]- axes to the cleavage surface. Thus Miyake's conclusion

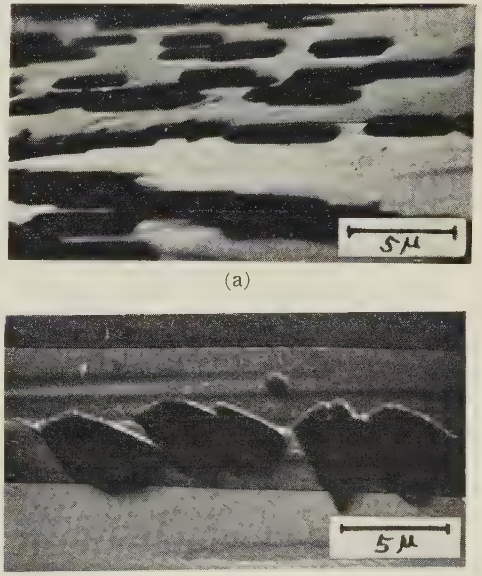


(a)

(b)

Photo. 1. Antimony oxide (Sb_2O_3) formed on the cleavage surface of stibnite (Sb_2S_3) heated at 280°C for 30 min. in atmosphere.

Note the lamellar growth of the octahedral faces.



(a)

(b)

Photo. 2. Reflexion electron micrographs of Sb_2O_3 crystals formed on stibnite cleavage face (010). Electron incidences nearly parallel to (a) [100]- and (b) [001]-axes of stibnite.

---

* In our previous experiment[6] utilizing collodion one step replica, only a round edge was observed at the top of oxide roofs on account of the unfaithfulness of the replica.

is clearly verified. Photos. 2a and 2b show also the existence of such protrusions, though it is less obvious because of the fore-shortening of the image and poor resolusion.

In Photo. 1b, which is a surface heated for 30 minutes, it can be seen that, besides well developed oxide protrusions of lateral size about 1 micron, there are many much thinner protrusions of lateral size of a few hundred Å, having an external form similar to that of larger ones. After oxidation of less than 5 minutes, only such thinner protrusions were observed on the surface, and such surfaces gave the most clearly the characteristic fine structures of diffraction spots as found by Miyake. When the time of oxidation was longer than 5 minutes, protrusions of a larger size appeared. However, protrusions of lateral size larger than 1 micron were scarce even after one hour oxidation. In spite of variation of oxidation time, the lateral sizes of almost all protrusions were either a few hundred Å or about 1 micron. Thus it seems that 1 micron is the limit of the lateral size of the protrusion and that the lateral growth from a few hundred Å to the limit is very rapid.

(ii) *Etched Surface of Zincblende*

Photo. 3 shows the transmission electron micrograph of a surface of zincblende etched by hydrochloric acid. Photos. 4a and 4b are reflexion electron micrographs of the same surface. Photos. 5 and 6 are electron diffraction patterns produced from the same surface. The directions of electron incidence for Photos. 5 and 6 were almost the same as those for the micrographs Photos. 4a and 4b, respectively. The reflexions in these electron diffraction patterns show in general streak-like elongations as observed by Uyeda et al.*.

In Photo. 3, there can be found wedge shapes with an angle of about 70°. A faint line bisects each of the wedges. The apex angle of the wedges observed in Photo. 4a and the angle between the streaks of diffraction spots in Photo. 5 are equal to 90°. The wedge found in Photo. 4b is composed of two edges, one being vertical and the other meeting the vertical one at an angle of 56°~57°. The streaks in Photo. 6 are elongated exactly perpendicular to these two edges.

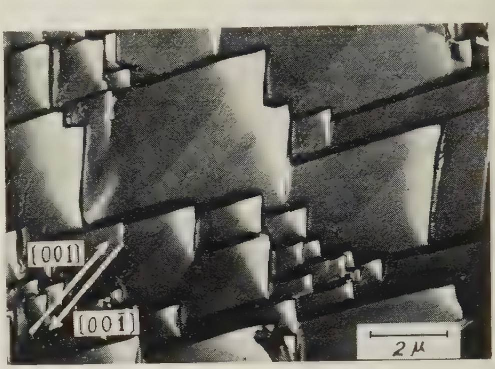


Photo. 3. (110) surface of zincblende (ZnS) etched by hydrochloric acid at about 80°C.

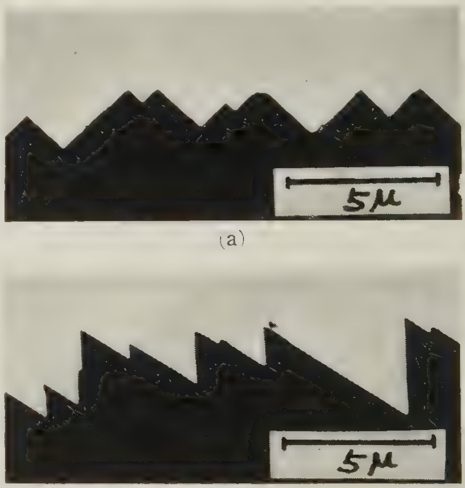


(a)

(b)

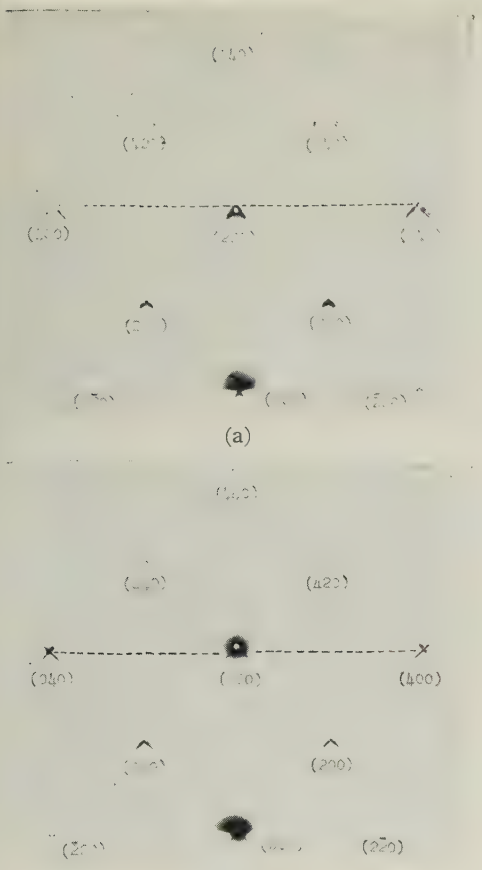
Photo. 4. Reflexion electron micrographs of etched (110) surface of zincblende with electron incidences parallel to (a) $[00\bar{1}]$- and (b) $[\bar{1}10]$-axes.

When we look at the negative triakis tetrahedron along [I] $[\bar{1}\bar{1}0]$-, [II] $[00\bar{1}]$- and [III] $[1\bar{1}0]$-directions, there will appear wedge shapes as follows (Fig. 2): [I] a wedge of apex angle 70°34′, bounded by edges [011]- and [101]-axes. It is bisected by the edge line [113]-axis, [II] a wedge of apex angle 90° bounded by [011]- and [101]-axes and [III] a wedge of apex angle 64°50′ bounded by [113]- and [001]-axes.

The wedge shapes found in Photos. 3 and 4a agree exactly with the wedges [I] and

---

* Uyeda et al. considered that the streaks of diffraction spots were due to the refraction effect. Thus the streak should be elongated along the direction perpendicular to the edge at which the two boundary faces penetrated by the electron beam intersect each other. More detailed observations and discussions will be given in §4 and §5.



(a)

(b)

Photo. 5. Electron diffraction patterns of etched (110) surface of zincblende. (a) and (b) are taken, respectively, with a- and b-incidences defined in § 4.

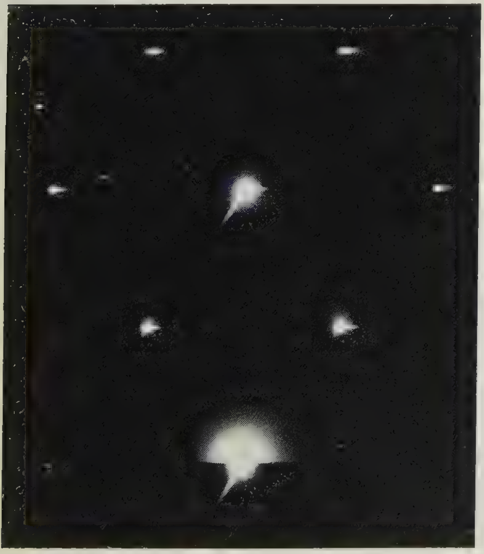


Photo. 6. Electron diffraction pattern of etched (110) surface of zincblende with electron incidence parallel to [$\bar{1}$10] axis.

[II], respectively. The apex angle of wedges in Photo. 4b, however, is different decidedly from that of the wedge [III]. Thus, we see that the protrusions on the etched zincblende surface have a form which is slightly different from the negative triakis tetrahedron. If we assume a form composed of {655} faces, there appears in the third view a wedge bounded by the edges [001]- and [55 11] -axes, the angle between them being 57°14′. In the other two views, this form gives the same wedges as those of the negative triakis tetrahedron. Thus we conclude that the etched surface of zincblende is composed of {655} faces.

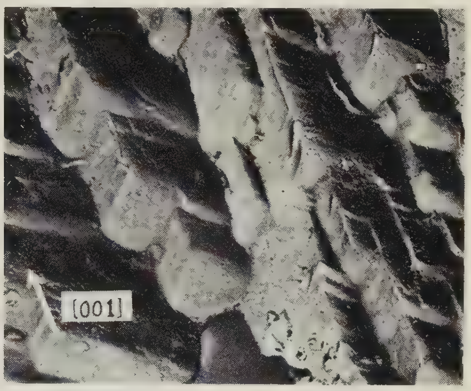

Photo. 7. (110) surface of zincblende etched by nitric acid.

Photo. 7 shows an electron micrograph of (110) face of zincblende etched by nitric acid. In this case, rough faces having indices {100} and {112} are revealed in the electron micrograph, but clean-cut feature as supposed by Uyeda et al. can not be detected.

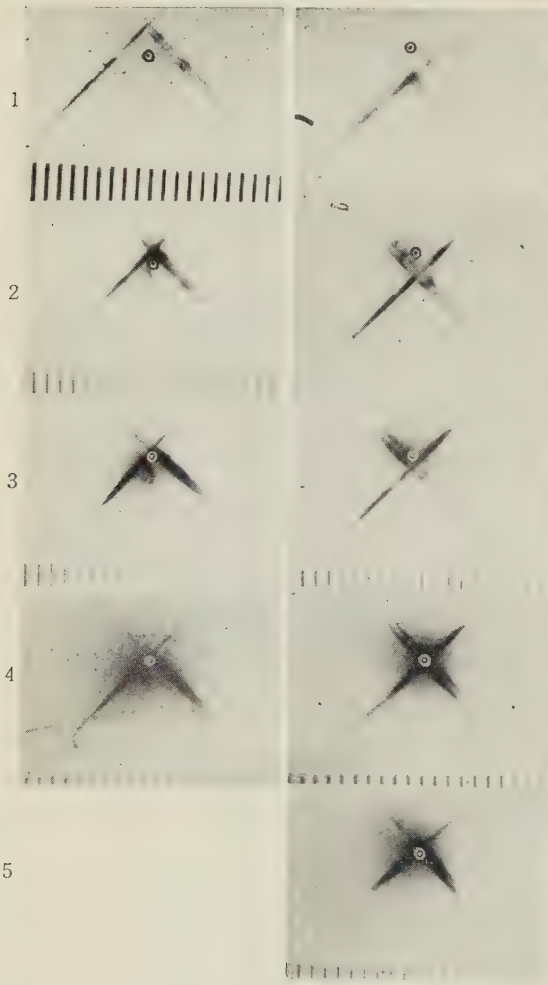
§ 4. Fine Structure of Electron Diffraction Pattern of Etched Zincblende Surface

Photos. 5a and 5b were taken with incident electron beams in plane of incidence (1$\bar{1}$0). In both cases Bragg condition was exactly satisfied for (220)-reflexion. In Photo. 5a the electron beam was along [001]-direction (a-incidence) and in Photo. 5b, along [00$\bar{1}$]-direction (b-incidence).

Each streak (Photos. 5a and 5b) shows a fine structure containing two or more spots. The fine structure depends not only on indices of reflexions but also on the direction of the incident electrons. The relative position of reflexions is different in the two patterns

(Photos. 5a and 5b); for example, the halation spot of (220) reflexion is under (Photo. 5a) or above (Photo. 5b) the dashed lines joining the cross points of streaks in (400) and (040).

It is found that such details of reflexions vary considerably according to slight variations of the crystal setting. A series of variations of (400) and (420) reflexions are reproduced in Photos. 8 and 9*. There, the angle of incidence was varied without changing the plane of incidence. Numbers 1, 2, ···, 5 correspond, respectively, to the crystal settings for which Ewald's sphere intersects the (hh0) reciprocal lattice plane along circles 1, 2, ···, 5 shown in Fig. 3. The circle with a dot in each photograph indicates the position of reflexion due to the simple Bragg's law. One division of the scale in the photographs corresponds to 0.1 mm. on the original plates which were taken by a diffraction camera with specimen-plate distance 29 cm. and with an accelerating voltage 50 kV.



(a) (b)

Photo. 8. Variation of fine structures of {400} reflexions. (a) and (b) are taken, respectively, with a- and b-incidences defined in § 4. Numbers 1, 2, ..., 5 indicate settings of crystals given in Fig. 3.

deviation varies according to the angle of incidence. Observed values of the deviation are tabulated in Table I, where + and − signs indicate up- and down-ward shifts, respectively.

§ 5. Theoretical Consideration

A Bragg reflexion from a crystallite of a well-defined external form splits into a multiplet, since it is deviated from the position of simple Bragg reflexion by the prism action of edges of the crystallite. If there exist some minute irregularities or curvature on the faces of the prism, the deviation may have various magnitudes resulting in a set of streaks. Through such a consideration, which is originally pointed out by T. Yamaguti⁷⁾, Uyeda et al. explained the streaks in the diffraction pattern of etched zincblende surface.

At the data of the study of Uyeda et al., only the effect of simple refraction was known. At present, however, it is well known that there occurs the double refraction effect which is explained by the dynamical theory of electron diffraction. For this effect, which was originally pointed out by Sturkey⁸⁾, Kato⁹⁾ has given a refined theory. Experimentally it was studied in detail by Honjo and Mihama¹⁰⁾,¹¹⁾ and by Molière et al.¹²⁾,¹³⁾,¹⁴⁾. It may be of interest to examine the observed details of reflexions (See § 4) in the light of this theory.

According to Honjo and Mihama¹¹⁾, the deviation of a reflexion from the directions predicted by simple Bragg law can be calculated by refering to a co-ordinate system (ξ, η, ζ), where ζ-axis is the normal to the reflecting lattice plane, ξ-axis is the intersection of the lattice plane with the plane of incidence, and η-axis is perpendicular to ξ and ζ. The angular deviation is given by

$$\left.\begin{aligned} \alpha_\eta^{(1),(2)} &= -\{\varepsilon\cdot\delta_h\cdot S_\eta+(\delta_0\pm\delta_h\sqrt{1+\varepsilon^2}\,)t_\eta\}\ , \\ \alpha_\zeta^{(1),(2)} &= -\{\varepsilon\cdot\delta_h\cdot S_\zeta+(\delta_0\pm\delta_h\sqrt{1+\varepsilon^2}\,)t_\zeta\}\ , \end{aligned}\right\} \tag{1}$$

where α_η and α_ζ are η- and ζ-components of the angular deviation, respectively; and the superscripts (1) and (2) correspond to + and − signs, respectively.

$$\delta_0 = V_0/2E, \quad \delta_h = V_h/2E ,$$

V_0 being the mean inner potential of the crystal; V_h, the h-th Fourier coefficient of the periodic potential of the crystal; and E, the accelerating voltage of the electron. $s_{\eta\cdot\zeta}$ and $t_{\eta\cdot\zeta}$ are parameters which are given by

$$s_\eta = (m/l + m'/l') ,$$
$$s_\zeta = (n/l + n'/l') ,$$
$$t_\eta = (m/l - m'/l') ,$$
$$t_\zeta = (n/l - n'/l') ,$$

where (l, m, n) and (l', m', n') are the direction cosines of the outward normals to the entrance and exit faces of the prism, respectively. ε is a parameter which represents the resonance error. It is defined by

$$\varepsilon \cdot \delta_h = \Theta \cdot \Delta\Theta , \qquad (2)$$

where Θ is the Bragg angle and $\Delta\Theta$, the deviation from Bragg angle.

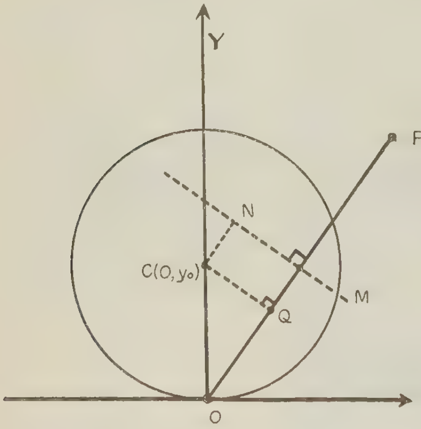

Fig. 4. (X, Y)-plane is (hh0) reciprocal lattice plane. $P(x_1, y_1)$ is a reciprocal lattice point (hk0). $C(0, y_0)$ is the center of circle along which Ewald's sphere intersects (hh0) reciprocal lattice plane.

When the plane of incidence is $(1\bar{1}0)$, ε for reflexion (hk0) can be calculated as follows: Under the present condition Ewald's sphere intersects (X, Y)-plane along a circle having the center $C(0, y_0)$ on Y-axis (Fig. 4). If Bragg condition is satisfied exactly, the center of the intersecting circle is on line $\overline{MN}$, $\overline{MN}$ being the perpendicular bisecthor of $\overline{OP}$. Thus $\Delta\Theta$ is given by

$$\Delta\Theta = (\overline{OQ} - \overline{OP}/2)/K ,$$

Since $\Theta = \overline{OP}/2K$, $\Theta \cdot \Delta\Theta$ is given by

$$\Theta \cdot \Delta\Theta = \frac{1}{4K^2}(y_1 y_0 - x_1^2 - y_1^2) , \qquad (3)$$

where K is the length of wave number vector of electrons. Values of V_0 is known to be 12 volts[15] and V_h are calculated from the known atom form factors as follows.

(hkl)	(200)	(220)	(400)	(420)	(440)
V_h	1.79 V	7.02 V	4.49 V	1.06 V	2.78 V

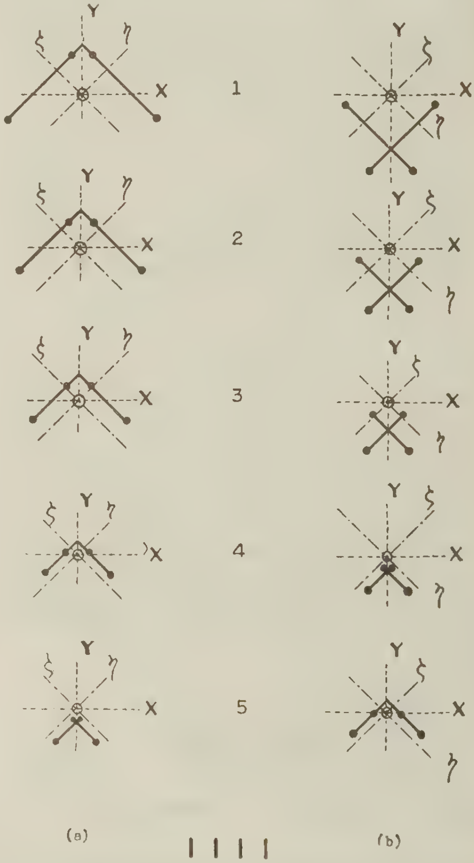

Fig. 5. Double refraction multiplet of {400} reflexions calculated for (a) a- and (b) b-incidences. Numbers 1, 2, ..., 5 correspond to settings of crystals given in Fig. 3.

$s_{\eta\cdot\zeta}$ and $t_{\eta\cdot\zeta}$ can be calculated easily from the known external form of crystallite. Thus, the theoretical multiplet structure can be known if the parameter y_0 is given.

The results for (400) and (420) reflexions are shown in diagrams of Figs. 5 and 6, respectively. Figs. 5 and 6 correspond to Photos. 8 and 9, respectively, and they are given in the same scale. In these diagrams two spots caused by a double refraction are joined by a thick line and the position of simple Bragg reflexion is indicated by white circles.

The following facts are in qualitative agreement with the observation.

(i) The separations between two spots of doublet are from 0.05 to 0.8 mm., which are the same order of magnitude found in Photos. 8 and 9.

(ii) The cross point of lines joining doublets deviates vertically from the position of simple Bragg reflexion. Values of the deviations are tabulated in Table II. They agree with the values in Table I in the order of magnitude.

(iii) The arrangement of component spots around the cross point is different considerably for a- and b-incidences of the same resonance error.

Diagrams (Figs. 5 and 6) are calculated under the assumption that only one strong reflexion is excited. Practically, however, many reflexions are excited simultaneously because the observation was made for plane of incidence $(1\bar{1}0)$ which is highly symmetric. Under such condition, there should occur more complicated effects than double refraction, resulting in a considerable variation of the effective values of V_0 and V_h[16]. Thus we must satisfy with the qualitative agreement.

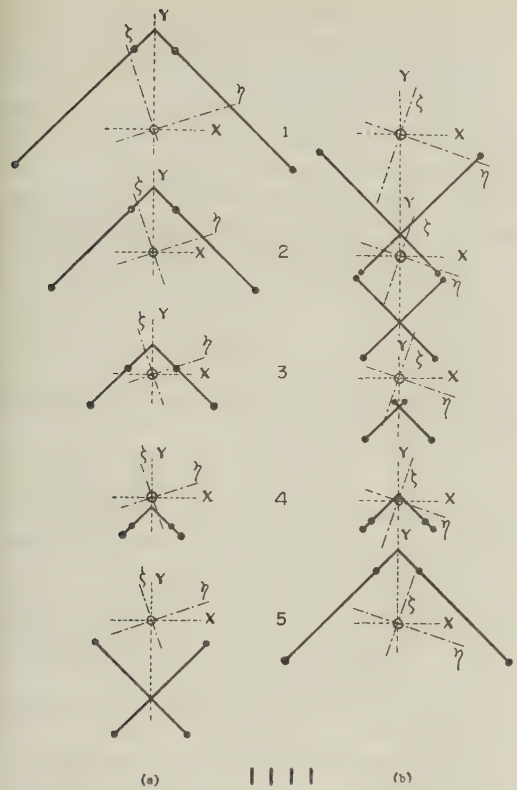

Fig. 6. Double refraction multiplet of {420} reflections calculated for (a) a- and (b) b-incidences. Numbers 1, 2, ..., 5 correspond to settings of crystals given in Fig. 3.

Table II*

(hkl)	1	2	3	4	5
(200)	±0.01 mm.	∓0.01 mm.	∓0.01 mm.	∓0.06 mm.	
(220)	±0.04	∓0.03	∓0.10	∓0.15	∓0.32 mm.
(400)	±0.20	±0.15	±0.10	±0.05	∓0.05
(420)	±0.47	±0.31	±0.14	∓0.03	∓0.35
(440)		±0.44	±0.31	±0.15	∓0.13

* Numbers 1, 2, ..., 5 indicate the crystal settings defined in Fig. 3 and upper and lower signs correspond to a- and b-incidences respectively.

The fact that the observed reflexions are different for a- and b- incidences can be explained neither by the simple theory of refraction nor by Sturkey's theory of double refraction. In these theories, the deviation of a reflexion spot from the position of simple Bragg reflexion is given by a vector sum of two deviations at the entrance and exit surface, the sum being a vector along $\boldsymbol{t}(t_\eta, t_\zeta)$. This quantity is independent of the directions of incident electrons, (a) or (b). According to the theory of Kato, the refractive index is different for entrance and for exit of electrons, as pointed out by Honjo and Mihama. Each deviation at an entrance and exit is a sum of two vectors, one along $\boldsymbol{s}(s_\eta, s_\zeta)$ and the other along $\boldsymbol{t}(t_\eta, t_\zeta)$. Since the change of $\boldsymbol{s}$ and $\boldsymbol{t}$ is asymmetric for the interchange of the entrance and exit faces, the asymmetry of the reflexions for a- and b- incidences appears. The asymmetry disappears only when Bragg condition is satisfied exactly, i. e. $\varepsilon=0$.

The present author examined also the fine structure of reflexions from Sb_2O_3. They could not, however, find any structure finer than that was observed by Miyake which was interpreted by himself by the simple theory of refraction. This fact seems to contradict the theory of double refraction. It can be reconciled, however, when we assume that one of spots of the refraction doublet is so weak that it cannot be observed. Such an effect was first pointed out by Honjo and Mihama¹¹⁾ for low order reflexions of cadmium oxide and was explained as due to the imaginary inner potential. The theoretical basis of the imaginary inner potential was recently given by Yoshioka¹⁷⁾. It is highly conceivable that the effect is more predominant in antimony oxide than in cadmium oxide, since the atomic weight of antimony oxide is larger than that of cadmium oxide.

Acknowledgement

The author wishes to express his sincere thanks to Dr. G. Honjo for his suggestions and discussions in this work. The author's thanks are also due to Dr. R. Ueda of Waseda University for his encouragement and interest, at whose Laboratory earlier parts of this work was carried out.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 8, AUGUST, 1957

Impedance of Bulk Semiconductor in Junction Diode

By Toshio MISAWA*

Central Labs., Matsushita Elec. Ind. Co., Ltd.
Kadoma-cho, Kitakawachi-gun, Osaka-fu

(Received March 9, 1957)

The impedance of bulk semiconductor in a junction diode, as defined as the "imref drop" for majority carrier divided by the total current through the junction, is calculated by using the low-level solution of minority carrier and is shown to have an inductive reactance, which becomes more and more dominant over the capacitive reactance of the impedance of the junction proper so that the impedance of the whole diode turns inductive as the injection level rises.

§ 1. Introduction

In discussing the small signal current voltage relation of the forward-biased junction diode, it is a common practice to treat the junction as consisting of the junction proper and the pure resistance of bulk semiconductor. The junction proper was studied by Shockley and his co-workers[1),2)] both theoretically, and experimentally, and can be represented by the equivalent circuit of a parallel connection of a resistance and a capacitance. But it is only a custom since the "pre-transistor" age to regard the bulk impedance as purely resistive. In the junction diode made of transistor material, the majority carrier density is modulated, according to the electrical neutrality condition, by those injected minority carriers which are essentially responsible for the rectification property of the junction. Also, while the current is carried by both majority and minority carriers in the vicinity of the barrier layer of the junction, its minority carrier component becomes less and less as a result of recombination of minority carriers, with increase in distance from the barrier. The situation in the bulk semiconductor is rather complicated. The purpose of this paper is to treat the process in bulk semiconductor.

---

* Now at Tokyo Tsushin Kogyo, Ltd., 351 Kitashinagawa-6, Shinagawa-ku, Tokyo.

The calculation, which is valid only at small forward bias current, shows that the impedance of bulk semiconductor is inductive and becomes comparable to that of the junction proper as the bias current increases. These results are qualitatively correct even if one takes into account the various high injection level effects, for the corrections due to these effects are of a small factor in the light of the high level behavior of the emitter junction in a transistor.[3)]

§ 2. Definition of Bulk Impedance

There has been used an expression "IR drop in bulk semi-conductor". But it is used rather vaguely. We must give it a clear-cut definition. In doing this we follow Shockley's imref method.

The imrefs, or quasi Fermi levels for electrons, φ_n, and holes, φ_p, are a very convenient tool in discussing the problem where both the drift and the diffusion currents are involved. According to Shockley the current densities carried by electrons and holes, I_n and I_p, are expressed in terms of imrefs by

$$I_n = -q\mu_n n \operatorname{grad} \varphi_n , \qquad (1)$$

$$I_p = -q\mu_p p \operatorname{grad} \varphi_p , \qquad (2)$$

where q is the elementary charge, μ_n and μ_p are mobilities of electrons and holes, and n and p are electron and hole densities. The formulae are the same as that for the current density in terms of electrostatic potential in an ordinary conductor in which only the drift current exists. The convenient point is that we can discuss the problem, at least formally, without particular knowledge of whether the current is by drift or by diffusion.

The important properties of the imrefs, which are apparent from their definition and which we shall use in the following discussion, are

(1) Their gradients are much larger in the minority region* than in the majority region.*

(2) φ_n and φ_p merge into the Fermi level where carrier densities assume thermal equilibrium values.

Using these properties, we can figure out the behavior of φ_n and φ_p in a forward-biased junction diode, as shown in Fig. 1. The externally applied bias, $\delta\varphi$, is the difference of Fermi levels in the contact electrodes. Beneath the contacts, where the minority carriers injected through the barrier layer of the junction have died away, φ_n and φ_p coincide according to (2) and assume the same values as the Fermi levels in the contacting electrode metals. Both φ_n and φ_p must change by $\delta\varphi$ in going from the p-region contact to the n-region contact. But there is considerable difference in the way of changing between φ_n and φ_p. According to (1) φ_n changes mainly in the p-region and φ_p in the n-region. As a result we have a bow-shaped figure. The width of the bow at the barrier layer, $\delta\varphi_j$, is the effective part in

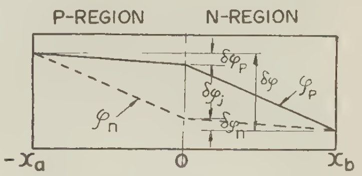

Fig. 1. Imref diagram of a forward-biased junction diode. The externally applied bias, $\delta\varphi$, is divided into $\delta\varphi_j$, the effective part in biasing the junction, and $\delta\varphi_n$ and $\delta\varphi_p$, the IR drops, in bulk semiconductors.

---

* We shall call a region as the majority or the minority region of the carrier according to weather the carrier under consideration is of majority or of minority in that region.

biasing the junction. The rest of $\delta\varphi$, $\delta\varphi_n$ and $\delta\varphi_p$, which are wasted in bulk semiconductors, are the *IR* drops.

When a small *ac* current $\tilde{I}\exp(i\omega t)$ is superposed on the bias current, the $\varphi_n-\varphi_p$ pattern vibrates about the steady state one. The phase of the vibration is different according to location in semiconductor. Therefore *ac* parts of $\delta\varphi_n$, $\delta\varphi_p$ and $\delta\varphi_j$ may have different phase with each other. Impedance of bulk are obtained by dividing $\delta\tilde{\varphi}_n$ and $\delta\tilde{\varphi}_p$ by the current $\tilde{I}$,

$$Z_n=\delta\tilde{\varphi}_n/\tilde{I}\,, \tag{3}$$

$$Z_p=\delta\tilde{\varphi}_p/\tilde{I}\,, \tag{4}$$

where the wave sign designates the *ac* part.

§ 3. Calculation of Bulk Impedance

Procedures of calculating a bulk impedance, Z_n for example, are as follows.

(1) Solving the continuity equations for minority carriers at a given value of $\delta\varphi_j$, one obtains $n(x)$ and $I_n(x)$ in the *p*-region, $p(x)$ and $I_p(x)$ in the *n*-region and the total current through the junction, I_0. This is a usual step followed in the theory of *p-n* junctions.

(2) Using results obtained in (1), one calculates $n(x)$ and $I_n(x)$ in the *n*-region from the electrical neutrality condition and constancy of current throughout the semiconductor, $I_n(x)=I_0-I_p(x)$, respectively.

(3) Insertion of $n(x)$ and $I_n(x)$ into and integration of Eq. (1) give $\delta\varphi_n$ in the *n*-region. We obtain Z_n from Eq. (3).

These procedures are followed successively.

Continuity equations for minority carriers have been solved by Shockly when $\delta\varphi_j$ consists of *dc* and small *ac* components,

$$\delta\varphi_j=\delta\bar{\varphi}_j+\delta\tilde{\varphi}_j\exp(i\omega t)\,, \tag{5}$$

where the bar means *dc* component. The hole density in the *n*-region

$$\bar{p}=p_n+p_0\exp(-x/L_p)\,, \tag{6}$$

$$\tilde{p}=p_1\exp[-x(1+i\omega\tau_p)^{1/2}/L_p]\,, \tag{7}$$

where

$$p_0=p_n[\exp(q\delta\bar{\varphi}_j/kT)-1]\,, \tag{8}$$

$$p_1=(qp_n\delta\tilde{\varphi}_j/kT)\exp(q\delta\bar{\varphi}_j/kT)\,, \tag{9}$$

τ_p and L_p are the lifetime and the diffusion length of holes in the *n*-region, p_n is the thermal equilibrium hole density in the *n*-region. The *ac* hole current in the *n*-region is

$$\tilde{I}_p=\frac{qD_pp_1}{L_p}\sqrt{1+i\omega\tau_p}\exp\left(-\frac{x\sqrt{1+i\omega\tau_p}}{L_p}\right). \tag{10}$$

Hole currents through the junction are

$$\bar{I}_{p0}=qD_pp_0/L_p\,, \tag{11}$$

$$\tilde{I}_{p0}=(qD_pp_1/L_p)(1+i\omega\tau_p)^{1/2}\,. \tag{12}$$

The corresponding expressions for electrons in the *p*-region are obtained by interchanging *p* and *n*.

From expressions derived in the preceding paragraph,

$$\begin{aligned}\tilde{n}&=\tilde{p}\\&=p_1\exp[-x(1+i\omega\tau_p)^{1/2}/L_p]\end{aligned} \tag{13}$$

and

$$\tilde{I}_n=\tilde{I}_0-\tilde{I}_p\,. \tag{14}$$

The constancy of the total current throughout the semiconductor used in Eq. (14) is easily verfied as in Appendix I.

Equation (1) is rewritten for *ac* components as

$$\tilde{I}_n=-q\mu_n\left(\tilde{n}\frac{d\bar{\varphi}_n}{dx}+\bar{n}\frac{d\tilde{\varphi}_n}{dx}\right). \tag{15}$$

The imref drop for electrons in the *n*-region can be obtained by

$$\delta\tilde{\varphi}=-\int_0^{x_b}\frac{d\tilde{\varphi}_n}{dx}dx_n\,. \tag{16}$$

In performing the above integration, we assume that the low injection level condition prevails in the *n*-region, namely, the electron density is not appreciably changed from its thermal equilibrium value, n_n:

$$\bar{n}=n_n\,. \tag{17}$$

Then

$$\delta\tilde{\varphi}=\frac{1}{q\mu_nn_n}J_1+\frac{1}{n_n}J_2\,, \tag{18}$$

where

$$\begin{aligned}J_1&=\int_0^{x_b}\tilde{I}_n dx\\&\simeq\tilde{I}_0x_b-\tilde{I}_{p0}L_p/(1+i\omega\tau_p)^{1/2}\,,\end{aligned} \tag{19}$$

$$\begin{aligned}J_2&=\int_0^{x_b}\tilde{n}\frac{d\bar{\varphi}_n}{dx}dx\\&\simeq\frac{p_1}{q\mu_nn_n}\left(-\frac{\bar{I}_0L_p}{\sqrt{1+i\omega\tau_p}}+\frac{\bar{I}_{p0}L_p}{1+\sqrt{1+i\omega\tau_p}}\right).\end{aligned} \tag{20}$$

The aprroximations are for the case when $x_b\gg L_p$.

The impedance of the n-region, Z_n, is

$$\begin{aligned} Z_n &= \delta\tilde{\varphi}_n / I\,, \\ &= Z_{n1} + Z_{n2} + Z_{n3}\,, \end{aligned} \tag{21}$$

where

$$Z_{n1} = \frac{x_b}{q\mu_n n_n} \tag{22}$$

$$\begin{aligned} Z_{n2} &= -\frac{L_p}{q\mu_n n_n} \frac{\tilde{I}_{p0}}{\tilde{I}_0} \frac{1}{\sqrt{1+i\omega\tau_p}} \\ &= -\frac{L_p}{q\mu_n n_n} \frac{1}{1+\tilde{I}_{n0}/\tilde{I}_{p0}} \frac{1}{\sqrt{1+i\omega\tau_p}}\,, \end{aligned} \tag{23}$$

$$\begin{aligned} Z_{n3} &= -\frac{L_p}{q\mu_n n_n n_n} p_1 \left(\frac{\bar{I}_0}{\tilde{I}_0} \frac{1}{\sqrt{1+i\omega\tau_p}} - \frac{\bar{I}_{p0}}{\tilde{I}_0} \frac{1}{1+\sqrt{1+i\omega\tau_p}} \right) \\ &= -\frac{L_p}{q\mu_n n_n} \frac{p_0}{n_n} \frac{1}{1+\tilde{I}_{n0}/\tilde{I}_{p0}} \\ &\quad \times \left[\left(1 + \frac{\bar{I}_{n0}}{I_{p0}} \right) \frac{1}{1+i\omega\tau_p} \right. \\ &\quad \left. - \frac{1}{(1+\sqrt{1+i\omega\tau_p})\sqrt{1+i\omega\tau_p}} \right]. \end{aligned} \tag{24}$$

Z_{n1} is purely resistive and its magnitude is what is expected from conductivity, $q\mu_n n_n$, and length, x_b, of the n-region. The magnitude-determining factor in Z_{n2}, $L_p/(q\mu_n n_n)$, is the resistance of bulk semiconductor whose conductivity is $q\mu_n n_n$ and length L_p. Namely only that part of the n-region which lies within L_p from the barrier layer contributes to this term. The phase factor of Z_{n2} is the same as that of the junction impedance with its sign reversed. Hence, Z_{n2} has an inductive reactance. Z_{n3} is also an inductive impedance but it has another factor, p_0/n_n, which is the ratio of the injected hole density to the thermal equilibrium electron density, P,

$$P \equiv p_0/n_n\,. \tag{25}$$

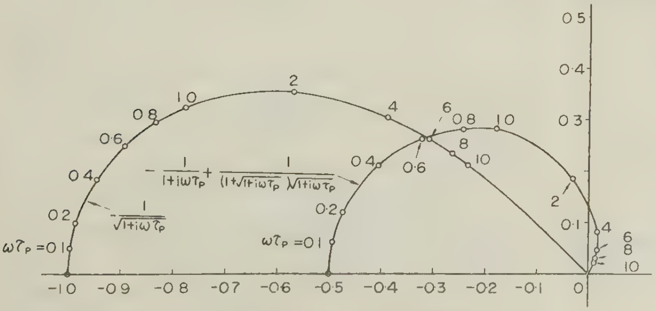

Fig. 2. Bulk impedance of the alloyed junction diode plotted on the complex plane with frequency as a parameter.

The radio of three terms is

$$|Z_{n1}| : |Z_{n2}| : |Z_{n3}| \sim x_b/L_p : 1 : P\,. \tag{26}$$

The impedance of the p-region is obtained by interchanging n and p,

$$\begin{aligned} Z_p &= \delta\tilde{\varphi}_p / \tilde{I} \\ &= Z_{p1} + Z_{p2} + Z_{p3}\,, \end{aligned} \tag{27}$$

where

$$Z_{p1} = \frac{x_a}{q\mu_p p_p}\,, \tag{28}$$

$$Z_{p2} = -\frac{L_n}{q\mu_p p_p} \frac{1}{1+\tilde{I}_{p0}/\tilde{I}_{n0}} \frac{1}{\sqrt{1+i\omega\tau_p}}\,, \tag{29}$$

$$\begin{aligned} Z_{p3} &= -\frac{L_n}{q\mu_p p_p} \frac{n_0}{p_p} \frac{1}{1+\tilde{I}_{p0}/\tilde{I}_{n0}} \\ &\quad \times \left[\left(1 + \frac{\bar{I}_{p0}}{I_{n0}} \right) \frac{1}{1+i\omega\tau_n} \right. \\ &\quad \left. - \frac{1}{(1+\sqrt{1+i\omega\tau_n})\sqrt{1+i\omega\tau_n}} \right]. \end{aligned} \tag{30}$$

Their ratio is

$$|Z_{p1}| : |Z_{p2}| : |Z_{p3}| \sim x_a/L_n : 1 : N\,, \tag{31}$$

where

$$N \equiv n_0/p_p\,. \tag{32}$$

For the symmetrical p–n junction where $I_{n0} = I_{p0}$,

$$Z_{n2} = -\frac{1}{2} \frac{L_p}{q\mu_n n_n} \frac{1}{\sqrt{1+i\omega\tau}}\,, \tag{33}$$

$$\begin{aligned} Z_{n3} &= -\frac{L_p}{q\mu_n n_n} \frac{p_0}{n_n} \\ &\quad \times \left(\frac{1}{1+i\omega\tau} - \frac{1}{2} \frac{1}{(1+\sqrt{1+i\omega\tau})\sqrt{1+i\omega\tau}} \right) \end{aligned} \tag{34}$$

and the similar ones for the p-region, where

$$\tau = \tau_n = \tau_p\,.$$

In the alloy junction in which p-region is heavily doped, most of the current through the junction is carried by holes, i.e.,

$$I_0 = I_{p0}\,.$$

The p-region impedance is negligible and the n-region one is

$$Z_{n2} = -\frac{L_p}{q\mu_n u_n} \frac{1}{\sqrt{1+i\omega\tau_p}}\,, \tag{35}$$

$$\begin{aligned} Z_{n3} &= -\frac{L_p}{q\mu_n n_n} \frac{p_0}{n_n} \times \left(\frac{1}{1+i\omega\tau_p} \right. \\ &\quad \left. - \frac{1}{(1+\sqrt{1+i\omega\tau_p})\sqrt{1+i\omega\tau_p}} \right). \end{aligned} \tag{36}$$

In Fig. 2, Eqs. (35) and (36) are plotted on the complex plane with frequency as a parameter.

§ 4. Discussion

In order to obtain more understanding on the subject, we shall investigate the inductive nature of the bulk impedance from another standpoint. We consider the transient response after the sudden increase of bias current.

First consider the steady state of a forward biased junction diode. In a junction diode which is biased in the direction of easy flow, the minority carrier densities have maxima on the both sides of the barrier layer and decrease monotonically with the distance from it. The minority carriers flow away from the barrier by the diffusion process, the rate of which is determined by their concentration gradients. On the other hand the majority carrier flow must be in the direction to the barrier in order to supply the opposite region of the barrier with the minority carriers. This direction of majority carrier flow is opposite to what is expected from the distribution and the diffusion process, for the majority carrier distribution which has the same gradient with that of minority carriers owing to the electrical neutrality condition is favorable to flowing-away from the barrier. Actually an electric field exists in the bulk semiconductor and produces the drift current to overshadow the diffusion component of the majority carrier current. The effect of this field on the minority carrier flow is negligible at small currents, because the drift current is proportional to the carrier density and the minority carrier density is much smaller than that of the majority carriers at low level. Thus the minority carrier current is by diffusion and the majority one is by drift. When injection level rises and the density of injected minority carriers becomes comparable to the thermal equilibrium one of majority carriers, the field which corrects the direction of the majority carrier flow grows up and its effect on the minority carriers becomes appreciable. Thus at high injection level the minority carrier current is composed of diffusion and drift components, both of which are of comparable magnitude and have the *same* flow direction.

Now let us consider the transient after the bias current through the diode is suddenly increased by ΔI. At the moment just after the application of the step current, the distributions of minority carriers and hence the minority carrier currents remain unchanged. ΔI is carried only by majority carriers. For example, in the n-region, p and I_p remain unchanged but I_n increases immediately by ΔI, since the electron current in the n-region is by drift and can change its magnitude in a very short time by an inertia-less change in the field. In the differential of Eq. (1),

$$\Delta I_n = -q\mu_n\left(\Delta n\cdot \frac{d\varphi_n}{dx} + n\cdot\Delta\frac{d\varphi_n}{dx}\right), \tag{37}$$

$\Delta I_n = \Delta I$ is responsible for the immediate increase in $|\Delta(d\varphi_n/dx)|$,

$$\begin{aligned}|\Delta(d\varphi_n/dx)|_{t=0} &\equiv \Delta(d\varphi_n/dx)_1 \\ &= \Delta I/q\mu_n n\,,\end{aligned} \tag{38}$$

with $\Delta n=0$, where Δ designates the change after the increase in I. Similarly in the p-region, the hole current increases immediately and the rate of hole injection into the n-region rises suddenly. These extra holes which are due to the increased rate of injection begin to increase p and I_p in the n-region. This re-distribution of holes is by the slow process of diffusion. At the same time Δn increases and ΔI_n decreases gradually, due to the electrical neutrality condition and the constancy of current through the diode, respectively. This stage of transient is charging-up of the so-called diffusion capacitance of the junction. Finally all quantities assume new values which correspond to the new value of current. Increase in Δn and decrease in ΔI_n during the whole transient entail the decrease in $|\Delta(d\varphi_n/dx)|$ from its initial value just after the application of the step current. Namely $|\Delta(d\varphi_u/dx)|$ decreases from its initial value given by Eq. (38) by

$$\Delta(d\varphi_n/dx)_2 = (\Delta I_p)_{t=\infty}/q\mu_n n \tag{39}$$

due to the gradual decrease in ΔI_n by $(\Delta I_p)_{t=\infty}$, and by

$$\Delta(d\varphi_n/dx)_3 = (\Delta n)_{t=\infty}|(d\varphi_n/dx)|/n \tag{40}$$

due to the gradual increase in n by

$$(\Delta n)_{t=\infty} = (\Delta p)_{t=\infty}\,.$$

This behavior of the gradual decrease after the sudden increase in $\delta\varphi_n$ after the application of the step current means that the small signal impedance of the n-region has an inductive reactance. It is shown in Appendix II that $\Delta(d\varphi_n/dx)_1$ is due to a pure resistance and $\Delta(d\varphi_n/dx)_2+\Delta(d\varphi_n/dx)_3$ to an impedance which has a negative resistance and inductive reactance at least at low frequencies. As is easily seen from their deduction, Z_{n2} in § 3 originates from the decrease in ΔI and Z_{n3} from the increase in Δn.

As is seen from the last part in Appendix II, integration and division by ΔI of Eqs. (38), (39), and (40) determine the magnitudes of Z_{n1}, Z_{n2}, and Z_{n3}, respectively. Using this, we can estimate the dependency of the latter upon the injection level. $(\Delta I_p)_{t=\infty}$ and ΔI are proportional to P, as is seen from Eqs. (9) and (12) and their counterparts for electrons. Therefore as long as the injection level is low, i.e. $n\simeq n_n$, $\Delta(d\varphi_n/dx)_2$ is proportional to, and the magnitude-determing factor in Z_{n2} is independent of P. As for $\Delta(d\varphi_n/dx)_3$, both Δn and $d\varphi_n/dx$ are proportional to P, and so Z_{n3} to P. When we substantialize this idea analytically for the alloy diode for example, the following expressions are obtained.

$$\frac{\Delta\varphi_{n1}}{\Delta I}=\frac{x_b}{q\mu_n n_n}\left[1-\frac{L_p}{x_b}\ln(1+P)\right], \qquad (41)$$

$$\frac{\Delta\varphi_{n2}}{\Delta I}=\frac{L_p}{q\mu_n n_n}\frac{\ln(1+P)}{P}, \qquad (42)$$

and

$$\frac{\Delta\varphi_{n3}}{\Delta I}=\frac{L_p}{q\mu_n n_n}\left[1-\frac{\ln(1+P)}{P}\right], \qquad (43)$$

where we took into account the conductivity modulation and used

$$\begin{aligned} n&=n_n+(p-p_n)\\ &=n_n(1+P\exp(-x/L_p)) . \end{aligned} \qquad (44)$$

These can als be obtained if we set $\omega=0$ in the calculation in § 3 and use Eq. (44). In the limit of $P\to 0$ they are in accordance with the results in § 3.

When injection level rises, the minority carrier current is enhanced by the above-mentioned electric field to a considerable degree. This changes the dependency on P of the quantities used in the calculation in the preceding paragraph and the rate at which the transient proceeds. But correction factors which are due to modification of the continuity equation, may be of the order of unity. This is analogized from the high level behavior of the emitter junction of a transistor. In the emitter junction those deviations from the low level expressions which are to the field (excluding other high level effects) did originate from the doubled effective diffusion constant of the minority carrier in the base region and were at most by a factor of 2.[3] In an (alloy) junction diode the situation is indeed, somewhat different from that in the emitter junction in a transistor. In a transistor the minority carrier distribution in the base region is artificially determined by another negatively biased junction (collector) which is near enough to the emitter for the ratio of minority carrier current density to majority carrier current density to be nearly constant and very large throughout the base region. While in the diode it is determined by the natural recombination of the injected minority carriers in the course of diffusion and drift away from the barrier and the whole current is carried by majority carriers at last, however high the injection efficiency may be. These differences are reflected in the diffusion capacitance. In the emitter junction the charge of the injected minority carriers in the base region behaves as if it were the charge on one of the condenser plates and the diffusion capacitance is obtained by differentiating it with the emitter bias[3] while in the diode only a part of the injected carriers is active and the capacitance is a half of the charge differentiated with bias.[4] This shows, however, the difference is not drastic and we can guess the behavior of a diode with the aids of knowledge of transistors. Therefore we are safe in concluding that the frequency and P dependencies of Z_n do not appreciably deviate from the results in § 3 and the preceding paragraph.

In this point it may be of interest to compare this bulk impedance with that of the junction proper, Z_j,

$$\begin{aligned} Z_j&=\delta\tilde{\varphi}_j/\tilde{I}_0\\ &=(\delta\tilde{\varphi}_j/\tilde{I}_{p0})/(1+\tilde{I}_{n0}/\tilde{I}_{p0})\\ &\simeq\frac{L_p}{q\mu_n p_0}\frac{1}{1+\tilde{I}_{n0}/\tilde{I}_{p0}}\frac{1}{\sqrt{1+i\omega\tau_p}} . \end{aligned} \qquad (45)$$

For the alloy junction

$$\begin{aligned} Z_j&=\frac{L_p}{q\mu_n p_0}\frac{1}{\sqrt{1+i\omega\tau_p}}\\ &=\frac{L_p}{q\mu_n n_n}\frac{1}{P}\frac{1}{\sqrt{1+i\omega\tau_p}} . \end{aligned} \qquad (46)$$

Therefore we have

$$|Z_{n2}|:|Z_{n3}|:|Z_j| \sim \frac{\ln(1+P)}{P} : \left[1-\frac{l(1n+P)}{P}\right] : \frac{1}{P} \,. \tag{47}$$

In Fig. 3 we show the P-dependent factors in Z's. At low injections level ($P \ll 1$), where the above calculations are valid rigorously, Z_j and $Z_{n1}+Z_{p1}$ are predominant and the equivalent circuit of the whole diode is a series connection of a capacitive impedance and a pure resistance. As level rises, the junction impedance becomes less and less important and the reactance of the whole diode is turned inductive, as is seen from Fig. 3. For $P \gtrsim 1$, Z_j decreases in a slower rate than the low level expression, Eq. (46), predicts, mainly due to the decrease in minority carrier injection. In this case also the essential nature of Eq. (45) does not change substantially, in the light of the behhavior of the emitter junction of the transistor.[3] It is very probable that at high injection level the reactance of the whole diode becomes inductive. Actually the inductive nature of the impedance of the junction diode was observed by many workers[6-8] at large bias currents.

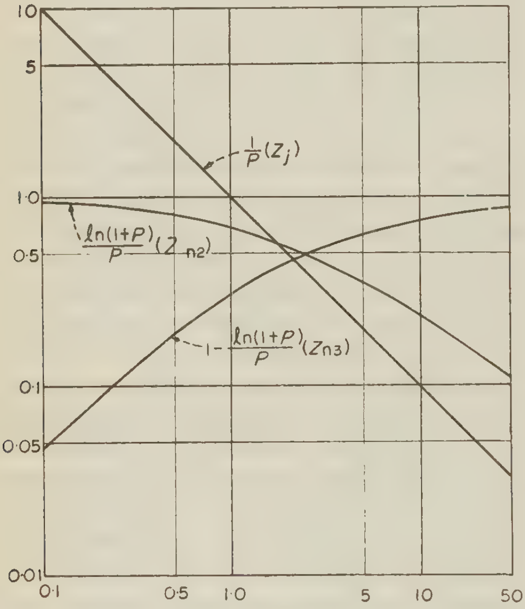

Fig. 3. Variation of Z_{n2}, Z_{n3} and Z_j with the injection level, P, for an alloy diode.

§ 5. Conclusion

The small signal impedance of bulk semiconductor in a junction diode was shown to have an inductive reactance by using the low level formulae. Although the reactance is small compared to the resistive part of the impedance, it becomes comparable to the junction impedance and makes the impedance of the whole diode reactive, as the injection level rises.

Appendix I

In this Appendix we prove that the current in semiconductor is source-free, i.e. constant in one dimension. The continuity equations for electrons and holes are

$$\frac{\partial n}{\partial t} = q_n + \frac{1}{q} \operatorname{div} I_n \,, \tag{A1}$$

$$\frac{\partial p}{\partial t} = q_p - \frac{1}{q} \operatorname{div} I_p \,, \tag{A2}$$

where g_n and g_p are the rates of generation for electrons and holes. The time-dependent parts in n and p are equal according to the electrical neutrality condition,

$$\frac{\partial n}{\partial t} = \frac{\partial p}{\partial t} \,.$$

The generation in this case is the mutual recombination of electrons and holes, therefore the rates are equal,

$$g_n = g_p \,.$$

Subtracting Eq. (A2) from Eq. (A1), we obtain

$$\operatorname{div}(I_n + I_p) = 0 \,,$$

which was to be proved.

Appendix II

We shall investigate the nature of an impedance $Z(i\omega)$, when the voltage, $v(t)$, developed on it increases suddenly by v_1 and later decreases gradually by v_2 after the application of unit step current as shown in Fig. 4.

According to the Laplace transform theory,[9] there exists the relation,

$$Z(s)(1/s) = \mathscr{L}[v(t)] \,, \tag{A3}$$

where $\mathscr{L}$ is the operator for the Laplace transformation, s the complex variable in the Laplace transform and $1/s$ the Laplace transform of the unit step function. Upon differentiating Eq. (A3) with t, we obtain

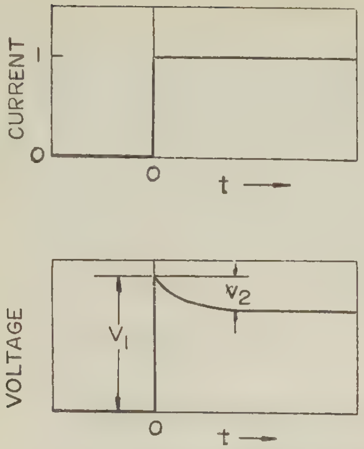

Fig. 4. Transient voltage developed on $Z(i\omega)$ after the application of unit step current.

$$Z(s)-v(0)=\mathscr{L}[v'(t)],$$

or

$$Z(s)=\int_0^\infty v'(t)\,e^{-st}\,dt+v_0\,. \qquad (A4)$$

The second term means that $Z(i\omega)$ has a component of pure resistance, which originates from the initial increase of the voltage developed on the impedance. The first term is analysed as was done by Shockley in discussing the negative resistance in a transistor structure.[10] The resistance part is

$$\mathrm{Re}[Z(i\omega)]=\frac{1}{2}\int_0^\infty v'(t)\cos\omega t\,dt$$
$$=-\frac{1}{2}\,\frac{1}{\omega}\int_0^\infty v''(t)\sin\omega t\,dt \qquad (A5)$$

and the reactance part is

$$\mathrm{Im}[Z(i\omega)]=-\frac{1}{2}\int_0^\infty v'(t)\sin\omega t\,dt\,. \qquad (A6)$$

All that we know is that $v'(t)<0$ for $t>0$. If the transient substantially finishes in the first half cycle of sine function, Eq. (A6) becomes positive and the reactance is inductive, and for such a low frequency that the transient fades away in the first quarter of the cosine function the resistance is negative. This is easily seen with the aid of Fig. 5. At higher frequencies we cannot obtain a definite conclusion only from negative $v'(t)$ for $t>0$; we must know the detail about the decrease rate of $v(t)$.[10] Anyway an impedance has the negative resistance and the inductive reactance at least for low frequencies, when its transient behavior is as shown in Fig. 4. The impedance of bulk semiconductor which was discussed in the text is of this kind.

Now we shall find the initial and final value of the voltage developed on Z_n in Eqs. (21), (22), (35), and (36) for an alloy diode when unit step current is applied. When $F(s)$ is the Laplace transform of $g(t)$, the following relations are valid.[11]

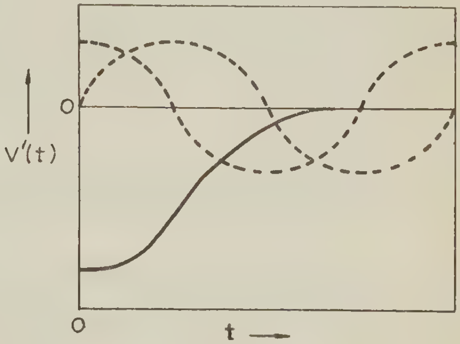

Fig. 5. Factors of integrands in Eqs. (A 5) and (A 6) for a small value of ω.

$$\lim_{s\to 0} sF(s)=\lim_{t\to\infty} g(t)$$

and

$$\lim_{s\to\infty} sF(s)=g(+0)\,.$$

Applying these relations to Eq. (A3) with $Z=Z_n$, one obtains

$$v_1=Z_n(\omega\to\infty)$$
$$=Z_{n1} \qquad (A7)$$

and

$$v_1-v_2=Z(\omega=0)$$
$$=Z_{n1}-\frac{L_p}{q\mu_n n_n}-\frac{1}{2}\,\frac{L_p}{q\mu_n n_n}P$$

or

$$v_2=\frac{L_p}{q\mu_n n_n}+\frac{1}{2}\,\frac{L_p}{q\mu_n n_n}P\,. \qquad (A8)$$

Rotational Lattice Vibration in Complex Crystals

Part II. Vibrational Modes in Optical Branches and Interaction with a Conduction Electron

Sumitada ASANO and Yasuo TOMISHIMA
Department of Physics, Faculty of Science, Okayama University

(Received April 3, 1957)

Under the assumption that the anionic radical may be regarded as a rigid symmetric rotor, both the translational and the rotational lattice vibrations in the optical branches, which may be excited in isotropic complex crystals, are described on a macroscopic basis. By using the results obtained on it, the relative magnitudes of the mechanical and the radiative energy densities in the crystal are discussed for transverse vibrational modes. In addition, the interaction of a conduction electron witn the rotational lattice vibration is investigated on the standpoint that the radiation field serves as a medium of the interaction.

§ 1. Introduction

In the previous part¹⁾, we have investigated the modes of the rotational lattice vibrations in complex crystals by using the one-dimensional lattice and its effects upon the specific heat at low temperatures. This part deals with (1) the macroscopic theory of the translational and rotational lattice vibrations in optical branches which may be excited in isotropic complex crystals; the natural generalization of the Huang's theory on the translational optical lattice vibrations in simple ionic crystals, (2) the relative magnitudes of the mechanical (translational and rotational) and the radiative energy densities in the crystal which intermix with each other in the transverse lattice vibrations, and (3) the interaction of a conduction electron with the rotational lattice vibration in the optical branch.

Here we will concern ourselves only with the iosotropic complex crystals, whose unit cell consists of a point-like cation and a rigid anionic radical with central symmetry. Then we have no need to take into account the RA-branch (that is, the acoustical branch in the rotational mode), as shown in part I¹⁾.

§ 2. Lattice Vibrations in the Optical Branches

Just as in the case of isotropic simple crystals²⁾, for isotropic complex ones the macroscopic theory of the translational vibration is also fully embodied in the following equations:

$$\ddot{\boldsymbol{w}}=b_{11}\boldsymbol{w}+b_{12}\boldsymbol{E}\,, \tag{2.1a}$$

$$\boldsymbol{P}=b_{21}\boldsymbol{w}+b_{22}\boldsymbol{E}\,, \tag{2.1b}$$

where $b_{11}=-\omega_{tt}{}^2$, $b_{12}=b_{21}=\left(\frac{\varepsilon_0-\varepsilon_\infty}{4\pi}\right)^{1/2}\omega_{tt}$, $b_{22}=\frac{\varepsilon_\infty-1}{4\pi}$, and

$$\boldsymbol{w}=\eta\sqrt{N'\overline{M}}\,. \tag{2.2}$$

E and ***P*** are the macroscopic electric field and the macroscopic dielectric polarization in the crystal, respectively. ω_{tt} is the Reststrahlen frequency, and $\mathcal{E}_0$ and $\mathcal{E}_\infty$ are the static and the optical dielectric constants respectively. η is the displacement of a cation relative to the adjacent radical, N' the number of cation-radical pairs per unit volume, and $\overline{M}$ the reduced mass of the cation and the radical.

In quite a similar manner, the macroscopic theory of the rotational lattice vibration may be embodied in the following equations:

$$\ddot{\boldsymbol{u}}=c_{11}\boldsymbol{u}-c_{12}\boldsymbol{H}\,, \tag{2.1c}$$

$$\boldsymbol{I}=c_{21}\dot{\boldsymbol{u}}\,, \tag{2.1d}$$

where

$$c_{11}=-\omega_{rt}{}^2\,,\qquad \boldsymbol{u}=\Theta\sqrt{N'I}\,,$$

$$c_{21}=\frac{\beta_M}{\hbar}\sqrt{N'I}\,,\qquad \beta_M=\frac{Z_c e\hbar}{2M_c c}\,. \tag{2.3}$$

$\boldsymbol{H}$ and $\boldsymbol{I}$ are the macroscopic magnetic field and the macroscopic magnetization in the crystal respectively. Θ is the angular displacement[1] of each radical with the moment of inertia I. $\boldsymbol{I}$ is induced by the rotational vibration of the radicals, then c_{21} may be derived on the basis that the symmetric radical which has some point-like coordinated ions with mass M_c and effective charge $Z_c e$ (e: electronic charge), rotates around the center of mass with the angular velocity $\dot{\Theta}$. In reality, the deformation of the electron cloud on the radical will influence the magnetic moment induced by the rotation of the radical, but this effect may be ignored here since they are quite negligible on account of the smallness of the electronic polarizability of the ions. The physical meaning of ω_{rt} and the value of c_{12} are discussed later. (cf. Fig. 1 and (3.12))

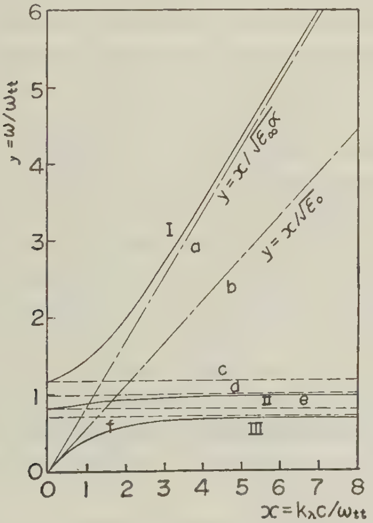

Fig. 1. Optical waves and lattice vibrations.

a: light wave (trans.) without dispersion.
b: light wave (trans.) with dispersion at long-wave limit.
c: translational lattice vibration (long.)
d: 〃 〃 〃 (trans.) ...approx.
e: rotational lattice vibration (long.)
f: 〃 〃 〃 (trans.) ...approx.

$\varepsilon_0=3.2$, $\varepsilon_\infty=2.0$, $\alpha=0.7$, $\sigma=0.5$

Let us seek the solutions, which satisfy the joint set of the lattice equations (2.1a, b c and d) and the following electromagnetic equations,

$$\operatorname{div}\boldsymbol{D}=0\,, \tag{2.4a}$$

$$\operatorname{div}\boldsymbol{B}=0\,, \tag{2.4b}$$

$$c\operatorname{curl}\boldsymbol{E}=-\dot{\boldsymbol{B}}\,, \tag{2.4c}$$

$$c\operatorname{curl}\boldsymbol{H}=\dot{\boldsymbol{D}}\,, \tag{2.4d}$$

$$\boldsymbol{D}=\boldsymbol{E}+4\pi\boldsymbol{P}\,,\quad \boldsymbol{B}=\boldsymbol{H}+4\pi\boldsymbol{I} \tag{2.4e}$$

and have the following sinusoidal forms:

$$\left.\begin{aligned}\boldsymbol{w}&=\boldsymbol{w}_0\\ \boldsymbol{P}&=\boldsymbol{P}_0\\ \boldsymbol{E}&=\boldsymbol{E}_0\\ \boldsymbol{u}&=\boldsymbol{u}_0\\ \boldsymbol{I}&=\boldsymbol{I}_0\\ \boldsymbol{H}&=\boldsymbol{H}_0\end{aligned}\right\}\times\exp\left[i(\boldsymbol{k}_\lambda\boldsymbol{r}-\omega t)\right]\,. \tag{2.5}$$

Substituting (2.5) into (2.1a and c), we obtain

$$\boldsymbol{w}=\frac{b_{12}}{-\omega^2-b_{11}}\boldsymbol{E}\,, \tag{2.6a}$$

$$\boldsymbol{u}=\frac{-c_{12}}{-\omega^2-c_{11}}\dot{\boldsymbol{H}}\,. \tag{2.6b}$$

Inserting (2.6a and b) into (2.1b and d) respectively, we obtain

$$\boldsymbol{P}=\left[b_{22}+\frac{b_{12}b_{21}}{-\omega^2-b_{11}}\right]\boldsymbol{E}\,, \tag{2.7a}$$

$$\boldsymbol{I}=\left[\frac{c_{12}c_{21}\omega^2}{-c_{11}-\omega^2}\right]\boldsymbol{H}\,. \tag{2.7b}$$

Using (2.7) and (2.5), we may transform (2.4) as follows.

$$(\boldsymbol{k}_\lambda\boldsymbol{E})\left[1+4\pi b_{22}+\frac{4\pi b_{12}b_{21}}{-b_{11}-\omega^2}\right]=0\,, \tag{2.8a}$$

$$(\boldsymbol{k}_\lambda\boldsymbol{H})\left[1+\frac{4\pi c_{12}c_{21}\omega^2}{-c_{11}-\omega^2}\right]=0\,, \tag{2.8b}$$

$$[\boldsymbol{k}_\lambda,\boldsymbol{E}]=\frac{\omega}{c}\left(1+\frac{4\pi c_{12}c_{21}\omega^2}{-c_{11}-\omega^2}\right)\boldsymbol{H}\,, \tag{2.8c}$$

$$[\boldsymbol{k}_\lambda, \boldsymbol{H}] = -\frac{\omega}{c}\left(1+4\pi b_{22}+\frac{4\pi b_{12}b_{21}}{-b_{11}-\omega^2}\right)\boldsymbol{E}\,. \tag{2.8d}$$

ω satisfying (2.8a, b, c and d) simultaneously may be obtained as follows[3]:

(I) When

$$1+4\pi b_{22}+\frac{4\pi b_{12}b_{21}}{-b_{11}-\omega^2}=0\,.$$

$$\omega^2=\left(\frac{\varepsilon_0}{\varepsilon_\infty}\right)\omega_{tt}^2\equiv\omega_{tl}^2\,. \tag{2.9}$$

Then

$$\boldsymbol{u}=\boldsymbol{I}=\boldsymbol{H}=0 \quad \text{and} \quad \boldsymbol{k}_\lambda /\!/ \boldsymbol{E} /\!/ \boldsymbol{P} /\!/ \boldsymbol{w}\,.$$

In this case only the longitudinal translational mode with the frequency ω_{tl} may exist.

(II) When

$$1+\frac{4\pi c_{12}c_{21}\omega^2}{-c_{11}-\omega^2}=0\,,$$

$$\omega^2=\frac{\omega_{rt}^2}{\alpha}\equiv\omega_{rl}^2\,, \tag{2.10}$$

where

$$\alpha=1-4\pi c_{12}c_{21}\,. \tag{2.11}$$

Then

$$\boldsymbol{w}=\boldsymbol{P}=\boldsymbol{E}=0 \quad \text{and} \quad \boldsymbol{k}_\lambda /\!/ \boldsymbol{H} /\!/ \boldsymbol{I} /\!/ \boldsymbol{u}\,.$$

In this case only the longitudinal rotational mode with the frequency ω_{rl} may appear.

(III) When $(\boldsymbol{k}_\lambda\boldsymbol{E})=0$ and $(\boldsymbol{k}_\lambda\boldsymbol{H})=0$, $(\boldsymbol{E}\boldsymbol{H})=0$ are concluded from (2.8c). Therefore, if we eliminate $\boldsymbol{E}$ and $\boldsymbol{H}$ from the equations (2.8c) and (2.8d), then we obtain

$$\frac{k_\lambda^2c^2}{\omega^2}=\left(\varepsilon_\infty+\frac{\varepsilon_0-\varepsilon_\infty}{\omega_{tt}^2-\omega^2}\omega_{tt}^2\right)\left(1+\frac{1-\alpha}{\omega_{rt}^2-\omega^2}\omega^2\right)\,. \tag{2.12}$$

This equation gives three branches of ω as a function of k_λ. At $k_\lambda=0$, (2.12) has three roots 0, ω_{rl} and ω_{tl}, and for $k_\lambda\to\infty$, there are also three types of solutions $\omega\to\omega_{rt}$, $\omega\to\omega_{tt}$, $\omega\to\infty\left(=\frac{c}{\sqrt{\varepsilon_\infty\alpha}}k_\lambda\right)$. For the question which one of the former three ω values at $k_\lambda=0$ continues to one of the latter three ω values for $k_\lambda\to\infty$, we cannot answer in general. There are several cases according as the magnitudes of ω_{tt}, ω_{tl}, ω_{rt} and ω_{rl}, and one example is shown in Fig. 1 for a set of given values of ε_0, ε_∞, α and $\kappa_t\equiv(\omega_{rt}/\omega_{tt})^2$. Hereafter, when we want to discuss the characters of these six branches for the limiting cases $k\to0$ and $k_\lambda\to\infty$, we will call them 0-, ω_{rl}- and ω_{tl}-branches (for $k_\lambda\to0$) and ω_{rt}-, ω_{tt}-, and ∞-branches (for $k_\lambda\to\infty$).

In this case, non vanishing $\boldsymbol{E}$, $\boldsymbol{H}$, $\boldsymbol{w}$ and $\boldsymbol{u}$ are all perpendicular to $\boldsymbol{k}_\lambda$, so there must coexist the electromagnetic wave, the transverse translational and the transverse rotational lattice vibrations.

§ 3. Equations of Motion

As well known, the effective electric field $\boldsymbol{E}_{\text{eff}}$ exerted on a particular cation of radical is related to the macroscopic field $\boldsymbol{E}$ by

$$\boldsymbol{E}_{\text{eff}}=\boldsymbol{E}+\frac{4\pi}{3}\boldsymbol{P} \tag{3.1}$$

and the equation of translational motion of a cation-radical pair is written as

$$\overline{M}\ddot{\boldsymbol{\xi}}=-k_t\boldsymbol{\xi}-Ze\boldsymbol{E}_{\text{eff}}\,, \tag{3.2}$$

where we have used for the later convenience $\boldsymbol{\xi}=-\boldsymbol{\eta}$; that is, the displacement of the radical relative to the adjacent cation, and Ze is the effective charge of the cation. (e: electronic charge, $Z<0$)

The first term on the right-hand side of (3.2) originates from the overlap forces and second term from all the elelctrostatic and the radiation field exerted on the cation-radical pair.

The equation of rotational motion of a particular radical may be written as

$$I\ddot{\boldsymbol{\Theta}}=-k_r\boldsymbol{\Theta}+Z_0e\sum_i[\boldsymbol{d}_i, \boldsymbol{E}_i]\,, \tag{3.3}$$

where $\boldsymbol{d}_i(|\boldsymbol{d}_i|=d)$ is the vector pointing from the center of the radical to the ith coordinated ion in the equilibrium orientation and $\boldsymbol{E}_i$ is the electric field of the radiation field exerted upon the ith ion. The summation is to be extended over all the coordinated ions belonging to the radical under consideration. The first term on the right-hand side of (3.3) represents the moments of the overlap forces and all the electrostatic forces exerted on the radical from the other constituents of the crystal.

If we denote the electric field at the center of the radical by $\boldsymbol{E}$, then $\boldsymbol{E}_i$ is expressed as

$$\boldsymbol{E}_i=\sum_{n=0}\frac{1}{n!}(\boldsymbol{d}_i\nabla)^n\boldsymbol{E}\,, \tag{3.4}$$

and

$$\sum_i[\boldsymbol{d}_i, \boldsymbol{E}_i]=\sum_{n=0}\sum_i\left[\boldsymbol{d}_i, \frac{1}{n!}(\boldsymbol{d}_i\nabla)^n\boldsymbol{E}\right]\,. \tag{3.5}$$

The first term with $n=0$ will vanish because of the symmetry of the radical, and the second term with $n=1$ will give

$$\frac{1}{2}d^2k_c \operatorname{curl} \boldsymbol{E}\,, \tag{3.6}$$

where k_c is a numerical constant peculiar to the type of the symmetry. (cf. (3.12) of part I.)

Omitting the higher order terms, we may rewrite (3.3) in the following form.

$$\begin{aligned} I\ddot{\Theta} &= -k_r\Theta + \frac{I\beta_M c}{\hbar} \operatorname{curl} \boldsymbol{E} \\ &= -k_r\boldsymbol{\Theta} - \frac{I\beta_M}{\hbar}\dot{\boldsymbol{B}}\,, \end{aligned} \tag{3.7}$$

where the relation $I = k_c d^2 M_c$ is used.

(3.7) may be considered as the equation of rotational motion of a particular radical, which corresponds to (3.2) in the case of translational motion.

It is advisable here to mention some complementary explanations on the equations of motion (3.2) and (3.7). We have neglected in (3.2) all the interactions of the multipole moments on the radical with the effective field acting on it, and in (3.7) the interactions of the multipole moments of higher order on the radical both with radiation field and with the external electrostatic field from additional free charges such as conduction electrons, since these interactions would be much smaller than the others effective to the translational and rotational motions of the radical. However, it should be noted that the electrostatic interactions of the multipole moments on the radical with the other constituents of the crystals, in particular in its neighbourhood, are retained in the first term in the right-hand side of (3.7), since they have a considerable effect upon the rotational motion of the radical together with the overlap forces as a result of superposition of the interactions in accordance with the crystal symmetry. This will actually be shown in part III.

If we insert $\boldsymbol{E}$ given by (3.1) into (2.1a and b), and eliminate $\boldsymbol{P}$ from the resulting two equations by taking account of (2.2), we may get

$$\begin{aligned} \ddot{\eta} &= -\left(\frac{\varepsilon_0+2}{\varepsilon_\infty+2}\right)\omega_{tt}^2\eta \\ &\quad + \frac{1}{\sqrt{N'\overline{M}}}\frac{3\omega_{tt}}{\varepsilon_\infty+2}\left(\frac{\varepsilon_0-\varepsilon_\infty}{4\pi}\right)^{1/2}\boldsymbol{E}_{\text{eff}}\,. \end{aligned} \tag{3.8}$$

Comparing the coefficients of η in the equations (3.2) and (3.8), we have the well-known relation

$$k_t = \overline{M}\left(\frac{\varepsilon_0+2}{\varepsilon_\infty+2}\right)\omega_{tt}^2\,. \tag{3.9}$$

On the other hand, (2.1c) may easily be transformed as follows:

$$\ddot{\Theta} = -\omega_{rl}^2\Theta - \frac{c_{12}}{\alpha\sqrt{N'I}}\dot{\boldsymbol{B}}\,, \tag{3.10}$$

where we have taken account of (2.1d), (2.3), (2.4e), (2.10) and (2.11). If we compare the coefficients in the equations (3.7) and (3.10), we may obtain

$$k_r = I\omega_{rl}^2 = I\omega_{rt}^2/\alpha\,, \tag{3.11}$$

and

$$c_{12} = \alpha\frac{\beta_M}{\hbar}\sqrt{N'I} = \alpha c_{21}\,. \tag{3.12}$$

Combining (3.12) with the definition of α (2.11), we may estimate α as follows.

$$\alpha = (1 + 4\pi N' I \beta_M^2/\hbar^2)^{-1}\,. \tag{3.13}$$

From (2.1a) we can easily derive the macroscopic equations of translational motion. (cf. App. I) In a similar manner we can obtain as below the corresponding macroscopic equations of rotational motion, which will be utilized for the later discussion.

We may deduce from (2.46)

$$\boldsymbol{B}_l = \boldsymbol{H}_l + 4\pi\boldsymbol{I}_l = 0\,.$$

Then

$$\boldsymbol{H}(=\boldsymbol{H}_t + \boldsymbol{H}_l) = \boldsymbol{H}_t - 4\pi\boldsymbol{I}_l\,, \tag{3.14}$$

where the suffixes l and t indicate the irrotational and solenoidal parts of the vector to which they are appended, respectively. Substituting (3.14) into (2.1c) and using the relations (2.1d), (2.3) and (2.10), we immediately obtain the macroscopic equations of motion:

$$\ddot{\boldsymbol{Q}}_l + \omega_{rl}^2\boldsymbol{Q}_l = 0 \tag{3.15a}$$

and

$$\gamma_{rt}(\ddot{\boldsymbol{Q}}_t + \omega_{rt}^2\boldsymbol{Q}_t) = -\dot{\boldsymbol{H}}_t\,, \tag{3.15b}$$

where

$$\boldsymbol{Q} \equiv IN'\beta_M/\hbar\cdot\boldsymbol{\Theta} \tag{3.16a}$$

and

$$1/\gamma_{rt} \equiv \alpha IN'\beta_M^2/\hbar^2\,. \tag{3.16b}$$

Starting from (3.10), (3.15b) takes the alternative expression such as

$$\gamma_{rl}(\ddot{\boldsymbol{Q}}_t + \omega_{rl}\boldsymbol{Q}_t) = -\dot{\boldsymbol{B}}_t\,, \tag{3.15b$'$}$$

where

$$1/\gamma_{rl} = IN'\beta_M^2/\hbar^2 = (c_{21})^2\,. \tag{3.17}$$

§ 4. Energy Density

If we define the energy density U in the lattice under vibration by the equation;

$$\frac{c}{4\pi}\int \operatorname{div}[\boldsymbol{E},\boldsymbol{H}]\,d\tau=-\int\left(\frac{dU}{dt}\right)d\tau\,,$$

then with the help of the Maxwell equation we may obtain

$$\frac{dU}{dt}=\frac{1}{4\pi}(\boldsymbol{E}\dot{\boldsymbol{E}}+\boldsymbol{H}\dot{\boldsymbol{H}})+\boldsymbol{E}\dot{\boldsymbol{P}}+\boldsymbol{H}\dot{\boldsymbol{I}}\,. \tag{4.1}$$

It is clear from the lattice equations (2.1) that different volume elements are coupled in the macroscopic theory only through their electrostatic and electromagnetic interaction, thus dU/dt must be equal to the rate of change of the total energy, including the kinetic energy of the lattice particles as well as all the electromagnetic and potential energies in the system. U satisfying (4.1) is given by

$$U=E_M+(\boldsymbol{H}\boldsymbol{I})+\frac{1}{8\pi}(\varepsilon_\infty\boldsymbol{E}^2+\boldsymbol{H}^2)\,, \tag{4.2}$$

where

$$E_M\equiv\frac{1}{2}\,(\dot{\boldsymbol{w}}^2-b_{11}\boldsymbol{w}^2)+\frac{1}{2}\,(\dot{\boldsymbol{u}}^2-c_{11}\boldsymbol{u}^2)\,\frac{1}{\alpha}\,. \tag{4.3}$$

By differentiating (4.2) with respect to time and taking account of (2.1), we can easily verify that (4.2) actually satisfies (4.1). From (A1-2), (2.1c) and (3.14), we obtain, when there are no free charges,

$$\boldsymbol{E}_l=\frac{-4\pi b_{21}}{1+4\pi b_{22}}\,\boldsymbol{W}_l\,, \tag{4.4}$$

and

$$\boldsymbol{H}_l=-4\pi\boldsymbol{I}_l=-4\pi c_{21}\dot{\boldsymbol{u}}_l\,. \tag{4.5}$$

If each vector in (4.2) is decomposed into the irrotational and solenoidal parts and the relations (2.9), (2.10), (4.4) and (4.5) are used, we may write U in the form

$$\begin{aligned}U=&\frac{1}{2}\,(\dot{\boldsymbol{w}}_l^2+\omega_{tl}^2\boldsymbol{w}_l^2)+\frac{1}{2}\,(\dot{\boldsymbol{u}}_l^2+\omega_{rl}^2\boldsymbol{u}_l^2)\\&+\frac{1}{2}\,(\dot{\boldsymbol{w}}_t^2+\omega_{tt}^2\boldsymbol{w}_t^2)+\frac{1}{2}\,(\dot{\boldsymbol{u}}_t^2+\omega_{rl}^2\boldsymbol{u}_t^2)\\&+\frac{1}{8\pi}(\varepsilon_\infty\boldsymbol{E}_t^2+\boldsymbol{B}_t^2)\,.\end{aligned} \tag{4.6}$$

When the longitudinal vibrations do not exist, the first and second terms vanish and the energy density is simply given by

$$\begin{aligned}U_t=&\frac{1}{2}\,(\dot{\boldsymbol{w}}_t^2+\omega_{tt}^2\boldsymbol{w}_t^2)+\frac{1}{2}(\boldsymbol{u}_t^2+\omega_{rl}^2\boldsymbol{u}_t^2)\\&+\frac{1}{8\pi}(\varepsilon_\infty\boldsymbol{E}_t^2+\boldsymbol{B}_t^2)\end{aligned} \tag{4.7}$$

The first and second terms are the densities of the mechanical energies in the translational and rotational transverse vibrations respectively, whereas the last term represents the density of the radiative energy.

Inserting (2.6) and (2.7) into (4.7) and taking account of (2.8c), we easily obtain

$$\begin{aligned}8\pi U_t/\overline{\boldsymbol{H}_t^2}=&(\varepsilon_0-\varepsilon_\infty)\frac{(1+y)(\kappa_t-\alpha y)}{(1-y)(\kappa_t-y)(\varepsilon_0-\varepsilon_\infty y)}\\&+(1-\alpha)\frac{y(\kappa_t+\alpha y)}{(\kappa_t-y)^2}\\&+\left[\varepsilon_\infty\frac{(1-y)(\kappa_t-\alpha y)}{(\kappa_t-y)(\varepsilon_0-\varepsilon_\infty y)}+\frac{(\kappa_t-\alpha y)^2}{(\kappa_t-y)^2}\right],\end{aligned} \tag{4.8}$$

where

$$y\equiv(\omega/\omega_{tt})^2\,,\qquad \kappa_t\equiv(\omega_{rt}/\omega_{tt})^2$$

and $\overline{\boldsymbol{H}_t^2}$ means the time average of $\boldsymbol{H}_t^2$. The first and second terms of (4.8) correspond to the densities of translational and rotational mechanical energies respectively, and the last one in the square brackets to the density of the radiative energy. For the set of the values of ε_0, ε_∞, α and κ_t, L_m, the ratio of the mechanical (translational and rotational) energy to the total energy and L_r, that of the rotational energy to the total energy are plotted in Fig. 2 against wave-number for each one of the three branches given in Fig. 1, (L_m-L_r indicates the ratio of the translational energy to the total energy.) In Fig. 2, the three vertical distances between the

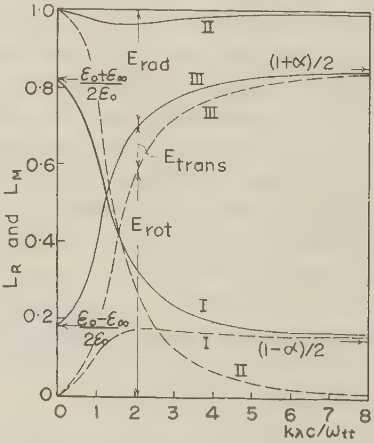

Fig. 2. Ratios of mechanical energy and rotational energy in the transverse modes.

$\varepsilon_0=3.2$, $\varepsilon_\infty=2.0$, $\alpha=0.7$, $\sigma=0.5$.
Real curves: L_m (mechanical energy/total energy)
Dotted curves: L_r (rotational energy/total energy)
The curve numbers correspond to those in Fig. 1.

base-line of the diagram and a dotted curve, between the dotted curve and the real curve with the same curve number, and between the real curve and the upside of the diagram indicate the ratios of the rotational, translational and radiative energies to the total energy for a particular transverse branch, respectively.

Referring to Fig. 2, we may point out in particular the following facts. In the ∞-branch, the radiative energy is predominant in short-wave region, that is, this branch represents the optical waves, whereas the ω_{tt}- and ω_{rt}-branches may be regarded as the translational and predominantly rotational lattice vibrations respectively, since the mechanical energy is predominant in short wave region of these branches. On the other hand, in long-wave region, the ω_{tl}- and ω_{rl}-branches are of predominantly translational and of rotational energies respectively, whereas in the 0-branch the radiative energy is predominant.

In short-wave region the rotational energy is not separated but mixed with the radiative one in the ω_{rt}- and ∞-branches, whereas the translational energy is lodged solely in the ω_{tt}-branch. On the other hand, in long-wave region the translational energy mixes with the radiative one in the ω_{tl}- and 0-branches, whereas the rotational energy is isolated in the other ω_{rl}-branch. As easily understood, the ratio ($\simeq(1-\alpha)/2$) of the radiative energy in the ω_{rt}-branch is markedly decreased when $\alpha(<1)$ approaches to unity, and the waves in this branch may be considered as purely mechanical rotational vibration with frequency ω_{rt}, which enables us to define the transverse rotational phonon.

§ 5. Interaction with a Conduction Electron

The interaction of a conduction electron with the translational lattice vibrations may be separated from that with the rotational ones as shown in (4.6) and treated by the usual manner. Hence we restrict ourselves to the optical modes of rotational vibration, assuming the constancy of the frequency.

Then the Hamiltonian of the system consisting of a conduction electron and the rotational phonon field is given by (cf. App. II)

$$
\begin{aligned}
H=&\frac{1}{2\kappa}\int[\boldsymbol{\pi}_t{}^2+\kappa^2c^2(\mathrm{curl}\,\boldsymbol{A}_t)^2]d\tau\\
&+\frac{1}{2\gamma_{rl}}\int[(\boldsymbol{P}_r-\mathrm{curl}\,\boldsymbol{A}_t)^2+\omega_{rl}{}^2\gamma_{rl}{}^2\boldsymbol{Q}^2]d\tau\\
&+\frac{1}{2m}\Big(\boldsymbol{p}_e-\frac{e}{c}\boldsymbol{A}_t(\boldsymbol{r}_e)\Big)^2\\
&-\boldsymbol{\mu}\cdot\mathrm{curl}\,\boldsymbol{A}_t(\boldsymbol{r}_e)\\
&+\frac{1}{2mc}\left[\boldsymbol{\mu},\frac{1}{c\kappa}\boldsymbol{\pi}_t(\boldsymbol{r}_e)\right]\boldsymbol{p}_e\,,
\end{aligned}
\tag{5.1}
$$

where $\boldsymbol{\mu}=\beta\boldsymbol{\sigma}$, $\kappa=1/4\pi c^2$ and $\boldsymbol{\sigma}$ is Pauli spin operator, β Bohr magneton. $(\boldsymbol{\pi}_t, \boldsymbol{A}_t)$ $(\boldsymbol{P}_r, \boldsymbol{Q})$ and $(\boldsymbol{p}_e, \boldsymbol{r}_e)$ are the sets of canonically conjugate momentum and coordinate of photon field, rotational phonon field, and electron respectively.

Making use of the Hamiltonian (5.1) we obtain the following field equations:

$$\Box\boldsymbol{A}_t=-\frac{4\pi e}{c}\dot{\boldsymbol{r}}_e{}^{(t)}\delta(\boldsymbol{r}-\boldsymbol{r}_e)-\frac{4\pi}{c}\boldsymbol{J}_s{}^{(t)}-\frac{4\pi}{c}\boldsymbol{J}_r\,, \tag{5.2}$$

and

$$\gamma_{rl}(\ddot{\boldsymbol{Q}}+\omega_{rl}{}^2\boldsymbol{Q})=-\mathrm{curl}\,\dot{\boldsymbol{A}}_t=c\,\mathrm{curl}\,\boldsymbol{E}_t\,, \tag{5.3}$$

where

$$\boldsymbol{J}_s{}^{(t)}=\frac{c}{4\pi}\Delta\boldsymbol{A}_s{}^{(m)}+\frac{1}{4\pi}\mathrm{curl}\,\dot{\boldsymbol{A}}_s{}^{(e)}\,, \tag{5.4}$$

$$\boldsymbol{J}_r=c\,\mathrm{curl}\,\dot{\boldsymbol{Q}}\,, \tag{5.5}$$

$$\boldsymbol{A}_s{}^{(m)}=\left[\boldsymbol{\mu},\,\mathrm{grad}_r\frac{1}{|\boldsymbol{r}-\boldsymbol{r}_e|}\right], \tag{5.6}$$

$$\boldsymbol{A}_s{}^{(e)}=\left[\frac{[\boldsymbol{\mu},\dot{\boldsymbol{r}}_e]}{2c},\,\mathrm{grad}_r\frac{1}{|\boldsymbol{r}-\boldsymbol{r}_e|}\right]. \tag{5.7}$$

$\dot{\boldsymbol{r}}_e{}^{(t)}$ means the solenoidal component of $\dot{\boldsymbol{r}}_e$. Here it should be noted that (5.3) is quite identical with the equations of motion (3.15a) and (3.15b)′.

Treating the interaction between the electron and the phonon as a perturbation, we can compute the probability when the electron absorbs or emits a phonon. Exactly speaking, this process is carried out by means of the interchange of virtual photons, so we need to calculated the second order perturbation. If we allow to neglect, however, the small contribution in transition probability, we may eliminate $\boldsymbol{A}_t$ from (5.1) by using (5.2).

Since the longitudinal rotational phonon does not interact with the radiation field and therefore also with the electron, we may consider only the transverse components of $\boldsymbol{P}_r$ and $\boldsymbol{Q}$. Introducting a solenoidal vector potential $\boldsymbol{A}_r$ such as

$$\dot{\boldsymbol{Q}}_t=\frac{1}{4\pi}\mathrm{curl}\,\boldsymbol{A}_r\,, \tag{5.8}$$

the Hamiltonian H can be transformed as follows.

$$H=H_0+H_{\text{int}}\,,$$

$$H_0=\frac{1}{2\gamma_{rl}}\int[\boldsymbol{P}_{rt}^2+\omega_{rl}\gamma_{rl}\boldsymbol{Q}_t^2]+\frac{1}{2m}\boldsymbol{p}_e^2\,, \tag{5.9}$$

$$H_{\text{int}}=-\frac{e}{c^2}\int\frac{\dot{\boldsymbol{r}}_e\boldsymbol{J}_r(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{r}_e|}d\tau-\frac{1}{c^2}\int\frac{\boldsymbol{J}_s^{(t)}(\boldsymbol{r}')\boldsymbol{J}_r(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{r}'|}d\tau d\tau' \tag{5.9a}$$

$$=-\frac{e}{mc}\boldsymbol{p}_e\boldsymbol{A}_r(\boldsymbol{r}_e)-\boldsymbol{\mu}\,\mathrm{curl}\,\boldsymbol{A}_r(\boldsymbol{r}_e)\,, \tag{5.9b}$$

where the self-energies of the electron and the phonon are neglected.

In (5.9a), the transverse rotational phonon field is destined to be purely mechanical vibration with the frequency ω_{rl}. This fact contradicts the conclusions of the last section that in short-wave region the transverse rotational branch i.e. ω_{rt}-branch has the frequencies near ω_{rt} somewhat different from ω_{rl}. (cf. the curve III in Fig. 1) and that it mixes with a considerable amount of radiative energy (cf. the dotted curve III in Fig. 2). However, $1/\gamma_{rl}\ll 1$ in actual complex crystals, as stated later. Then α is regarded as nearly equal to unity and $\gamma_{rl}\simeq\gamma_{rt}$. Since the radiative energy mixed may be ignored and $\omega_{rl}\simeq\omega_{rt}$ in such case, the difficulty mentioned above will not be serious in practice. Thus the first term in (5.9a) may be considered approximately as the Hamiltonian of the transverse rotational phonon field.

According to the usual procedure, $W_{12}^{(e)}$ the transition probability from the state $1(\boldsymbol{k},+,n_W)$, where the electron has the wave-number $\boldsymbol{k}$ and up spin, and the number of the phonons belonging to the wave-number $\boldsymbol{W}$ is n_W, to the states $2(\boldsymbol{k}',\pm,n_W+1)$ and $W_{12}^{(a)}$ that from the state $1(\boldsymbol{k},+,n_W)$ to the states $2(\boldsymbol{k}',\pm,n_W-1)$ may be obtained as follows:

$$W_{12}^{(e,a)}=\frac{2\pi}{\hbar}U_{12}^{(e,a)}\delta(E_1-E_2)\,, \tag{5.10}$$

$$\left.\begin{matrix}U_{12}^{(e)}\\ U_{12}^{(a)}\end{matrix}\right\}=(4\pi\beta)^2\frac{\hbar\omega_{rl}}{\gamma_{rl}V}\left\{\begin{matrix}(n_W+1)\delta_{\boldsymbol{k}',\boldsymbol{k}-\boldsymbol{W}}\\ n_W\delta_{\boldsymbol{k}',\boldsymbol{k}+\boldsymbol{W}}\end{matrix}\right\}$$

$$\times(1+2k^2\sin^2\theta/W^2)\,, \tag{5.11}$$

where θ is the angle between $\boldsymbol{k}$ and $\boldsymbol{W}$, and the two independent directions of $\boldsymbol{Q}_t$ belonging to each wave-number $\boldsymbol{W}(\boldsymbol{W}\perp\boldsymbol{Q}_t)$ are taken into account.

By integrating the above results in $\boldsymbol{W}$-space, we obtain the scattering probability $1/\tau_r$ of a conduction electron, as a function of its wave number k, due to the rotational phonon.

For large values of k, $1/\tau_r$ takes the following form.

$$1/\tau_r\sim 8\alpha_r\omega_{rl}(2n_W+1)g_r\eta\log(2v_0\eta)\,, \tag{5.12}$$

where

$$\alpha_r=\frac{2\pi e^2u_r}{\hbar\gamma_{rl}\omega_{rl}}\,,\quad u_r^2=\frac{2m\omega_{rl}}{\hbar}\,,\quad g_r=\frac{\hbar\omega_{rl}}{4mc^2}$$

$$\eta=k/u_r\,,\qquad v=w/u_r\,, \tag{5.13}$$

and v_0 is the cut-off value of the reduced wave number v of the rotational phonon.

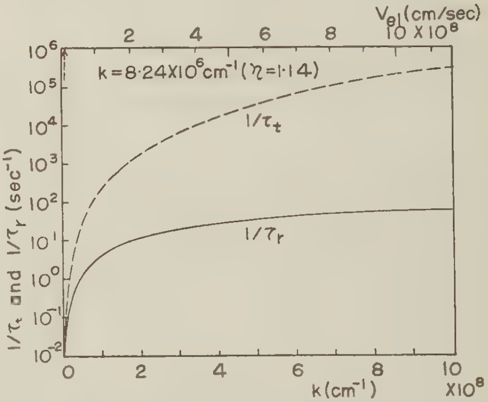

Fig. 3. Scattering probabilities of conduction electron due to rotational and transverse translational phonons *versus* wave number or velocity of the conduction electron.
$\omega_{tt}=\omega_{rl}=3\times10^{13}\,\mathrm{sec}^{-1}$, $\alpha_t=1$,
$v_0=6.10$ (for both cases), $\alpha_r=10^{-8}$, $T=300°K$
The arrow on the upside of the diagram indicates the point corresponding to thermal electron at 300°K.

Fig. 3 shows the dependence of $1/\tau_r$ upon the wave number k of a conduction electron for the given values of ω_{rl}, α_r and T. Besides, for the purpose of comparison, the dependence of the scattering probability $1/\tau_t$ by transverse translational phonons is plotted in the same figure. (cf. App. III) In contrast to the behavior of $1/\tau_t$, $1/\tau_r$ increases with increasing η values as $\eta\log\eta$. (cf. (5.12) and (AIII–4))

Referring to (3.17), let us estimate the order of magnitude of γ_{rl}, by using, as an example, the radical $[SO_4]^{2-}$ which has the tetrahedral structure around the central S-ion[4,5]. Since the binding force within an anionic radical would be essentially covalent, and the binding state of the radical may be expected to be formed by the resonance of several electronic states[6], the estimation of the effective charge on a coordinated ion in the radical, in general, would be difficult. But if we assume the state $S^{2+}(O^-)_4$ as the most predominant binding state for $[SO_4]^{2-}$ radical, then the effective charge on the oxygen atom may be infered to be approximately equal to e. Then $d=1.51$ Å[6)], $k_c=8/3$, $Z_c=1$, and $M_c=16M_H$ (M_H: mass of a H-atom). Furtuer we may take $N'=\mathfrak{N}\rho_0/M_m$, wher $\mathfrak{N}$ is Loschmidt number, ρ_0 and M_m the density and the molecular weight of the crystal respectively. In the case of the orthorhombic $PbSO_4$ crystal, $\rho_0=6.38\,g/cm^3$ [7)], and $M_m=303.27$. Therefore we obtain $1/\gamma_{rl}=1.87\times10^{-11}$. Then $\gamma_{rl}\simeq\gamma_{rt}$ and $\omega_{rl}\simeq\omega_{rt}$.

If we take $\omega_{rl}\simeq10^{13}\,\text{sec}^{-1}$ and $1/\gamma_{rl}\simeq10^{-11}$, then $\alpha_r\simeq10^{-8}$, $g_r\simeq10^{-8}$ and $\alpha_r g_r\simeq10^{-16}$. For the case of the scattering by transverse translational phonons, the factor corresponding to $\alpha_r g_r$ is $\alpha_t g_t^2$ which has the order of $10^{-15}\sim10^{-16}$. (cf. (5.12) and (AIII–4)) Therefore, we may conclude that the scattering probability due to rotational phonons would be comparable to that of transverse phonons for $\eta\simeq1$, if ω_{rl} is of order of magnitude $10^{13}\,\text{sec}^{-1}$. (cf. (5.12) and (AIII–4))

§ 6. Conclusions

In the ω_{tt} -branch the translational energy of lattice particles is abnormally high relative to the electromagnetic energy flux. (cf. the real curve II in Fig. 2.) In such a case, a stong absorption of the optical wave with frequency ω_{tt} must occur. In a steady state, whatever energy is lost by the lattice vibration must be supplied by the electromagnetic enery flux, and under such circumstances a small percentage energy loss by the former through a small coupling such as anharmonic potentials drastically reduces the latter.[8)]

Let us investigate the optical properties in infrared region in the case, where the rotational lattice vibration is taken into account. For this purpose, it is convenient to consider the dispersion formula which takes account of the energy dissipation. Namely, we add the simple damping terms $-\sigma_t\boldsymbol{W}$ and $-\sigma_r\dot{\boldsymbol{u}}$ to the right-hand sides of the equations of motion (2.1a) and (2.1c) respectively, where σ_t and σ_r are positive constants with dimension of frequency. Then, for the periodic solutions (2.5), we obtain

$$-\omega^2\boldsymbol{w}=(b_{11}+i\omega\sigma_t)\boldsymbol{w}+b_{12}\boldsymbol{E}\,, \tag{6.1a}$$

$$-\omega^2\boldsymbol{u}=(c_{11}+i\omega\sigma_r)\boldsymbol{u}+i\omega c_{12}\boldsymbol{H}\,. \tag{6.1b}$$

The addition of these damping terms is thus equivalent to the replacements of b_{11} and c_{11} by $b_{11}+i\omega\sigma_t$ and $c_{11}+i\omega\sigma_r$, respectively. Hence, we obtain

$$\begin{aligned}\mathcal{E}(\omega)&=(\boldsymbol{E}+4\pi\boldsymbol{P})/\boldsymbol{E}=1+4\pi b_{22}+\frac{4\pi b_{12}b_{21}}{-b_{11}-i\omega\sigma_t-\omega^2}\\&=\mathcal{E}_\infty+\frac{\mathcal{E}_0-\mathcal{E}_\infty}{1-y-i\sqrt{y}\,\Gamma_t}\,,\end{aligned} \tag{6.2a}$$

and

$$\begin{aligned}\mu(\omega)&=(\boldsymbol{H}+4\pi\boldsymbol{I})/\boldsymbol{H}=1+\frac{4\pi c_{12}c_{21}\omega^2}{-c_{11}-i\omega\sigma_r-\omega^2}\\&=1+\frac{(1-\alpha)y}{\kappa_t-y-i\sqrt{y}\,\Gamma_r}\,,\end{aligned} \tag{6.2b}$$

where

$$\Gamma_t\equiv\sigma_t/\omega_{tt}\,,\qquad \Gamma_r\equiv\sigma_r/\omega_{tt}\,.$$

If we denote by $\bar{n}$ the complex refractive index,

$$\bar{n}=n(1+i\kappa)=\sqrt{\mathcal{E}(\omega)\mu(\omega)}\,, \tag{6.3}$$

where n and κ are the optical constants of the absorbing medium. Inserting (6.2a and b) into (6.3) and squaring it, we obtain

$$\begin{aligned}n^2(1-\kappa^2)=&\left[\mathcal{E}_\infty+(\mathcal{E}_0-\mathcal{E}_\infty)\frac{1-y}{F_t(y)}\right]+\mathcal{E}_\infty(1-\alpha)\frac{y(\kappa_t-y)}{F_r(y)}\\&+(\mathcal{E}_0-\mathcal{E}_\infty)(1-\alpha)\frac{y[(1-y)(\kappa_t-y)-y\Gamma_t\Gamma_r]}{F_t(y)F_r(y)}\,,\end{aligned} \tag{6.4a}$$

$$\begin{aligned}2n^2\kappa=&(\mathcal{E}_0-\mathcal{E}_\infty)\Gamma_t\frac{\sqrt{y}}{F_t(y)}+\mathcal{E}_0(1-\alpha)\Gamma_r\frac{y\sqrt{y}}{F_r(y)}\\&+(\mathcal{E}_0-\mathcal{E}_\infty)(1-\alpha)\frac{y\sqrt{y}[\Gamma_t(\kappa_t-y)+\Gamma_r(1-y)]}{F_t(y)F_r(y)}\,,\end{aligned} \tag{6.4b}$$

where

$$F_t(y)\equiv(1-y)^2+\Gamma_t^2y\,,$$

$$F_r(y)\equiv(\kappa_t-y)^2+\Gamma_r^2y\,.$$

As well known, n gives the usual refractive index of the medium and $4\pi n\kappa$ the absorbancy coefficient in unit of reciprocal vacuum wavelength. If Γ_t and Γ_r are given numerically besides $\mathcal{E}_0$, $\mathcal{E}_\infty$, α and κ_t, we may compute n

and $n\kappa$ for an arbitrary wave-length by making use of (6.4a and b). Thus we may clarify the general features of infrared dispersion and absorption in the case, where the translational and rotational lattive vibrations simultaneously contribute to them.

The first terms in (6.4a and b) purely originate from the translational vibration, whereas the second and third terms in both equations appear first by taking account of the rotational vibration. Since in actual complex crystals $1/\gamma_{rl}\simeq 1/\gamma_{rt}=1-\alpha\sim 10^{-11}$ (cf. § 5, (3.13) and (3.16b)), the energy density of the ω_{rt}-branch is lodged predominantly in the radicals of the crystal as mechanical energy of lattice vibration rather than in the electromagnetic field just as in the case of the ω_{tt}-branch. (cf. § 4 and curves III in Fig. 2) Then a strong absorption due to the rotational vibration may be expected to exist. However, if $\Gamma_t\sim\Gamma_r$ and $\kappa_t\sim 1(\omega_{rt}\sim\omega_{tt})$, the second and third terms in (6.4a and b) may be neglected in this case, compared with the first terms in these equations, since we may expect the magnitude of $\varepsilon_0-\varepsilon_\infty$ to be of order of unity. Furthermore, the former terms will be still much smaller than the latters even in the neighbourhood of $y=\kappa_t(\omega=\omega_{rt})$. Hence, the former terms will not have any appreciable contribution to the values of n and $n\kappa$.

Accordingly we would not be able to recognize experimentally the definite existence of the absorption band due to the rotational lattice vibration, since this weak band will be covered by the strong absorption band resulting from the translational lattice vibration.

With respect to the scattering probability of conduction electrons we may conclude as follows: According to the order estimation in § 5, if ω_{rl} is of the order of magnitude 10^{13} sec^{-1}, the interaction of conduction electron with rotational phonons is of order comparable to that with transverse translational phonons at $\eta\simeq 1$, although the scattering probability due to rotational phonons increases with η as $\eta\log\eta$, whereas that due to transverse translational phonons as η^3. (cf. Fig. 3 and App. III)

Finally, the authors are indebted to Prof. K. Umeda for reading the manuscript in part and giving them valuable advices.

Appendix I

If free charges exist,

$$\mathrm{div}\,(\boldsymbol{E}+4\pi\boldsymbol{P})=4\pi\rho\ .$$

Therefore

$$\mathrm{div}\,\boldsymbol{E}=\frac{4\pi}{1+4\pi b_{22}}\,(-b_{21}\,\mathrm{div}\,\boldsymbol{w}_l+\rho(\boldsymbol{r},t))\ . \qquad \text{(cf. (2.1b))} \quad \text{(AI–1)}$$

If we put

$$\boldsymbol{D}_l(\boldsymbol{r},t)=-\mathrm{grad}\int\frac{\rho(\boldsymbol{r}',t)}{|\boldsymbol{r}'-\boldsymbol{r}|}d\tau'\ ,$$

we have

$$\boldsymbol{E}=\frac{-4\pi b_{12}}{1+4\pi b_{22}}\,\boldsymbol{w}_l+\frac{\boldsymbol{D}_l}{1+4\pi b_{22}}+\boldsymbol{E}_t\ . \qquad \text{(AI–2)}$$

Inserting (AI–2) into (2.1a) and (2.1b), we obtain

$$\ddot{\boldsymbol{w}}_l=-\omega_{tl}^2\boldsymbol{w}_l+\frac{b_{12}}{\varepsilon_\infty}\boldsymbol{D}_l\ , \qquad \text{(AI–3a)}$$

$$\ddot{\boldsymbol{w}}_t=-\omega_{tt}^2\boldsymbol{w}_t+b_{12}\boldsymbol{E}_t\ , \qquad \text{(AI–3b)}$$

$$\boldsymbol{P}_l=\frac{1}{\varepsilon_\infty}\,b_{21}\boldsymbol{w}_l+\frac{b_{22}}{\varepsilon_\infty}\boldsymbol{D}_l\ , \qquad \text{(AI–3c)}$$

and

$$\boldsymbol{P}_t=b_{21}\boldsymbol{w}_t+b_{22}\boldsymbol{E}_t\ . \qquad \text{(AI–3d)}$$

Further, from (2.2) and (AI–3c and d) we obtain, for the atomic polarization $\boldsymbol{P}_A$,

$$\boldsymbol{P}_{Al}=\frac{1}{\varepsilon_\infty}\left(\frac{\varepsilon_0-\varepsilon_\infty}{4\pi}\right)^{1/2}\omega_{tl}\boldsymbol{w}_l\ , \qquad \text{(AI–4a)}$$

and

$$\boldsymbol{P}_{At}=\left(\frac{\varepsilon_0-\varepsilon_\infty}{4\pi}\right)^{1/2}\omega_{tt}\boldsymbol{w}_t\ . \qquad \text{(AI–4b)}$$

Substituting (AI–4) into (AI–3a and b), we may get finally the macroscopic equations of motion:

$$\ddot{\boldsymbol{P}}_{Al}+\omega_{tl}^2\boldsymbol{P}_{Al}=\frac{\omega_{tl}^2}{4\pi}\left(\frac{1}{\varepsilon_\infty}-\frac{1}{\varepsilon_0}\right)\boldsymbol{D}_l\ , \qquad \text{(AI–5a)}$$

$$\ddot{\boldsymbol{P}}_{At}+\omega_{tt}^2\boldsymbol{P}_{At}=\frac{\omega_{tt}^2}{4\pi}(\varepsilon_0-\varepsilon_\infty)\boldsymbol{E}_t\ . \qquad \text{(AI–5b)}$$

Appendix II

Derivation of the Hamiltonian of the Rotational Phonon in the Electromagnetic Field.

We denote the position of the center of a radical by $\boldsymbol{r}$, and the displacement of the ith coordinated ion belonging to this radical from its equilibrium position by $\boldsymbol{r}_i$, then we have the following Hamiltonian of the system consisting of such radicals of the same kind.

$$H_r=\frac{N'}{2M_c}\int\sum_i\left\{\left(\boldsymbol{p}_i-\frac{Z_ce}{c}\boldsymbol{A}_i\right)^2+\omega_{rl}^2M_c^2\boldsymbol{r}_i^2\right\}d\tau\ , \qquad \text{(AII–1)}$$

where $\boldsymbol{p}_i$ is the canonically conjugate momentum of $\boldsymbol{r}_i$. The summation is to be taken over all the coordinated ions belonging to the radical at $\boldsymbol{r}$.

The equations of motion for each ion are thus written as

$$\partial H_r/\partial \boldsymbol{P}_i = N'\dot{\boldsymbol{r}}_i\,,\quad \partial H_r/\partial \boldsymbol{r}_i = -N'\dot{\boldsymbol{p}}_i\,. \qquad \text{(AII–2)}$$

When the magnitude of the angular displacement $\boldsymbol{\Theta}$ of the radical is small, $\boldsymbol{r}_i$ may be written as

$$\boldsymbol{r}_i = [\boldsymbol{\Theta}, \boldsymbol{d}_i]\,. \qquad \text{(AII–3)}$$

By using (3.16a) and (AII–3), we obtain

$$\frac{\delta H_r}{\delta Q_x} = \sum_{\beta=x,y,z}\sum_i \frac{\delta H_r}{\delta r_{i\beta}}\frac{\partial r_{i\beta}}{\partial Q_x} = \frac{\hbar}{I\beta_M}\sum_i [\dot{\boldsymbol{p}}_i, \boldsymbol{d}_i]_x\,.$$

Using the relations

$$\sum_i [[\boldsymbol{s}, \boldsymbol{d}_i], \boldsymbol{d}_i] = -k_c d^2 \boldsymbol{s},\ \text{(for arbitrary } \boldsymbol{s}) \qquad \text{(AII–4)}$$

and

$$\boldsymbol{p}_i - \frac{Z_c e}{c}\boldsymbol{A}_t = M_c\dot{\boldsymbol{r}}_i = \frac{M_c\hbar}{N' I\beta_M}[\dot{\boldsymbol{Q}}, \boldsymbol{d}_i]\,, \qquad \text{(AII–5)}$$

we may transform the above equation into

$$\delta H_r/\delta \boldsymbol{Q} = -\dot{\boldsymbol{P}}_r\,, \qquad \text{(AII–6)}$$

where

$$\boldsymbol{P}_r \equiv \gamma_{rt}\dot{\boldsymbol{Q}} + \text{curl}\,\boldsymbol{A}_t\,. \qquad \text{(AII–7)}$$

On the other hand, we can easily prove the equation

$$\delta H_r/\delta \boldsymbol{P}_r = \dot{\boldsymbol{Q}}\,. \qquad \text{(AII–8)}$$

Equations (AII–6) and (AII–8) indicate that $\boldsymbol{P}_r$ and $\boldsymbol{Q}$ are canonically conjugate.

Substituting (AII–3) (AII–5) and (AII–7) into (AII–1), the Hamiltonian changes into the second term in (5.1).

Appendix III

Scattering Probability of a Conduction Electron due to the Transverse Translational Phonon.

The Hamiltonian of the system consisting of a conduction electron and the transverse translational phonon field will be given by

$$H = H^0 + H_{\text{int}}^{(t)}\,, \qquad \text{(AIII–1)}$$

$$H^0 = \frac{1}{2\gamma_t}\int [\mathfrak{P}_t^2 + \omega_{tt}^2\gamma_t^2\boldsymbol{P}_t^2]\,d\tau + \frac{1}{2m}\boldsymbol{p}_e^2\,, \qquad \text{(AIII–1a)}$$

$$H_{\text{int}}^{(t)} = -\frac{e}{mc}\boldsymbol{p}_e\boldsymbol{A}_t(\boldsymbol{r}_e) - (\boldsymbol{\mu}\,\text{curl}\,\boldsymbol{A}_t(\boldsymbol{r}_e))\,, \qquad \text{(AIII–1b)}$$

where

$$\Delta \boldsymbol{A}_t = -\frac{4\pi}{c}\dot{\boldsymbol{P}}_t$$

and

$$1/\gamma_t = \frac{\omega_{tt}^2}{4\pi}(\varepsilon_0 - \varepsilon_\infty)\,.$$

$\boldsymbol{P}_t$ is the solenoidal component of the polarization $\boldsymbol{P}$, and $\mathfrak{P}_t$ is the momentum canonically conjugate to $\boldsymbol{P}_t$.

Treating this interaction Hamiltonian as a perturbation, we may calculate $W_{12}^{(e)}$, the transition probability from the state $1(\boldsymbol{k}, +, n_W)$ to the states $2(\boldsymbol{k}', \pm, n_W+1)$ and $W_{12}^{(a)}$, that from the state $1(\boldsymbol{k}, +, n_W)$ to the states $2(\boldsymbol{k}', \pm, n_W-1)$, where n_W is the number of transverse translational phonons with wave number $\boldsymbol{W}$.

$$W_{12}^{(e,a)} = \frac{2\pi}{\hbar}U_{12}^{(e,a)}\delta(E_1 - E_2)\,, \qquad \text{(AIII–2)}$$

$$\left.\begin{array}{l} U_{12}^{(e)} \\ U_{12}^{(a)} \end{array}\right\} = \frac{16\pi^2\hbar\omega_{tt}}{\gamma_t V}\frac{\beta^2}{c^2 W^2}\left\{\begin{array}{l}(n_W+1)\delta_{\boldsymbol{k}',\,\boldsymbol{k}-\boldsymbol{W}} \\ n_W\delta_{\boldsymbol{k}',\,\boldsymbol{k}+\boldsymbol{W}}\end{array}\right\}$$
$$\times(1 + 2k^2\sin^2\theta/W^2)\,. \qquad \text{(AIII–3)}$$

Integrating the above results in $\boldsymbol{W}$-space, we may obtain the scattering probability $1/\tau_t$ as a function of the electron wave number $\boldsymbol{k}$, which is shown in Fig. 3 in order to compare with $1/\tau_r$. With increasing $\boldsymbol{k}$ values, $1/\tau_t$ behaves such as

$$1/\tau_t \sim 16\alpha_t\omega_{tt}(2n_W+1)g_t^2\eta^3\,, \qquad \text{(AIII–4)}$$

where

$$\alpha_t = \frac{2\pi e^2 u_t}{\hbar\gamma_t\omega_{tt}^3}\,,\quad g_t = \frac{\hbar\omega_{tt}}{4mc^2}\,,\quad u_t^2 = 2m\omega_{tt}/\hbar$$

$$\eta = k/u_t \quad\text{and}\quad v = w/u_t\,. \qquad \text{(AIII–5)}$$

Rotational Lattice Vibration in Complex Crystals

Part III. Vibrational Frequencies in Cubic NaClO$_4$ Crystals

By Sumitada ASANO and Yasuo TOMISHIMA

Department of Physics, Faculty of Science, Okayama University

(Received April 3, 1957)

The frequencies of the translational and rotational vibrations (in optical branches) in the cubic NaClO$_4$ crystal, which is one of the complex crystals with simplest structure, are expressed in terms of the force constants of the interionic forces. The expression obtained with respect to the translational vibration is quite similar to that in the case of isotropic simple crystals, which is already known. Furthermore, by assuming reasonable values for these force constants, the orders of magnitudes of the both frequencies are estimated and compared with one another. The comparison shows that the both frequencies are nearly of the same order of magnitude.

§ 1. Introduction

In the preceding papers[1,2], we have assumed that the frequencies of the rotational vibrations in optical branches are of the same order of magnitude as those of the translational ones. Therefore, we will here determine the orders of magnitudes of the frequencies of both the rotational and the translational vibtrations for an actual crystal cubic NaClO$_4$ which is stable above 380°C[3]. This has one of the simplest structure in the complex crystals, which is obtained by replacing Cl-ions in NaCl crystal with tetrahedral $[\mathrm{ClO}_4]^-$ radicals, as shown in Fig. 1.

In such a crystal which has one cation and one anionic radical in a unit cell, the rotational lattice vibrations may be idealized by the motion such that all the radicals perform rotational vibrations in phase and all the cations are at rest. (There is only the optical branch in this case as discussed in part I.) On the other hand, the translational vibrations in optical branch are characterized by the motion such that all the radicals make the same translation remaining their orientation unchanged, and all the cations are at rest.

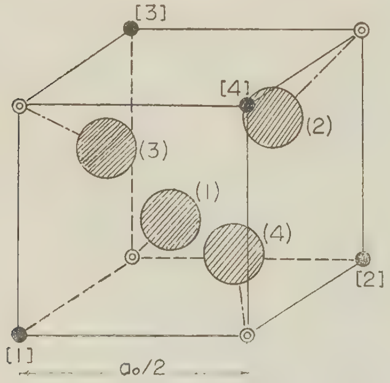

Fig. 1. Sketch illustrating the atomic arrangement in the cubic NaClO$_4$ crystal.
Dots: Na-ions. Double circles: Cl-ions.
Large hatched circles: O-ions.

Assuming an appropriate form, including adjustable parameters, for exchange potentials between constituent ions, we will first calculate the forces and their moments acting on a particular radical for the idealized translation and rotation stated above, and then determine the frequency of the rotational lattice vibration for some reasonable values of these parameters.

§ 2. Forces Acting on One Radical

Let us consider one cation-radical pair $\mathrm{Na}^+-[\mathrm{ClO}^4]^-$. We shall call them the central Na$^+$-ion and the central $[\mathrm{ClO}_4]^-$-ratical, and designate by $\boldsymbol{x}(i)$ the vectors specifying the positions of the Cl-ion ($i=0$) and the four coordinated O-ions ($i=1, 2, 3, 4$) relative to the equilibrium position of the Cl-ion, and the vector specifying the position of the central Na-ion ($i=5$) relative to its equilibrium position. (cf. Fig. 2) Further, we will use $\boldsymbol{x}_0(i)$ to signify $\boldsymbol{x}(i)$ for the equilibrium configuration, then

$$\boldsymbol{x}_0(0)=0\,, \tag{2.1a}$$

$$\boldsymbol{x}_0(5)=0\,, \tag{2.1b}$$

and

$$\left.\begin{aligned} \boldsymbol{x}_0(1)&=(\ \ ua_0,\ \ \ ua_0,\ \ \ ua_0)\,,\\ \boldsymbol{x}_0(2)&=(\ \ ua_0,\ -ua_0,\ -ua_0)\,,\\ \boldsymbol{x}_0(3)&=(-ua_0,\ \ \ ua_0,\ -ua_0)\,,\\ \boldsymbol{x}_0(4)&=(-ua_0,\ -ua_0,\ \ \ ua_0)\,, \end{aligned}\right\}\qquad(2.1\text{c})$$

where $a_0=7.25\,\text{Å}$ and $u=0.1314$. (cf. Fig. 1 and App. I)

In order to simplify the later calculation, all the ions are classified into groups, each of which consists of the ions sitting at a constant distance $r(ki)$ from the i-th ion ($i=0, 1, \cdots, 5$) in equilibrium and is called ki-group, where k is a positive integer labeling each group as $r(ki)>r(k'i)$ for $k>k'$. We should mention that with the variation of the standard ion, namely, with the variation of i from 0 to 5 there are six kinds of different classifications. Further we will define $\boldsymbol{y}(j;\,ki)$, a vector specifying the position of the j-th ion of the ki-group relative to the same origin as that of $\boldsymbol{x}(i)$; therefore the origin of $\boldsymbol{y}(j;\,ki)$ is the equilibrium position of the Cl-ion of the central radical for $i=0, 1, \cdots, 4$ and that of the central Na-ion for $i=5$. (cf. Fig. 2) Then, regardless of j, we have

$$|\boldsymbol{y}_0(j;\,ki)-\boldsymbol{x}_0(i)|=r(ki)\,,\qquad(2.2)$$

where $\boldsymbol{y}_0$ is the vector $\boldsymbol{y}$ in the equilibrium configuration.

In the interest of simplicity, Na-, O- and Cl-ions in the crystal are regarded as point charges with effective charges $-e$ (e: electronic charge), Z_ce and $(1-4Z_c)e$, respectively. If we assume that the potential between two ions may be expressed as the sum of the Coulomb and the overlap potentials and that the latter is also a function of only the distance between the two ions, then the potential between the i-th ion and the j-th ion belonging to the ki-group may be written as

$$\phi_{ki}(|\boldsymbol{y}(j;\,ki)-\boldsymbol{x}(i)|)\equiv\phi_{ki}(r(j;\,ki))\,,\qquad(2.3)$$

where only the suffixes i and k are appended to ϕ, because all the ions belonging to the ki-group are of the same kind regardless of j, and the form of potential function ϕ is dependent on the kinds of the both ions only.

In the equilibrium configuration, the atomic arrangements of the crystal around the four O-ions of the central radical are completely similar to each other owing to the crystal symmetry. Therefore, we may conclude

$$\left.\begin{aligned} &r(ki)=r(ki')\equiv r(k)\,,\\ &\phi_{ki}(r(ki))=\phi_{ki'}(r(ki'))\equiv\phi_k(r(k))\,,\\ &\qquad\qquad(i,\,i'=1, 2, 3, 4;\ i\neq i') \end{aligned}\right\}\qquad(2.4)$$

where $r(k)$ and $\phi_k(r(k))$ are independent of i.

The x-component* of $\boldsymbol{F}(j;\,ki)$, the force acting on the ith ion of the central radical from the jth ion of the ki-group is given by

$$F_1(j;\,ki)=-\frac{\partial}{\partial x_1(i)}\phi_{ki}(r(j;\,ki))\,.$$
$$(i=0, 1, 2, 3, 4)\qquad(2.5)$$

If we denote by $\delta\boldsymbol{x}(i)$ and $\delta\boldsymbol{y}(j;\,ki)$ the displacements of the ith ion and the jth ion of the ki-group from their own equilibrium positions respectively, we may obtain the following relations:

$$\left.\begin{aligned} &\boldsymbol{x}(i)=\boldsymbol{x}_0(i)+\delta\boldsymbol{x}(i)\\ \text{and}\ \ &\boldsymbol{y}(j;\,ki)=\boldsymbol{y}_0(j;\,ki)+\delta\boldsymbol{y}(j;\,ki) \end{aligned}\right\}$$
$$(\text{cf. Fig. 2})\ (2.6)$$

Inserting (2.3) and (2.6) into (2.5) and expanding the right-hand side of (2.5), we may get the following approximate expression:

$$F_1(j;\,ki)=F_1^{(0)}(j;\,ki)+F_1^{(1)}(j;\,ki)\,,\qquad(2.7)$$

where

$$F_1^{(0)}(j;\,ki)\equiv\left[\frac{\partial}{\partial y_1(j;\,ki)}\,\phi_{ki}(r(j;\,ki))\right]_0,\qquad(2.7\text{a})$$

$$F_1^{(1)}(j;\,ki)\equiv\sum_{\beta=1}^{3}\left[\frac{\partial^2}{\partial y_1(j;\,ki)\partial y_\beta(j;\,ki)}\right.$$
$$\left.\times\,\phi_{ki}(r(j;\,ki))\right]_0\{\delta y_\beta(j;\,ki)-\delta x_\beta(i)\}\,.\qquad(2.7\text{b})$$

The suffix 0 represents the value for the equilibrium configuration: $\boldsymbol{x}(i)=\boldsymbol{x}_0(i)$ and $\boldsymbol{y}(j;\,ki)=\boldsymbol{y}_0(j;ki)$.

$\boldsymbol{N}(j;\,ki)$, the moment of $\boldsymbol{F}(j;\,ki)$ with respect to the center of the central radical, is given by

$$\boldsymbol{N}(j;\,ki)=\boldsymbol{N}^{(0)}(j;\,ki)+\boldsymbol{N}^{(1)}(j;\,ki)\,,\qquad(2.8)$$

where

$$\boldsymbol{N}^{(s)}(j;\,ki)\equiv[\boldsymbol{x}_0(i)+\delta\boldsymbol{x}(i)-\delta\boldsymbol{x}(0),\ \boldsymbol{F}^{(s)}(j;\,ki)]$$
$$(s=0,\ 1;\ i=1,\ 2,\ 3,\ 4)\qquad(2.8\text{a})$$

The total force $\boldsymbol{F}$ and the total moment $\boldsymbol{N}$ acting on the central radical are given by

$$\left.\begin{aligned} \boldsymbol{F}&=\sum_{i=1}^{4}\sum_{k}\sum_{j=1}^{n(ki)}\boldsymbol{F}(j;\,ki)\,,\\ \text{and}\quad\boldsymbol{N}&=\sum_{i=1}^{4}\sum_{k}\sum_{j=1}^{n(ki)}\boldsymbol{N}(j;\,ki)\,, \end{aligned}\right\}\qquad(2.9)$$

---

* x-, y- and z-components of a vector are indicated hereafter by the suffixes 1, 2 and 3 respectively.

respectively, where $n(ki)$ is the total number of the ions belonging to the ki-group.

On the other hand, we have, owing to the T_d symmetry,

$$\sum_{i=1}^{4}\sum_{j=1}^{n(ki)}\boldsymbol{F}^{(0)}(j;ki)=\sum_{j=1}^{n(k0)}\boldsymbol{F}^{(0)}(j;\,k0)=0\ , \tag{2.10}$$

and

$$\sum_{i=1}^{4}\sum_{j=1}^{n(ki)}[\boldsymbol{x}_0(i),\ \boldsymbol{F}^{(0)}(j;\,ki)]=0\ . \tag{2.11}$$

Substituting (2.7) and (2.8) into (2.9), we have

$$\left.\begin{aligned} F_1=&-\sum_{i=1}^{4}\sum_{k}\sum_{j=1}^{n(ki)}\sum_{\beta=1}^{3}T_{1\beta}(j;\,ki)[\delta x_\beta(i)\\ &-\delta y(j;\,ki)]\ ,\\ N^1=&\sum_{i=1}^{4}\sum_{k}\sum_{j=1}^{n(ki)}[\{\delta x_2(i)-\delta x_2(0)\}F_3{}^{(0)}(j;\,ki)\\ &-\{\delta x_3(i)-\delta x_3(0)\}F_2{}^{(0)}(j;\,ki)]\\ &-\sum_{i=1}^{4}\sum_{k}\sum_{j=1}^{n(ki)}\sum_{\beta=1}^{3}[x_{02}(i)T_{3\beta}(j;ki)\\ &-x_{03}T_{2\beta}(j;\,ki)]\{\delta x_\beta(i)-\delta y_\beta(j;ki)\} \end{aligned}\right\} \tag{2.12}$$

where

$$T_{\alpha\beta}(j;\,ki)\equiv\left[\frac{\partial^2}{\partial y_\alpha(j;\,ki)\partial y_\beta(j;\,ki)}\phi_{ki}(\boldsymbol{r}(j;\,ki))\right]_0\ . \tag{2.13}$$

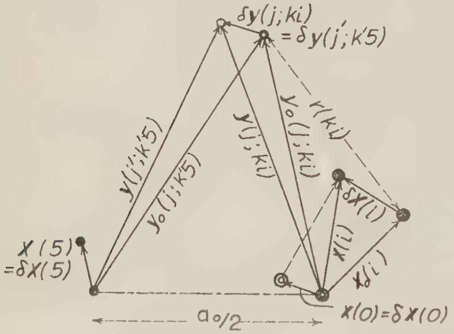

Fig. 2. Schematic diagram illustrating the relations among the vectors $\boldsymbol{x}(i)$, $\boldsymbol{x}_0(i)$, $\boldsymbol{y}(j;\,ki)$ and $\boldsymbol{y}_0(j;\,ki)$.
Hatched Circles: ith O-ion of central radical. ($i=1,\ 2,\ 3,\ 4$)
Double Circles: Cl-ion of central radical.
Dots: Central Na-ion.
Single Circles: jth ion of ki-group.

In deriving (2.12), we have used the relations (2.10) and (2.11), and furthermore neglected the small terms such as the squares of $\delta x_\alpha(i)$ and the cross products of $\delta x_\alpha(i)$ and $\delta y_\beta(j;\,ki)$.

When the ki-group is of O-ions, we may decompose the vector $\boldsymbol{y}_0(j;\,ki)$ into two parts as follows:

$$\boldsymbol{y}_0(j;\,ki)=\boldsymbol{y}_L(j;\,ki)+\boldsymbol{x}_0(j;\,ki)\ . \tag{2.14}$$

where $\boldsymbol{y}_L(j;\,ki)$ is the vector specifying the equilibrium position of the parent Cl-ion (to which the j-th O-ion belongs) relative to the same origin as that of $\boldsymbol{y}_0(j;\,ki)$, and $\boldsymbol{x}_0(j;\,ki)$ is the vector pointing from this Cl-ion to the j-th O-ion. Then $\boldsymbol{x}_0(j;\,ki)$ has the components similar to one of (2.1c). When the ki-group is of Na-ions or Cl-ions, $\boldsymbol{x}_0(j;\,ki)=0$ and $\boldsymbol{y}_0(j;\,ki)=\boldsymbol{y}_L(j;\,ki)$,

As stated in §1, for the optical branches we may assume the idealized displacements:

$$\left.\begin{aligned} &\delta\boldsymbol{x}(i)=\boldsymbol{\xi}+[\boldsymbol{\Theta},\,\boldsymbol{x}_0(i)] \qquad (i=0,1,2,3,4)\\ &\delta\boldsymbol{y}(j;\,ki)=\begin{cases}\boldsymbol{\xi}+[\boldsymbol{\Theta},\,\boldsymbol{x}_0(j;\,ki)] & \text{(for radicals)}\\ 0 & \text{(for cations),}\end{cases} \end{aligned}\right\} \tag{2.15}$$

where $\boldsymbol{\xi}$ respresents the translation common to all the radicals, relative to the Na-ions, and $\boldsymbol{\Theta}$ is the angular displacement[1] of each radical.

Further let us define the symmetric tensors $\boldsymbol{T}(ki)$ and $\boldsymbol{T}^\gamma(ki)$, whose components $T_{\alpha\beta}(ki)$ and $T_{\alpha\beta}{}^\gamma(ki)$ are defined as follows:

$$T_{\alpha\beta}(ki)\equiv\sum_{j=1}^{n(ki)}T_{\alpha\beta}(j;\,ki)\ , \qquad (i=0,1,2,3,4) \tag{2.16}$$

$$T_{\alpha\beta}{}^\gamma(ki)\equiv\frac{1}{ua_0}\sum_{j=1}^{n(ki)}T_{\alpha\beta}(j;\,ki)x_{0\gamma}(j;\,ki)\ . \qquad (i=1,2,3,4;\ \gamma=1,2,3) \tag{2.17}$$

We should mention that $T^\gamma(ki)$ vanishes unless the members of the ki-group are O-ions, acording to the definition of $\boldsymbol{x}_0(j;\,ki)$. Owing to the T_d symmetry, we have

$$\left.\begin{aligned} &\sum_{i=1}^{4}T_{\alpha\beta}(ki)=0\ (\alpha\neq\beta)\ , \quad T_{\alpha\beta}{}^\gamma(k0)=0\ ,\\ &\text{and}\\ &\sum_{i=1}^{4}\sum_{j=1}^{n(ki)}[\boldsymbol{\Theta},\,\boldsymbol{x}_0(i)],\,\boldsymbol{F}^{(0)}(j;\,ki)]=0\ . \end{aligned}\right\} \tag{2.18}$$

Substituting (2.15) into (2.12), and using the relations (2.16), (2.17), (2.18) and (AII-1 and 3), we obtain finally

$$F_1=-\sum_{k}^{(+)}[4T_{11}(k1)+T_{11}(k0)]\xi_1 \tag{2.19a}$$

$$\begin{aligned} N_1=-8\Big\{&\sum_{k}[T_{11}(k1)-T_{23}(k1)]-\sum_{k}^{(-)}T_{11}{}^3(k1)\\ &-T_{23}{}^2(k1)]\Big\}u^2a_0{}^2\theta_1\ , \end{aligned} \tag{2.19b}$$

where $\sum\limits_{k}^{(+)}$ and $\sum\limits_{k}^{(-)}$ mean the summations with respect to Na-ion groups only and O-ion groups only respectively.

§ 3. Vibrational Frequencies

Let us correlate F_1 and N_1 given by (2.19) to the frequencies of the translational and the rotational vibrations of the radical.

By using (2.3), (2.4), (2.13), (2.16) and (2.17), the tensor components in (2.19) may be written in the follwing forms:

$$\left.\begin{aligned} T_{11}\,(k1)&=A(k)\,\Phi_k{}^{(+)}\,,\\ T_{11}\,(k0)&=C(k)\,\Phi_{k0}{}^{(+)}\,,\\ T_{11}{}^3(k1)&=A(k)'\,\Phi_k{}^{(+)}\,,\\ T_{23}\,(k1)&=B(k)\,\Phi_k{}^{(-)}\,,\\ T_{23}{}^2(k1)&=B(k)'\,\Phi_k{}^{(-)}\,,\end{aligned}\right\}\tag{3.1}$$

where

$$\left.\begin{aligned} \Phi_k{}^{(+)}&\equiv\phi_k''(r(k))+\phi_k'(r(k))\,\frac{2}{r(k)}\\ &=\Delta\phi_k(r(k))\\ \Phi_{k0}{}^{(+)}&\equiv\phi_{k0}''(r(k0))+\phi_{k0}'(r(k0))\,\frac{2}{r(k0)}\\ &=\Delta\phi_{k0}(r(k0))\\ \Phi_k{}^{(-)}&\equiv\phi_k''(r(k))-\phi_k'(r(k))\,\frac{1}{r(k)}\end{aligned}\right\}\tag{3.2}$$

and $A(k)$ $B(k)$ $C(k)$ $A(k)'$ and $B(k)'$ are the numerical constants, whose general expressions are given in App. III.

As easily seen in (3.1) and (3.2), the Coulomb interactions of the ion-pairs do not enter into $T_{11}(k1)$ and $T_{11}(k0)$, accordingly into F_1 expressed by (2.19a). If we neglet all the overlap forces but those between an O-ion of the central radical and the three nearest Na-ions ((1) and (1) (2) (3) in Fig. 1) and those between the O-ion and the three nearest O-ions ((1) and (2) (3) (4) in Fig. 1), then $T_{11}(k0)=0$, Furthermore, F_1 given by (2.19a) contains the former overlap forces only, for $\overset{(+)}{\sum\limits_{k}}$ means the summation over Na-ion groups only. Then the summation sign in (2.19a) may be removed, by identifying the $k1$-group with three nearest Na-ions, and the expression (2.19a) becomes quite similar to that in the case of isotropic simple crystals[4].

However, long-range Coulomb interactions unfavorably remain in N_1 given by (2.19b), since in $T_{23}(k1)$ and $T_{23}{}^2(k1)$ the Coulomb interactions do not vanish. (cf. (3.1) (3.2)) Referring to (2.8a), the moment, $\boldsymbol{N}^{(c)}(j;\,ki)$, due to the electrostatic field $\boldsymbol{E}(j;\,ki)$ on the central radical from the jth ion of the ki-group may be given by

$$\boldsymbol{N}^{(c)}(j;\,ki)=Z_ce\sum_{i'=1}^{4}[\boldsymbol{x}(i')_r,\ \boldsymbol{E}_{i'}(j;\,ki)]\,,\tag{3.3}$$

where the suffix i' appended to $\boldsymbol{E}(j;\,ki)$ indicates its value at the i'-th O-ion of the central radical, and

$$\left.\begin{aligned}\boldsymbol{x}(i')_r=\boldsymbol{x}(i')-\boldsymbol{x}(0)&=\boldsymbol{x}(i')-\boldsymbol{\xi}\\ &=\boldsymbol{x}_0(i')+[\boldsymbol{\Theta},\,\boldsymbol{x}_0(i')]\end{aligned}\right\}$$

(cf. (2.6) and (2.15))

Expanding $\boldsymbol{E}_{i'}(j;\,ki)$ in (3.3) around the Cl-ion of the central radical, we obtain

$$\boldsymbol{N}^{(c)}(j;\,ki)=Z_ce\sum_{n=0}^{\infty}\sum_{i'=1}^{4}\frac{1}{n!}\times[\boldsymbol{x}(i')_r,\,(\boldsymbol{x}(i')_r,\,\boldsymbol{\nabla})^n\boldsymbol{E}_0(j;\,ki)]\,,\tag{3.4}$$

where $\boldsymbol{E}_0(j;\,ki)$ is the value of $\boldsymbol{E}(j;\,ki)$ on the Cl-ion sitting at $\boldsymbol{x}(0)=\boldsymbol{\xi}$. The terms with $n=0$ and 1 in (3.4) vanish, if the relations $\sum\limits_{i'=1}^{4}\boldsymbol{x}(i')_r=0$ and curl $\boldsymbol{E}_0(j;\,ki)=0$ are taken into account. Then we have

$$\boldsymbol{N}^{(c)}(j;\,ki)=Z_ce\sum_{n=2}^{\infty}\sum_{i'=1}^{4}\frac{1}{n!}\times[\boldsymbol{x}(i')_r,\,(\boldsymbol{x}(i')_r,\,\boldsymbol{\nabla})^n\boldsymbol{E}_0(j;\,ki)]\,.\tag{3.5}$$

(3.5) represents the moment acting on the radical due to the electrostatic interactions between the multipole moments of higher order (than dipole) on the radical and the jth ion of the ki-group.

Even when the jth ion is located in the vicinity of the radical, $\boldsymbol{N}^{(c)}(j;\,ki)$ given by (3.5) wouldn't have so large order of magnitude. But the sum of these moments originating from a number of ions in the vicinity of the central radical may have a contribution to its rotational motion comparable to that from the overlap forces, being enhanced as a result of superposition i. e. the summation with respect to j in each ki-group. This is autually shown in the later calculation.

However, the electrostatic field from all the ion comparatively distant from the central radical will be small and approximately replaced by a central field around the equilibrium position of the Cl-ion of the central radical. If we denote by $\varphi\{|\boldsymbol{x}(i)|\}$ the potential of this central field at the ith ion, $\boldsymbol{E}(\boldsymbol{x}(i))$, the field acting on it is given by

$$\boldsymbol{E}(\boldsymbol{x}(i))=-\mathrm{grad}\,\varphi(|\boldsymbol{x}(i)|)\,,\tag{3.6}$$

Since $\boldsymbol{x}(i)=\boldsymbol{x}(i)_r+\boldsymbol{\xi}$, $\boldsymbol{E}(\boldsymbol{x}(i))$ may be expanded approximately as

$$\boldsymbol{E}(\boldsymbol{x}(i))=\boldsymbol{E}(\boldsymbol{x}(i))+(\boldsymbol{\xi}\boldsymbol{\nabla})\boldsymbol{E}(\boldsymbol{x}(i)_r)\,,\tag{3.7}$$

where

$$\boldsymbol{E}(\boldsymbol{x}(i)_r) \equiv -\mathrm{grad}\,\varphi(|\boldsymbol{x}(i)_r|)\,. \tag{3.7a}$$

Similarly to (3.3), $\boldsymbol{N}^{(c)}$, the moment due to the fields $\boldsymbol{E}(\boldsymbol{x}(i))$'s ($i=1, 2, 3, 4$) is given by

$$\boldsymbol{N}^{(c)} = Z_c e \sum_{i=1}^{4} [\boldsymbol{x}(i)_r, \boldsymbol{E}(\boldsymbol{x}(i))]\,. \tag{3.8}$$

Substituting (3.7) and (3.7a) into (3.8) and taking account of the relations

$$\sum_{i=1}^{4} \boldsymbol{x}(i)_r = 0$$

$$\varphi'(|\boldsymbol{x}(i)|) = \varphi'(|\boldsymbol{x}(i')|)$$

and

$$\varphi''(|\boldsymbol{x}(i)|) = \varphi''(|\boldsymbol{x}(i')|) \quad (i \neq i';\ i, i' = 1, 2, 3, 4)\,,$$

we may easily verify that $\boldsymbol{N}^{(c)}$ vanishes.

According to the inferences stated above, we may take the summations $\sum\limits_k$ and $\overset{(-)}{\sum\limits_k}$ in (2.19b) only over some groups near the central radical, neglecting the effect from the other groups comparatively distant from it. Therefore in our actual calculation, these summations are taken up to the eight radicals sitting at $(\pm a_0/2, \pm a_0/2, \pm a_0/2)$. (cf. Fig. 1)

As stated in § 3 of part II, the equations of translational and rotational motion of a particular radical are given by

$$\overline{M}\,\ddot{\boldsymbol{\xi}} = -k_t \xi - Ze\boldsymbol{E}_{eff}\,, \tag{3.9a}$$

$$I\,\ddot{\boldsymbol{\Theta}} = -k_r \boldsymbol{\Theta} - \frac{I\beta_M}{\hbar}\dot{\boldsymbol{B}}\,, \tag{3.9b}$$

respectively, where $-k_t\boldsymbol{\xi}$ and $-k_r\boldsymbol{\Theta}$ represent the overlap force acting on the radical, and the moment of the overlap force and electrostatic forces from the other constituents in the crystal respectively. Accordingly F_1 and N_1 given by (2.19) should be identified with $-k_t\xi_1$ and $-k_r\theta_1$ respectively. Furthermore, k_t and k_r in (3.9) are given by

$$k_t = \left(\frac{\varepsilon_0+2}{\varepsilon_\infty+2}\right)\overline{M}\omega_{tt}^2 \tag{3.10a}$$

$$k_r = I\,\omega_{rt}^2/\alpha \tag{3.10b}$$

respectively, where $\overline{M} = M_R M_K/(M_R+M_K)$, $I = 8/3\, M_c(\sqrt{3}\, u a_0)^2$, M_R, M_K and M_c are the masses of a radical, a Na-ion and a coordinated O-ion respectively. (cf. § 3 in part II) Then we immedinately obtain

$$\omega_{tt}^2\left(\frac{\varepsilon_0+2}{\varepsilon_\infty+2}\right) = \overset{(+)}{\sum_k}[4T_{11}(k1) + T_{11}(k0)]/\overline{M}\,, \tag{3.11a}$$

$$\omega_{rt}^2/\alpha = \left\{\sum_k [T_{11}(k1) - T_{23}(k1)] - \overset{(-)}{\sum_k}[T_{22}{}^3(k1) - T_{23}{}^2(k1)]\right\}\Big/ M_c\,. \tag{3.11b}$$

We will assume the overlap potentials for the Na-O pair and for the O-O pair to be expressed by

$$b_1 \exp(-r/\rho_1) \text{ and } b_2 \exp(-r/\rho_2) \tag{3.12}$$

respectively, where r is the interionic distance, and b_1, b_2, ρ_1 and ρ_2 are the adjustable parameters.

If we substitute (3.1) (3.2) and (3.12) into (3.11) and calculating it with the actual $NaClO_4$ crystal, we may obtain the following forms:

$$\omega_{tt}^2 = 4\left[\left(\frac{1}{\rho_1} - \frac{2}{r_1}\right)s_1\right]\Big/\overline{M}Q^2\,, \tag{3.13a}$$

$$\omega_{rt}^2 = \left[\left(\frac{1.4671}{\rho_1} - \frac{1.5329}{r_1}\right)s_1 - \frac{3s_2}{r_2} + f_1(Z_c)\right]\alpha\Big/M_c\,, \tag{3.13b}$$

where

$$s_1 \equiv \frac{b_1}{\rho_1}\exp\left(-\frac{r_1}{\rho_1}\right), \qquad s_2 = \frac{b_2}{\rho_2}\exp\left(-\frac{r_2}{\rho_2}\right),$$

$$Q \equiv \left(\frac{\varepsilon_0+2}{\varepsilon_\infty+2}\right)^{1/2}, \qquad \overline{M} = 18.69 M_H \text{ and}$$

$M_c = 16.00 M_H$ (M_H: mass of a H-atom). $r_1 (= 2.993\times 10^{-8}\text{ cm})$ and $r_2 (= 2.432\times 10^{-8}\text{ cm})$ are the equilibrium distances of the Na-O pair and the O-O pair respectively. $f_1(Z_c)$ originates from the Coulomb interactions and depends on the effective charge $Z_c e$ of the O-ion as

$$f_1(Z_c) \equiv -(4.935 Z_c^2 + 0.729 Z_c)\times 10^4 \ (\text{erg/cm}^2) \tag{3.13c}$$

§ 4. Cohesive Energy and Compressibility

If the state consisting of free Na^+-ions and free $[ClO^4]^-$-radicals is taken as the reference level of the energy, the cohesive energy per cation-radical pair, E_p, for an arbitrary lattice constant a, is expressed by

$$E_p = \frac{1}{2}\sum_{i=0}^{5}\sum_k \sum_{j=1}^{n(ki)} \phi_{ki}(\bar{r}(j;ki)) - \frac{(M_\alpha + p)e^2}{a}\,, \tag{4.1}$$

where

$$\bar{r}(j;\,ki) \equiv |\boldsymbol{y}_L(j;\,ki)'a + \boldsymbol{x}_0(j;\,ki)'a_0 - \boldsymbol{x}_0(i)|\,,$$

(cf. (2.2) and (2.16))

$$\boldsymbol{y}_L(j;\,ki) \equiv \boldsymbol{y}_L(j;\,ki)'a_0$$

and

$$\boldsymbol{x}_0(j;\,ki) \equiv \boldsymbol{x}_0(j;\,ki)'a_0\,.$$

The summation sign with respect to k means the summation up to the third neighbours. M_α is the Madelung constant (=3.4951) and

$p\,(=-4.2668)$ the numerical constant to cancell the summation of the Coulomb interactions up to the third neighbours, which is included also in the first term.

In (4.1) the size and the orientation of the radical are assumed to remain unchanged with the variation of the parameter a on account of its rigidity and the crystal symmetry, and furthermore radicals are regarded as point charges with the electronic charge e, when the distance between two different radicals or between a radical and a Na-ion is larger than the third-neighbour distance $(=\sqrt{3}\,a_0/2)$.

From (4.1) $(E_p)_{a=a_0}$ is given actually by

$$(E_p)_{a=a_0}=\left[12b_1\exp\left(-\frac{r_1}{\rho_1}\right)+6b_2\exp\left(-\frac{r_2}{\rho_2}\right)+f_2(Z_c)\right]. \tag{4.2}$$

$f_2(Z_c)$ in (4.2) represents the Coulomb interaction and has the form:

$$f_2(Z_c)\equiv-(0.440Z_c^2-0.048Z_c+0.256) \tag{4.2a}$$

when the energy is expressed in atomic units. (1 atomic unit of energy equals 4.354×10^{-11} ergs or 623.96 Kcal/mol).

As well-known, E_p should satisfy the following relations[5)]

$$\left(\frac{\partial E_p}{\partial a}\right)_{a=a_0}=0 \tag{4.3}$$

and

$$\frac{1}{\beta_c}=\frac{a_0^2}{9v_0}\left(\frac{\partial^2 E_p}{\partial a^2}\right)_{a=a_0}, \tag{4.4}$$

where $v_0\equiv a_0^3/8$ and β_c is the compressibility of the crystal.

Substituting (4.1) into (4.3) and (4.4), we obtain

$$\left(\frac{\partial E_p}{\partial a}\right)_{a=a_0}=\frac{1}{2}\sum_{i=0}^{5}\sum_{k}\sum_{j=1}^{n(ki)}\phi'_{ki}(r(ki))\times\left(\frac{\partial\overline{\mathbf{r}}(j;ki)}{\partial a}\right)_{a=a_0}+\frac{(M_\alpha+p)e^2}{a_0^2}=0 \tag{4.5}$$

$$\frac{9v_0}{a_0^2\beta_c}=\left(\frac{\partial^2 E_p}{\partial a^2}\right)_{a=a_0}=\frac{1}{2}\sum_{i=0}^{5}\sum_{k}\sum_{j=0}^{n(ki)}\left[\phi_{ki}''(r(ki))\times\left(\frac{\partial\overline{\mathbf{r}}(j;ki)}{\partial a}\right)^2+\phi_{ki}'(r(ki))\left(\frac{\partial^2\overline{\mathbf{r}}(j;ki)}{\partial a^2}\right)\right]_{a=a_0}-\frac{2(M_\alpha+p)e^2}{a_0^3}, \tag{4.6}$$

where

$$\left.\begin{aligned}
&\left(\frac{\partial\overline{\mathbf{r}}(j;ki)}{\partial a}\right)_{a=a_0}\\
&=(\mathbf{y}_L(j;ki)',\ \mathbf{y}_0(j;ki)'-\mathbf{x}_0(i)')/r(ki)'\\
&\left(\frac{\partial^2\overline{\mathbf{r}}(j;ki)}{\partial^2 a}\right)_{a=a_0}\\
&=\left[\mathbf{y}_L(j;ki)'^2-\left(\frac{\partial\overline{\mathbf{r}}(j;ki)}{\partial a}\right)_{a=a_0}\right]\Big/r(ki)\\
&\mathbf{y}_0(j;ki)'\equiv\mathbf{y}_L(j;ki)+\mathbf{x}_0(j;ki)'\\
&r(ki)\equiv a_0r(ki)'\quad\text{and}\quad\mathbf{x}_0(i)\equiv a_0\mathbf{x}_0(i)'
\end{aligned}\right\} \tag{4.7}$$

When the ith ion is a Cl-ion or a Na-ion ($i=0$ or 5) and the ki-group is of Na-ions or Cl-ions also, then $\mathbf{x}_0(i)'=0$ and $\mathbf{y}_L(j;ki)'=\mathbf{y}_0(j;ki)'=r(ki)'$.

Therefore, $\left(\frac{\partial\overline{\mathbf{r}}(j;ki)}{\partial a}\right)_{a=a_0}=r(ki)'$ and $\left(\frac{\partial^2\overline{\mathbf{r}}(j;ki)}{\partial a^2}\right)_{a=a_0}=0$. Substituting (4.7) into (4.5) and (4.6) and calculating them with the actual NaClO$_4$ crystal, we obtain

$$10.2308s_1+3.8092s_2=f_3(Z_c)\,, \tag{4.8}$$

$$\frac{1}{\beta_c}=\frac{a_0^2}{9v_0}\left[\left(\frac{2.3923}{\rho_1}-\frac{0.6077}{r_1}\right)s_1+\left(\frac{0.5970}{\rho_2}-\frac{2.4030}{r_2}\right)s_2+f_4(Z_c)\right], \tag{4.9}$$

where $f_3(Z_c)$ and $f_4(Z_c)$ are the contributions from Coulomb interaction and given by

$$f_3(Z_c)\equiv(28.882Z_c^2-3.855Z_c+3.036)\times10^{-4}\ \text{(dyne)} \tag{4.8a}$$

and

$$f_4(Z_c)\equiv-(10.139Z_c^2-0.969Z_c-0.368)\times10^{-4}\ \text{(erg/cm}^2\text{)}\,, \tag{4.9a}$$

respectively.

§ 5. Conclusion

(3.13a), (3.13b), (4.2), (4.8) and (4.9) contain the four unknown parameters b_1, b_2, ρ_1 and ρ_2 together with Z_c. Therefore it is necessary to know four experimental data for ω_{tt}, ω_{rt}, $(E_p)_{a=a_0}$ and β_c besides $\mathcal{E}_0$, $\mathcal{E}_\infty$ and α, in order to determine these parameters unambiguously from these five equations. Unfortunately we cannot find none of them for the cubic NaClO$_4$ crystal. However, we can obtain some suggestions on the order of magnitude of ω_{rt} as well as that of ω_{tt}, by surveying the general aspects of the overlap forces in other crystals, which have been investigated with considerable accuracy.

We may infer as below that the overlap force of the O-O pair is attractive and its magnitude is nearly of the same order as that of the repulsive overlap force of the Na-O pair.

Referring to (3.13b) and (3.13c), the term $f_1(Z_c)$ originating from the Coulomb interactions, to which those of the O-O pairs ((1) and (2) (3) (4) in Fig. 1) considerably contribute, takes a negative value for a value of Z_c within the range 0~1 and the magnitude of the quantity in the square brackets in (3.13b) accordingly ω_{rt} is sensitively decreased with increasing Z_c value. Thus the Coulomb interaction tends to make unstable the equilibrium orientation of the radical.

The ionic radius of the coordinated O-ion with effective charge Z_ce ($Z_c=0\sim1$) may be roughly estimated to be 0.66~1 Å, since the ionic radii of the neutral O-atom and O^{2-}-ion are 0.66 Å and 1.40 Å respectively. The sum of the ionic radii of the two ions constituting the ion-pair is 1.3~2 Å for the O-O pair with the interionic distance $r_2=2.432$ Å and 1.6~2 Å for the Na-O pair with the interionic distance $r_1=2.993$ Å. (Ionic radius of Na^+-ion: 0.95 Å) Therefore the O-ions of the O-O pair would overlap at least to the extent that this overlap cannot be ignored for that between the Na-ion and the O-ion of the Na-O pair. Accordingly, it would be somewhat unreasonable to assume a much smaller magnitude for s_2, compared with that of s_1.

The overlap forces of the Na-O pairs are obviously repulsive ($b_1>0$), whereas those of the O-O pairs will be attractive ($b_2<0$). If it were not so ($b_2<0$), the cubic $NaClO_4$ crystal would be unstable or not exist, in particular, at high temperatures, since the quantity in the square brackets in (3.13b) takes a very small posive value or even a negative value for reasonable orders of magnitudes of ρ_1, s_1 (>0) and s_2 (>0). The fact that the overlap force of the O-O pair may be attractive has been infered also in the cubic MgO crystal⁶⁾. Therefore, we assume that b_2 accordingly s_2 are negative, whereas b_1 and s_1 are positive.

As regards the repulsive overlap forces for the ion-pairs of the cubic sodium halide crystals, the orders of magnitudes of $b/\rho\exp(-r_0/\rho)$ and ρ are about $1.25\sim0.64\times10^{-4}$ dyne and $0.29\sim0.36\times10^{-8}$ cm respectively⁷⁾, where r_0 is the equilibrium distance of the ion-pair. For the attractive overlap force of the O-O pair in the cubic MgO crystal, the values of $b/\rho\exp(-r_0/\rho)$ and ρ, giving the reasonable cohesive energy have been estimated to be about 1.33×10^{-4} dyne and 0.20×10^{-8} cm respectively⁶⁾.

If we fix s_1, $s_1/s_2\equiv q(<0)$ and ρ_1 at given values, we can find the corresponding Z_c value by means of (4.8) and (4.8a) and furthermore the value of $f_1(Z_c)$ corresponding to this Z_c value by using (3.13c). Therefore, the values of $\omega_{tt}Q$ and $\omega_{rt}/\sqrt{\alpha}$ may be calculated numerically by means of (3.13a) and (3.13b) respectively. Fig. 3 shows the curves of $\omega_{tt}Q$ and $\omega_{rt}/\omega_{tt}Q\sqrt{\alpha}$ thus obtained, in the case where ρ_1 is fixed at the reasonable value 0.3×10^{-8} cm and s_1 and q at various values within the probable ranges $0.5\sim1.5\times10^{-4}$ dyne and $-0.50\sim-2.00$ respectively. $f_3(Z_c)$ takes a minimum value f_m at $Z_c=0.066$ and the corresponding Z_c values in the above procedure are taken within the range 0.066~1. Since the selection of the set of the values of s_1 and q is restricted by the condition that $f_3(Z_c)$ in (4.8) $\geq f_m$, the $\omega_{rt}/\omega_{tt}Q\sqrt{\alpha}$ curves with $q=-1.50$ and -2.00 are cut off at intermediate points.

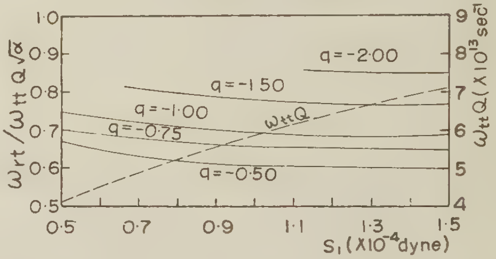

Fig. 3. Dependences of $\omega_{tt}Q$ and $\omega_{rt}/\omega_{tt}Q\sqrt{\alpha}$ upon s_1.
The real curves show $\omega_{rt}/\omega_{tt}Q\sqrt{\alpha}$ and the dotted curve $\omega_{tt}Q$. $\rho_1=0.3\times10^{-8}$ cm.

Referring to the curves of $\omega_{rt}/\omega_{tt}Q\sqrt{\alpha}$ in Fig. 3, we may point out that they are nearly insensitive to the selection of s_1 value, so far as q is kept constant. $\omega_{rt}/\omega_{tt}Q\sqrt{\alpha}$ slowly increases with increasing magnitude of q and lies within the range 0.6~0.8. Since $Q\gtrsim1$ and $\alpha\doteqdot1$ (cf. § 6 in part II) we may mention that the frequency of the rotational vibration ω_{rt} has an order of magnitude comparable to the frequency of the translational vibration ω_{tt}, that is, to the Reststrahlen frequency.

Therefore, the order estimation which has been made on the scattering probability of a conduction electron by the rotational phonon field (cf. § 6 in part II) would be reasonable.

When $q=-1$, $\rho_1=0.3\times10^{-8}$cm and $s_1=1\times10^{-4}$ dyne, the corresponding Z_c value is 0.41, $\omega_{tt}Q=5.86\times10^{13}\,\mathrm{sec}^{-1}$ and $\omega_{rt}/\sqrt{\alpha}=4.10\times10^{13}\,\mathrm{sec}^{-1}$. Then the cohesive energy per cation-radical pair and the compressibility of the cubic $NaClO_4$ crystal, which are calculated by making use of (4.2), (4.2a), (4.9) and (4.9a) and by using 0.3×10^{-8} cm also for ρ_2, are about 0.27 in atomic unit (=168 Kcal/mol) and 1.40×10^{-12} barye^{-1} respectively.

If the electronic structure assumed for $[SO_4]^{2-}$ radical is available also for $[ClO_4]^-$ radical, the normal state of the latter is considered to be the reasonce of several electronic structures which contain single and double covalent bonds and double ionic bonds and in which the effective charge on a coordinated O-ion is estimated to be 0, 0.25e, 0.5e, 0.75e and e8). The most typical one of them may be represented by the structure such as  $\begin{smallmatrix}O^-\\O^-\end{smallmatrix}\!>Cl^+\!\lessdot\begin{smallmatrix}O\\O\end{smallmatrix}$. Therefore, the effective charge 0.41e on a coordinated O-ion which is estimated in our calculation would be reasonable.

Appendix I.

The atomic arrangement in the cubic $NaClO_4$ crystal is as follows:

Na:	$\frac{1}{2}\ 0\ 0$;	$0\ \frac{1}{2}\ 0$;	$0\ 0\ \frac{1}{2}$;	$\frac{1}{2}\ \frac{1}{2}\ \frac{1}{2}$
Cl:	$0\ 0\ 0$;	$\frac{1}{2}\ \frac{1}{2}\ 0$;	$\frac{1}{2}\ 0\ \frac{1}{2}$;	$0\ \frac{1}{2}\ \frac{1}{2}$
O :	$u\ u\ u$;	$u\ \bar{u}\ \bar{u}$;	$\bar{u}\ u\ \bar{u}$;	$\bar{u}\ \bar{u}\ u$

and the twelve equivalent points about the Cl-ion sites $(\frac{1}{2}\ \frac{1}{2}\ 0)$ $(\frac{1}{2}\ 0\ \frac{1}{2})$ and $(0\ \frac{1}{2}\ \frac{1}{2})$.

Appendix II.

The four tensors $\boldsymbol{T}(\boldsymbol{k}i)$ $(i=1, 2, 3, 4)$ and the twelve tensors $\boldsymbol{T}^\gamma(\boldsymbol{k}i)$ $(i=1, 2, 3, 4: \gamma=1, 2, 3)$ are dependent with each other. The components of $\boldsymbol{T}(\boldsymbol{k}i)$ and $\boldsymbol{T}^\gamma(\boldsymbol{k}i)$ $(i=2, 3, 4)$ may be expressed in terms of those of $\boldsymbol{T}(\boldsymbol{k}1)$ and $\boldsymbol{T}^\gamma(\boldsymbol{k}1)$ respectively by the ordinary transformation formulae:

$$\left.\begin{aligned}
&T_{\alpha\beta}(\boldsymbol{k}i)=\sum_{\xi,\eta=1}^{3}C_{\alpha\xi}^{(i)}C_{\beta\eta}^{(i)}T_{\xi\eta}(\boldsymbol{k}1)\\
&T_{\alpha\beta}^{\gamma}(\boldsymbol{k}i)=\begin{cases}\displaystyle\sum_{\xi,\eta=1}^{3}C_{\alpha\xi}^{(i)}C_{\beta\eta}^{(i)}T_{\xi\eta}^{\gamma}(\boldsymbol{k}1)\\ \quad(\text{for }\gamma=i-1)\\ \displaystyle-\sum_{\xi,\eta=1}^{3}C_{\alpha\xi}^{(i)}C_{\beta\eta}^{(i)}T_{\xi\eta}^{\gamma}(\boldsymbol{k}i)\\ \quad(\text{for }\gamma\equiv i\ (\mathrm{mod.}\ 3)\\ \quad\ \text{and }\gamma\equiv i+1\ (\mathrm{mod.}\ 3))\end{cases}\\
&\qquad(i=2,\ 3,\ 4:\ \gamma=1,\ 2,\ 3),
\end{aligned}\right\}\quad(\mathrm{AII\text{-}1})$$

where the transformation matrices $C^{(i)}$ are given by

$$C^{(2)}=\begin{pmatrix}1&0&0\\0&-1&0\\0&0&-1\end{pmatrix},\quad C^{(3)}=\begin{pmatrix}-1&0&0\\0&1&0\\0&0&-1\end{pmatrix},$$

$$C^{(4)}=\begin{pmatrix}-1&0&0\\0&-1&0\\0&0&1\end{pmatrix}.$$

Relations between the components of $\boldsymbol{T}(\boldsymbol{k}0)$, $\boldsymbol{T}(\boldsymbol{k}1)$ and $\boldsymbol{T}^\gamma(\boldsymbol{k}1)$ $(\gamma=1, 2, 3)$ are as follows: For an arbitrary orientation of the coordinate system,

$$\left.\begin{aligned}
&T_{\alpha\beta}(\boldsymbol{k}0)=0\quad(\alpha\neq\beta)\\
&\text{and}\\
&T_{11}(\boldsymbol{k}0)=T_{22}(\boldsymbol{k}0)=T_{33}(\boldsymbol{k}0)\ .
\end{aligned}\right\}\quad(\mathrm{AII\text{-}2})$$

If the principal axes of the crystal are taken as the coordinate axes (cf. (2.1c), Fig. 1 and App. I), then

$$\left.\begin{aligned}
&T_{11}(\boldsymbol{k}1)=T_{22}(\boldsymbol{k}1)=T_{33}(\boldsymbol{k}1)\ ,\\
&T_{11}^{\gamma}(\boldsymbol{k}1)=T_{22}^{\gamma}(\boldsymbol{k}1)=T_{33}^{\gamma}(\boldsymbol{k}1)\ ,\\
&T_{\alpha\alpha}^{\gamma}(\boldsymbol{k}1)=T_{\alpha\alpha}^{\gamma'}(\boldsymbol{k}1)\quad(\gamma\neq\gamma')\ ,\\
&\text{and}\\
&T_{12}(\boldsymbol{k}1)=T_{23}(\boldsymbol{k}1)=T_{31}(\boldsymbol{k}1)\ ,\\
&T_{12}^{1}(\boldsymbol{k}1)=-T_{23}^{1}(\boldsymbol{k}1)=T_{31}^{1}(\boldsymbol{k}1)\\
&=T_{12}^{2}(\boldsymbol{k}1)=T_{23}^{2}(\boldsymbol{k}1)=-T_{31}^{2}(\boldsymbol{k}1)\\
&=-T_{12}^{3}(\boldsymbol{k}1)=T_{23}^{3}(\boldsymbol{k}1)=T_{31}^{3}(\boldsymbol{k}1)\ .
\end{aligned}\right\}\quad(\mathrm{AII\text{-}3})$$

Appendix III.

Expressions for $A(\boldsymbol{k})$, $B(\boldsymbol{k})$, $C(\boldsymbol{k})$, $A(\boldsymbol{k})'$ and $B(\boldsymbol{k})'$.

$$\left.\begin{aligned}
&A(\boldsymbol{k})=\frac{1}{r(\boldsymbol{k})^2}\sum_{j=1}^{n(k1)}[y_1(j;\,\boldsymbol{k}1)-x_1(1)]^2\ ,\\
&B(\boldsymbol{k})=\frac{1}{r(\boldsymbol{k})^2}\sum_{j=1}^{n(k1)}[y_2(j;\,\boldsymbol{k}1)-x_2(1)]\\
&\qquad\times[y_3(j;\,\boldsymbol{k}1)-x_3(1)]\ ,\\
&C(\boldsymbol{k})=\frac{1}{r(\boldsymbol{k}0)^2}\sum_{j=1}^{n(k0)}[y_1(j;\,\boldsymbol{k}0)]^2\ .
\end{aligned}\right\}\quad(\mathrm{AIII\text{-}1})$$

$$\left.\begin{aligned} A(k)' &= \frac{1}{ua_0 r(k)^2}\sum_{j=1}^{n(k1)}[y_1(j;\,k1)-x_1(1)]^2 \\ &\quad\times x_3(j;\,k1) \\ B(k)' &= \frac{1}{ua_0 r(k)^2}\sum_{j=1}^{n(k1)}[y_2(j;\,k1)-x_2(1)] \\ &\quad\times[y_3(j;\,k1)-x_3(1)]x_2(j;\,k1) \end{aligned}\right\}\quad\text{(AIII-2)}$$

$A(k)'$ and $B(k)'$ have non-zero values for O-ion groups only.

Electronic States of the *F*-Center in Lithium Fluoride. I

By Tadanobu KOJIMA*

Department of Physics, Osaka University

(Received April 24, 1957)

The electronic states of the *F*-center in LiF are theoretically investigated taking account of the detailed atomic structure of the crystal. The Hamiltonian of an *F*-center including polarization effects is presented. The polarizabilities of the ions in the crystal are determined from the static and high-frequency dielectric constants and the reststrahl frequency. Approximate eigenfunctions and energy levels are calculated with the use of variational wave functions comprising linear combinations of the $2s$ and $2p$ atomic functions on the six lithium ions adjacent to the missing negative-ion site. For both the ground and excited states, the resulting wave functions have larger coefficients of the $2p$ functions than those of the $2s$ functions. The first optical excitation energy is obtained to be somewhat smaller than the experimental value; possible sources of this discrepancy are discussed. The g-factor of the *F*-center is also computed. A more satisfactory theory will be given in the next paper.

§ 1. Introduction

The electronic structure of the *F*-centers in alkali halide crystals has been explored theoretically by various authors since it was first treated by Tibbs[1]. In all the former theories, except that of Inui and Uemura, the crystal was replaced by a continuous dielectric medium with a spherical hole which represented a negative ion vacancy. It has remained an open question, however, to what extent such a continuum approximation could be legitimate from the atomistic view-point; actually, the wave functions obtained by this method were not very accurate as indicated by electron spin resonance experiments[2][3]. It is therefore desirable to make a more detailed calculation, taking full account of the atomic structure of the crystal. Inui and Uemura's work may be considered to have made a step toward this direction. In their work, however, the displacements and deformations of ions were entirely neglected, and the wave functions were chosen merely so as to satisfy the symmetry requirements (without solving the wave equation). The primary purpose of this and next papers is to carry through detailed calculations which are based on the atomistic standpoint and to clarify the nature of the approximations hitherto employed. Calculations were made on LiF, which is the simplest crystal of alkali halides for the purpose of making numerical calculations, but the methods developed here may equally be adapted to other alkali halides, with certain appropriate modifications.

---

* Present address: Research Institute for Atomic Energy, Osaka City University, Awaza-Nakadori Osaka.

The method of the present calculation is essentially a variational method: We first take a trial function of a suitable symmetric form for the wave function of the trapped electron, fix a variational parameter to an arbitrary value, look for the displacements and induced dipole-moments of all the ions which are consistent with the assumed wave function, and calculate the total energy of the crystal. In this way, we get the energy of the crystal as a function of the parameter. Then, finding the minimum of this energy, we obtain the desired energy and wave function.

In § 2 the ionic polarizabilities of the crystal are discussed, in § 3 the Hamiltonian for an *F*-center including polarization effects is presented, in § 4 the eigenfunctions and eigenenergies of the Hamiltonian are computed in the *LCAO* approximation, and in § 5 the *g*-factor is calculated making use of the obtained wave function.

§ 2. Polarizabilities of the Ions in the Crystal

The polarizabilities of the ions in crystals differ from those of the ions in free space owing to their interactions with the surroundings. Let α_+^o and α_-^o be the polarizabilities of the positive and negative ions, respectively, when the crystal is subject to a high-frequency electric field for which no displacements of the ions occur. These polarizabilities are related to the high-frequency dielectric constant κ_0 by the Lorenz-Lorentz formula:

$$\alpha_+^o+\alpha_-^o=\frac{3v}{4\pi}\,\frac{\kappa_0-1}{\kappa_0+2} \qquad (1)$$

where v $(=2a^3)$ is the volume per ion pair in the crystal. Now a static field be applied to the crystal. The polarization then arises not only from ionic deformations but also from displacements of the ions. Let the contribution of the latter to the polarizability be α_d, and the contribution of the former α_+^s and α_-^s, for the positive and negative ions respectively. These quantities and the static dielectric constant κ are related by Clausius-Mosotti formula:

$$\alpha_+^s+\alpha_-^s+\alpha_d=\frac{3v}{4\pi}\,\frac{\kappa-1}{\kappa+2}\,. \qquad (2)$$

Further, defining e^*_{sphere} for a spherical specimen by the expression:

$$e^*_{\text{sphere}}=\frac{(\alpha_+^s+\alpha_-^s+\alpha_d)-(\alpha_+^o+\alpha_-^o)}{\alpha_d} \qquad (3)$$

we have between e^*_{sphere} and κ, κ_0, ω_t (=the angular frequency of transverse lattice wave) the Lyddane-Sachs-Teller relation[4]:

$$\kappa-\kappa_0=4\pi\left(\frac{\kappa_0+2}{3}\right)^2\frac{e^{*2}_{\text{sphere}}}{\overline{M}v\omega_t^2}\,, \qquad (4)$$

$\overline{M}$ being the reduced mass of the ions.

Using the experimental values for LiF: $\kappa=9.27$, $\kappa_0=1.92$, $\omega_t=5.78\times10^{13}\,\text{sec}^{-1}$ and $a=2.01\text{Å}$, we obtain from the above relations

$$\begin{aligned}&\alpha_d=2.34_9\text{Å}^3\,,\\&\alpha_+^s+\alpha_-^s=0.49_6\text{Å}^3\,,\\&\alpha_+^o+\alpha_-^o=0.91_0\text{Å}^3\,.\end{aligned} \qquad (5)$$

To separate the contributions from the positive and negative ions, we first notice that the requirements $\alpha_+^f<\alpha_+^o<\alpha_+^s$ and $\alpha_-^f>\alpha_-^o>\alpha_-^s$ should be satisfied, where α_+^f and α_-^f denote the polarizabilities of the positive and negative ions in free space. Adopting Pauling's values[5]: $\alpha_+^f=0.029\text{Å}^3$ and $\alpha_-^f=1.04\text{Å}^3$ (Pauling's value of α_+^f is very close to that obtained by a variational method: 0.031Å^3 [6]) and setting $\alpha_+^o=0.04\text{Å}^3$ and $\alpha_+^s=0.07\text{Å}^3$ as reasonable values, we get values shown in Table I. It is interesting to compare these values with those given by other authors. Shockley[7] assumed α^o to be a quantity characteristic of each ion, irrespectively of the sort of the crystal which contains the ion, and so determined α^o's of the alkali and

Table I. Polarizabilities of Li^+ and F^- ions in Å^3

	α^f	α^o	α^s
α_+	0.03	0.04	0.07
α_-	1.04	0.87	0.42_6
α_d			2.35

halogen ions as to get a best fit of the Lorenz-Lorentz formula for all the alkali halides. His values for Li^+ and F^- are $\alpha_+{}^o=0.045\text{Å}^3$ and $\alpha_-{}^o=0.86\text{Å}^3$. The method used by Mott and Littleton[8)] is essentially to calculate $\alpha_+{}^s$, $\alpha_-{}^s$ and α_d, assuming that

$$\alpha_+{}^s:\alpha_-{}^s:\alpha_d=\alpha_+{}^f:\alpha_-{}^f:\alpha_d{}' ,$$

(which contradicts with the requirement $\alpha_+{}^f<\alpha_+{}^s$) where $\alpha_d{}'$ is given from the expression

$$\kappa-\kappa_0=\frac{4\pi\beta}{1-4\pi\beta/3} , \qquad \beta=\frac{\alpha_d{}'}{v} .$$

These are derived under the assumption that the polarizations due to displacement and deformation do not interfere one another, $\alpha_d{}'$ corresponds to α_d for an effective field which cares for the overlap effect between neighboring ions. Their method when applied to LiF yields $\alpha_+{}^s=0.02\text{Å}^3$, $\alpha_-{}^s=0.77\text{Å}^3$ and $\alpha_d=2.06\text{Å}^3$. This value of $\alpha_-{}^s$ is presumably too large (compare with given in Table I).

Now, resorting to the continuum approximation, let Maxwell's displacement vector be $\boldsymbol{D}$, whose spatial variation in the crystal is assumed to be sufficiently slow in the range of interatomic distances. When a high-frequency field is applied, there is an induced dipole of strength per ion pair of $(v/4\pi)(1-1/\kappa_0)\boldsymbol{D}$. Then, if we denote the contributions of the positive and negative ions to this dipole by $M_+{}^o\boldsymbol{D}a^3$ and $M_-{}^o\boldsymbol{D}a^3$, respectively, $M_\nu{}^o(\nu=+$ or $-)$ can be expressed as

$$M_\nu{}^o=\frac{1}{4\pi}\left(1-\frac{1}{\kappa_0}\right)\frac{\alpha_\nu{}^o}{\alpha_+{}^o+\alpha_-{}^o} . \qquad (6)$$

When a static field is applied, there is an induced dipole of $(v/4\pi)(1-1/\kappa)\boldsymbol{D}$ per ion pair, so that, denoting the contributions of the positive and negative ions to this dipole by $M_+\boldsymbol{D}a^3$ and $M_-\boldsymbol{D}a^3$, respectively, $M_\nu(\nu=+$ or $-)$ can be expressed as

$$M_\nu=\frac{1}{4\pi}\left(1-\frac{1}{\kappa}\right)\frac{\alpha_\nu{}^s+\alpha_d\overline{M}/\overline{M}_\nu}{\alpha_+{}^s+\alpha_-{}^s+\alpha_d} , \qquad (7)$$

where $\overline{M}_\nu$ is the mass of the ν-th ion. If we assumed, with Mott and Littleton, equal amounts of displacement for ions of the two kinds for a static field, it would have turned out that a strain field was produced in the crystal for an inhomogeneous $\boldsymbol{D}$. In (7) we assumed that the center of gravity does not displace when a static field is applied, in order to separate the effect of strain.

The above assumptions are applicable only if $\boldsymbol{D}$ varies slightly from ion to ion and the effect of the vacancy on the polarizabilities can be ignored. This does not seem very satisfactory especially for those ions which are immediate neighbors of the vacancy. Neverthless we apply these assumptions in the following calculations taking $\boldsymbol{D}=e\boldsymbol{r}/r^3$ (Mott and Littleton's zeroth approximation). In the next paper, however, we shall proceed to higher approximations, where it will be shown that most results of the zeroth approximation are not appreciably affected.

While this zeroth approximation is used throughout this paper, for simplicity, in discussing polarization effects, all the necessary expressions applicable to higher approximations are given. One has merely to replace M_ν and $M_\nu{}^o$ of the next section by more accurate values.

§ 3. The Hamiltonian

The Hartree-Fock Hamiltonian and its expectation value for an F-center in its ground state consist of the following terms, neglecting the effects of lattice vibrations and magnetic interactions:

I. *Kinetic Energy of the Trapped Electron.*—This contributes to the Hamiltonian,

$$\mathscr{H}_1=-(\hbar^2/2m)\nabla^2 , \qquad (8)$$

and to the energy,

$$\int\psi\mathscr{H}_1\psi d\tau=-(\hbar^2/2m)\int\psi\nabla^2\psi d\tau , \qquad (8a)$$

where $\psi(\boldsymbol{r})$ denotes the wave function of the trapped electron in the ground state.

II. *Interactions between the Trapped Electron and the Ions.*

(a) *The interactions not concerned with polarization effects.*—Disregarding the overlap between ions, these contribute to the Hamiltonian

$$\mathscr{H}_2=-e^2\sum_\nu\frac{Z_\nu}{|\boldsymbol{r}-\boldsymbol{R}_\nu|}+2e^2\sum_{\nu,j}\int\frac{\chi_{\nu j}{}^2(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|}d\tau', \qquad (9)$$

in which $\boldsymbol{R}_\nu$ is the position vector of the ν-th lattice site, Z_ν the atomic number of the ν-th ion, and $\chi_{\nu j}$ is the undistorted j-th core wave function of the ν-th ion. The corresponding energy is

$$\int\psi\mathscr{H}_2\psi d\tau=-e^2\sum_\nu Z_\nu\int\frac{\psi^2(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{R}_\nu|}d\tau$$

$$+2e^2\sum_{\nu,j}\iint\frac{\psi^2(\boldsymbol{r})\chi_{\nu j}{}^2(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|}d\tau d\tau' . \qquad (9a)$$

The effect of overlap between ion cores might be calculated by the method of Löwdin[9] which was developed in his theory of the cohesive energy of ionic crystals. However, we shall neglect it since the overlap integrals between core functions are no greater than about 0.05.

(b) *Interactions between the trapped electron and the polarizations induced by the vacancy.*—A dipole of strength $-M_\nu e a^3 \nabla_\nu R_\nu^{-1}$ is induced on the ν-th ion by the vacancy charge e. The interaction between the trapped electron and all such dipoles in the Hamiltonian is

$$\mathscr{H}_3 = \sum_\nu M_\nu e^2 a^3 \nabla_\nu \frac{1}{|\boldsymbol{r}-\boldsymbol{R}_\nu|} \cdot \nabla_\nu \frac{1}{R_\nu}, \tag{10}$$

and the corresponding interaction energy is

$$\int \psi \mathscr{H}_3 \psi d\tau = -\sum_\nu \frac{M_\nu e^2 a^3}{R_\nu^2} \frac{\partial}{\partial R_\nu} \int \frac{\psi^2(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{R}_\nu|} d\tau. \tag{10a}$$

Contributions from higher multipoles will be small and may safely be neglected. In the above expressions all the displacement dipoles and ion-core dipoles have been assumed to be point dipoles; although this approximation is fairly good for the calculation of the interaction energy, it cannot be used in a more careful calculation as that given in the next paper.

(c) *Interactions between the trapped electron and the optical polarizations induced by it.*—The optical dipole moment induced on the ν-th ion by the charge element $-e\psi^2(\boldsymbol{r})d\tau$ of the trapped electron is given by

$$M_\nu^o e a^3 \nabla_\nu \frac{\psi^2(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{R}_\nu|} d\tau,$$

and the time-average electric field at $\boldsymbol{R}_\nu$ due to the trapped electron is

$$e\nabla_\nu \int \frac{\psi^2(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{R}_\nu|} d\tau.$$

Hence the contribution from such dipoles is

$$\mathscr{H}_{4a} = -\sum_\nu M_\nu^o e^2 a^3 \nabla_\nu \int \frac{\psi^2(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{R}_\nu|} d\tau \cdot \nabla_\nu \frac{1}{|\boldsymbol{r}-\boldsymbol{R}_\nu|}, \tag{11}$$

and the interaction energy,

$$\int \psi \mathscr{H}_{4a} \psi d\tau = -\sum_\nu M_\nu^o e^2 a^3 \left| \nabla_\nu \int \frac{\psi^2(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{R}_\nu|} d\tau \right|^2. \tag{11a}$$

(d) *Interaction between the trapped electron and the infrared polarization induced by it.*—The infrared part of the polarization is defined as a difference between the total polarization and the optical part of the polarization. Accordingly, the necessary expressions are obtained merely by inserting $M_\nu - M_\nu^o$ in place of M_ν^o in (11) and (11a). Writing explicitly,

$$\mathscr{H}_{4b} = -\sum_\nu (M_\nu - M_\nu^o) e^2 a^3 \times \nabla_\nu \int \frac{\psi^2(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{R}_\nu|} d\tau \cdot \nabla_\nu \frac{1}{|\boldsymbol{r}-\boldsymbol{R}_\nu|}, \tag{12}$$

$$\int \psi \mathscr{H}_{4b} \psi d\tau = -\sum_\nu (M_\nu - M_\nu^o) e^2 a^3 \times \left| \nabla_\nu \int \frac{\psi^2(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{R}_\nu|} d\tau \right|^2. \tag{12a}$$

(e) *Exchange interactions between the trapped electron and the core electrons.*—The exchange interactions contribute to the Hamiltonian,

$$\mathscr{H}_5 = -e^2 \sum_j \int \frac{\psi(\boldsymbol{r}')\chi_{\nu j}(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|} d\tau' \frac{\chi_{\nu j}(\boldsymbol{r})}{\psi(\boldsymbol{r})}, \tag{13}$$

and to the energy,

$$\int \psi \mathscr{H}_5 \psi d\tau = -e^2 \times \sum_{\nu, j} \iint \frac{\psi(\boldsymbol{r})\chi_{\nu j}(\boldsymbol{r})\psi(\boldsymbol{r}')\chi_{\nu j}(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|} d\tau d\tau'. \tag{13a}$$

III. *Internal Energy of the Polarized Lattice.*—This is composed of the self-energy of the ion-core dipoles induced by the trapped electron and the change in interaction energy among all the ions due to this polarization. This energy can be expressed as

$$\int \psi \mathscr{H}_6 \psi d\tau = -\frac{1}{2} \int \psi (\mathscr{H}_{4a} + \mathscr{H}_{4b}) \psi d\tau. \tag{14a}$$

For the derivation of this expression, see Appendix A. (14a) suggests an equivalent Hamiltonian for the internal energy:

$$\mathscr{H}_6 = -\frac{1}{2} (\mathscr{H}_{4a} + \mathscr{H}_{4b}). \tag{14}$$

The total energy of the F-center in its ground state is thus given by

$$E = \int \psi \mathscr{H} \psi d\tau, \tag{15}$$

where $\mathscr{H}$ stands for the complete Hamiltonian:

$$\mathscr{H} = \mathscr{H}_1 + \mathscr{H}_2 + \cdots + \mathscr{H}_6. \tag{16}$$

For excited states, we must distinguish between two cases, *i.e.*, optically excited states in which all the ions are fixed, by the Franck-Condon principle, to their positions in the ground state, and thermally excited states in which they are allowed to move to new equilibrium positions. For optically excited states, we have to use the infrared polarization of the ground state, when calculating the interaction energy with the trapped electron. Thus, for optically excited states, we use, instead of (11), (13) and (14),

$$\mathscr{H}_{4a}^{e}=-\sum_{\nu} M_{\nu}^{0}e^{2}a^{3}$$

$$\times \nabla_{\nu}\int\frac{\psi_{e}^{2}(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{R}_{\nu}|}d\tau\cdot\nabla_{\nu}\frac{1}{|\boldsymbol{r}-\boldsymbol{R}_{\nu}|}, \tag{17}$$

$$\mathscr{H}_{5}^{e}=-e^{2}\sum_{j}\int\frac{\psi_{e}(\boldsymbol{r}')\chi_{\nu j}(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|}d\tau'\ \frac{\chi_{\nu j}(\boldsymbol{r})}{\psi_{e}(\boldsymbol{r})}, \tag{18}$$

$$\mathscr{H}_{6}^{e}=-\frac{1}{2}\mathscr{H}_{4a}^{e}, \tag{19}$$

where $\psi_e(\boldsymbol{r})$ is the wave function of the excited state. The corresponding total energy is

$$E_{e}=\int\psi_{e}\mathscr{H}^{e}\psi_{e}d\tau-\frac{1}{2}\int\psi\mathscr{H}_{4b}\psi d\tau, \tag{20}$$

with

$$\mathscr{H}_{e}=\mathscr{H}_{1}+\mathscr{H}_{2}+\mathscr{H}_{3}+\mathscr{H}_{4a}^{e}+\mathscr{H}_{4b}+\mathscr{H}_{5}^{e}+\mathscr{H}_{6}^{e}. \tag{21}$$

The optical excitation energy is E_e-E. For thermally excited states, all the expressions are the same as for the ground state.

In all previous theories of the continuum model, the interaction energy between the trapped electron and the optical polarization induced by it has been assumed to be a constant independent of the electronic state, whether ground or excited. This assumption corresponds to putting $\mathscr{H}_{4a}=\mathscr{H}_{4a}^{e}=\text{const.}$ in our Hamiltonian. We shall refer to this approximation as 'quasi-adiabatic', against the conventional Hartree-Fock approximation. The quasi-adiabatic approximation in the continuum model is based on the idea that, if the motion of the trapped electron is much slower than that of the ion-core electrons, the induced optical polarization will follow quite easily, or adiabatically, the motion of the trapped electron, so that the interaction between them will be independent of the positions of the trapped electron. This idea has proved to be fruitful for donors and acceptors in most valence semiconductors, in which cases the orbit of the trapped carrier is large compared with the interatomic distance of the host crystal. In the case of *F*-centers, however, the optical polarization due to the trapped electron will not easily follow the motion of the electron. Furthermore, the presence of a negative ion vacancy will affect the optical polarization induced by the trapped electron and hence gives rise to an interaction between the negative ion vacancy and the trapped electron. It would, however, be very difficult to deal duly with the interaction between the electron and the induced optical polarization from the atomistic standpoint, since it is essentially the calculation of the correlation energy between the trapped electron and the core electrons that comes out of the second and higher order perturbation terms taking the interaction as the perturbation.

Notwithstanding all these, use is made of the quasi-adiabatic approximation in the present paper, in line with previous theories, but a comparison of both the approximations will be made in the next paper where it will be shown that they lead to not radically different results.

§4. The *LCAO* Approximation

We shall now calculate the eigenfunctions of the Hamiltonian described in the preceding section using a variation method. As a trial wave function for the trapped electron, we take a linear combination of the 2*s* atomic orbitals, *s*, and the 2*p* atomic orbitals, p_x, p_y and p_z, each localized on one of the six Li$^+$ ions which surround the negative ion vacancy. Numbering the six ions as illustrated in Fig. 1, the wave function for the ground state may be written,

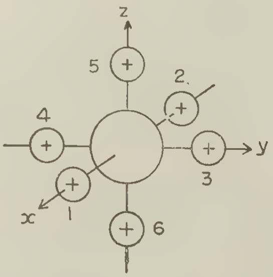

Fig. 1. Numbering the six positive ions around a negative ion vacancy.

$$\psi(\boldsymbol{r})=a_1\sum_{k=1}^{6}s(\boldsymbol{r}-\boldsymbol{R}_k)+a_2\{p_x(\boldsymbol{r}-\boldsymbol{R}_1)-p_x(\boldsymbol{r}-\boldsymbol{R}_2)+p_y(\boldsymbol{r}-\boldsymbol{R}_3)-p_y(\boldsymbol{r}-\boldsymbol{R}_4)+p_z(\boldsymbol{r}-\boldsymbol{R}_5)-p_z(\boldsymbol{r}-\boldsymbol{R}_6)\}, \tag{22}$$

in which, and also in the next expression, the sign of each p function is so chosen that its positive lobe points toward the positive lobe points toward the positive direction of the coordinate axis on which it locates. The first excited states which combine optically with the ground state are triply degenerate. The wave function for one of them may be written

$$\psi_e(\boldsymbol{r})=b_1\{s(\boldsymbol{r}-\boldsymbol{R}_5)-s(\boldsymbol{r}-\boldsymbol{R}_6)\}+b_2\sum_{k=1}^{4}p_z(\boldsymbol{r}-\boldsymbol{R}_k)+b_3\sum_{k=5}^{6}p_z(\boldsymbol{r}-\boldsymbol{R}_k). \tag{23}$$

In (22) and (23), a_i and b_i are variational parameters which are to be so determined as to minimize the corresponding expectation value of the Hamiltonian.

The trial functions constructed in such a way, are not strictly orthogonal to the ion core functions and hence violate the Pauli exclusion principle. As a consequence, it might occur that the energy obtained by minimizing the expectation value of the Hamiltonian becomes much lower than the actual energy value. Since the extension of the wave function and so its overlap with the core functions are larger for the excited state than for the ground state, the above-mentioned lowering of the energy would be more appreciable for the excited state. One would therefore obtain a too low value of the excitation energy by using our trial functions. A possible way of getting out this difficulty would be to orthogonalize the trial functions to the core functions, or as it is practically the same thing, to construct complete determinantal wave functions for the whole crystal. Obviously, however, this procedure is very complicated since we have to use from the start trial functions composed of a large number of atomic orbitals. Another way to go round the difficulty, which is actually adopted in this paper, is to suitably modify the potential function, leaving the trial functions unaltered. We simply replace the ions, to whose core functions the atomic orbitals composing the trial functions are not orthogonal, by point charges.

The atomic orbitals chosen in our actual calculation are the Hartree-Fock functions for a free Li atom[10]. Details of the method of calculation are given in Appendix B. The results are summarized in Table II. The optical first excitation energy obtained is 4.18 ev when polarizations are neglected, and 3.50 ev when they are included. The agreement with experimental value, 4.96 ev, is rather poor. The main source of this discrepancy can be seen by comparing the results with those of a more detailed calculation presented in the next paper. A large part of the discrepancy was found to come from the following: the ground state energy obtained is somewhat too low, and still more so for the excited state. First, our modification of the potential to avoid the nonorthogonality difficulty was not very satisfactory. Second, an additional discrepancy when polarization was included resulted from our use of Mott-Littleton's zeroth approximation. If the positions and deformations of the ions were rearranged to attain the equilibrium configuration, the excited level would have been lowered, but still more lowering would have occured with the ground level. Third, another possible source of the discrepancy may be due to our use of the quasi-adiabatic approximation, as will be discussed in the next paper.

It may be interesting to note that the contribution of the p functions predominates over that of the s functions, as indicated in the caption of Table II, and that by mixing the

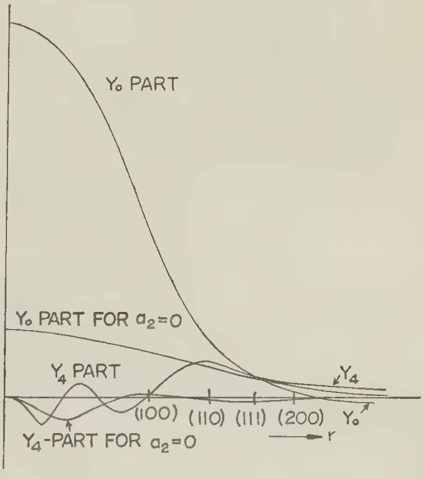

Fig. 2. Behavior of the Y_0 parts and Y_4 parts of the ground state wave function and of the contribution to it from the s functions alone ($a_2=0$).

p functions the ground state energy is lowered by as large as 1.9 ev. Fig. 2 shows the Y_0 and Y_4 parts of the ground state wave function, and for comparison also those parts when only the s functions are used for the linear combination. It may be seen that the Y_0 part is very similar in shape to that obtained by the continuum model, whereas the Y_4 part oscillates violently. It is also noted that the wave function constructed of the s functions only is widely spread over many surrounding ions. This is the main reason why this function gave poor energy levels. In Fig. 3, we have plotted the charge distribution of the trapped electron, $Q(r)=\int_{r'<r}\psi^2(\boldsymbol{r}')d\tau'$, against r. The wave functions obtained will be seen to be somewhat too diffuse when one compares these curves with those in the next paper.

Table II. Calculated energy levels in a.u. The minimum of the expectation value of the Hamiltonian is attained at $a_1=0.064_5$ and $a_2=-0.303$ for the ground state and $b_1=0.174$, $b_2=0.312$ and $b_3=-0.339$ for the first excited state. The values when some of the atomic functions composing the trial functions are omitted are also given for comparison.

State	Atomic Function Employed	Neglecting Polarization	Including Polarization
Ground State	2s only ($a_2=0$)	−0.176	−0.022
	2p only ($a_1=0$)	−0.261	−0.084
	2s and 2p	−0.271	−0.094
First Excited State	2s only ($b_2=b_3=0$)	0.075	0.220
	2p only ($b_1=b_3=0$)	−0.076	0.052
	2p only ($b_1=b_2=0$)	−0.102	0.041
	2s and 2p	−0.118	0.035

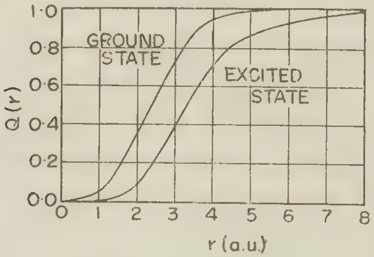

Fig. 3. Charge distributions of a trapped electron.

As is seen in Fig. 2, the computed wave function for the ground state have an extraneous nodal surface, which is unlikely to occur in reality. This evidently comes from the dominant contribution of the p functions or rather a superfluous admixture of them. An improvement might be made by mixing more atomic orbitals located on further ions, but to manipulate a large number of then appearing complicated many-center integrals would make such a calculation very cumbersome.

§ 5. The *g*-Value

In order to obtain the spectroscopic splitting factor, g, for the F-center, we include in the Hamiltonian two additional terms

$$\mathscr{H}_7=\frac{\hbar}{4m^2c^2}[\boldsymbol{\sigma}\times\nabla(-eV)]\cdot\boldsymbol{p}, \tag{24}$$

$$\mathscr{H}_8=\frac{e\hbar}{2mc}\left(\frac{[\boldsymbol{r}\times\boldsymbol{p}]}{\hbar}+\boldsymbol{\sigma}\right)\boldsymbol{H}, \tag{25}$$

where $-eV=\mathscr{H}_2+\mathscr{H}_3+\mathscr{H}_4$, $\boldsymbol{\sigma}$ the Pauli spin vector, and $\boldsymbol{H}$ the external magnetic field. If one already had the eigenfunction, ϕ, of the Hamiltonian which includes $\mathscr{H}_7$ but not $\mathscr{H}_8$, one could calculate the g-value by

$$g\frac{e\hbar}{2mc}H=\frac{\int(\phi\alpha)^*\mathscr{H}_8\phi\alpha d\tau}{\int|\phi\alpha|^2d\tau}-\frac{\int(\phi\beta)^*\mathscr{H}_8\phi\beta d\tau}{\int|\phi\beta|^2d\tau}, \tag{26}$$

where α and β are the usual spin functions. To obtain this ϕ, let us now take the trial function of the form:

$$\phi\alpha=(1+\lambda\mathscr{H}_7)\psi\alpha \tag{27}$$

for the spin state α, and minimize the expectation value of the energy

$$E=\frac{\int(\phi\alpha)^*(\mathscr{H}+\mathscr{H}_7)\phi\alpha d\tau}{\int|\phi\alpha|^2d\tau} \tag{28}$$

with respect to the variational parameter λ. Denoting the minimizing value of λ by λ_m, we have

$$\lambda_m=\frac{4JL^2}{K^2-4L(JK-JL-L^2)}, \tag{29}$$

with

$$J=\int\psi^*\mathscr{H}\psi d\tau,$$

$$K=3\left(\frac{e\hbar^2}{4m^2c^2}\right)^2\int[\nabla V\times\nabla]_z\psi\mathscr{H}[\nabla V\times\nabla]_z\psi d\tau,$$

$$L=3\left(\frac{e\hbar^2}{4m^2c^2}\right)^2\int|[\nabla V\times\nabla]_z\psi|^2d\tau,$$

in which $[\nabla V\times\nabla]_z$ denotes the component of the vector operator, $\nabla V\times\nabla$, along the direction of the magnetic field. Putting $\xi=(e\hbar^2/$

$4m^2c^2)\lambda_m$, the wave function is given by

$$\phi\alpha=\psi\alpha+i\xi\{[\nabla V\times\nabla]_z\psi\alpha+[\nabla V\times\nabla]_x\psi\beta +i[\nabla V\times\nabla]_y\psi\beta\}\,. \tag{30a}$$

Similarly, we have for the spin state β,

$$\phi\beta=\psi\beta+i\xi\{-\nabla V\times\nabla]_z\psi\beta+[\nabla V\times\nabla]_x\psi\alpha -i[\nabla V\times\nabla]_y\psi\alpha\}\,. \tag{30b}$$

Then $\varDelta g(=g-2)$ becomes

$$\varDelta g=-4\xi\int[\nabla V\times\nabla]_z\psi\cdot[\boldsymbol{r}\times\nabla]_z\psi d\tau\,, \tag{31}$$

neglecting terms of the order of ξ^2.

A rough estimation (see Apendix B) using these expressions and the wave function found in §4 yields $\varDelta g\simeq-10^{-3}$. Recently, Lord[11)] has made very careful measurements of the g-factor upon LiF and obtained a positive value, $\varDelta g=+6.2\times10^{-4}$, contrary to our prediction.* However, our theory when applied to KCl, assuming the same value for $a_1:a_2$ as that obtained for LiF, gives a g-value fairly close to the observed one. Kahn and Kittel[2)] state that when the wave function of the ground state is developed in spherical harmonics, in the form

$$\psi=\text{const.}\times[\psi_S+b(\psi_{G^4}+\psi_{G^{-4}})]\,, \tag{32}$$

where ψ_S, $\psi_{G^{-4}}$ and $\psi_{G^{-4}}$ are normalized functions possessing the symmetry properties of Y_0, $Y_{4,4}$ and $Y_{4,-4}$ respectively, the value of b to explain the g-value observed for KCl should be much larger than unity. However, our wave function yields $b=0.13$ and still gives a correct order-of-magnitude value of the g-factor. It should be emphasized that use of an accurate potential function in (31) is of vital importance.

To evaluate the electron resonance line width of the F-center, which is associated with the hyperfine interaction of the trapped electron with the nuclei of the ions surrounding the vacancy and hence with the values of the wave function at these nuclei, we have to use a wave function orthogonalized to all the ion-core functions. Our wave function is only partially orthogonal to the core functions, and so its values at the nuclei can not be expected to be satisfactory. A calculation of the line width using an orthogonalized wave function will be performed in the next paper.

§6. Summary and Conclusions

We used variational wave functions composed of the $2s$ and $2p$ atomic functions of the six lithium ions adjacent to the vacancy to calculate the energy levels and also the g-value. The contribution of the p functions was found to be much larger than that of the s functions, as seen in Table II; wave functions composed of only the s atomic functions gave very poor energy levels, probably because they extend over many ions as indicated in Fig. 2. Our *LCAO* method yielded a value of the first excitation energy which is in fair agreement with experiment but this method does not seem to be convenient for more accurate computations, primarily because we have to deal with complicated many-center molecular integrals. The g-value was also calculated. Although our method of approach presented in §5 will be able to explain the observed g-value of F-centers in most alkali halides, a complicated situation seems to exist in the case of LiF and a more careful investigation will be necessary.

The author would like to express his sincere thanks to Professor T. Nagamiya for his kind interest and encouragement during the course of this work. Thanks are also expressed to Mrs. K. Kojima for helpful discussions and assisting with numerical calculations.

Appendix A. Derivation of (14a)

The Maxwell's displacement vector in the Hartree approximation produced by the trapped electron is

$$\boldsymbol{D}(\boldsymbol{r})=e\nabla\int\frac{\psi^2(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|}d\tau'\,. \tag{A1}$$

Through this $\boldsymbol{D}(\boldsymbol{r})$ ions deform and displace to their new equilibrium configurations. Considering the displacements and deformations of the ions separately, denote the components of the corresponding dipole moments by x_i ($i=1,2,\cdots 6N$; N: the total number of the ions). Their origin be so chosen that $x_i=0$ in the absence of the trapped electron. Let the component of $\boldsymbol{D}$ associated with x_i be D_i, and imagine the quantity, $\lambda D_i (0 \leqslant \lambda \leqslant 1)$. x_i will vary approximately linearly with λ. The total energy of the crystal, U, may then be written in the form

---

* F. J. Adrian (private communication) also made a similar calculation using a perturbation technique and obtained a value $\varDelta g\approx-5\times10^{-3}$. He suggested that holes produced by the deformation of the surrounding ions may be responsible for the positive $\varDelta g$ value.

$$U = U_0 + U_1\lambda + \sum_{i,j} k_{ij} x_i x_j + \sum_i k_i x_i \lambda \ , \tag{A2}$$

where k_{ij} and k_i are the coefficients which may depend on ψ but not on x_i; $U_1\lambda$ is the energy associated with $\mathscr{H}_1$, $\mathscr{H}_2$, $\mathscr{H}_3$ and $\mathscr{H}_5$. The third term comprises the self-energy of the dipoles induced by the trapped electron and the interaction energy among these dipoles. The fourth term is the interaction between these dipoles and the trapped electron. Now the values of x_i is so determined that U attains an extremum for a fixed ψ, we have for these values of x_i,

$$\sum_{i,j} k_{ij} x_i x_j = -\frac{1}{2} \sum_i k_i x_i \lambda \ ,$$

which states the relation (14a).

Appendix B. Evaluation of Integrals and Lattice Sums

1. Kinetic energy integrals are reduced to sum of one-center integrals and two-center integrals over atomic functions. Each two-center integral was calculated by expanding one atomic function in spherical harmonics around the center of the other atom. Similar convension was adopted also for overlap integrals. Each one-center integral, together with the corresponding one-center potential energy integral (the first term of (A8)), was substituted by the negative of the ionization energy of a free Li atom.

2. Potential energy integrals were calculated through the following two steps:

(a) First, all the ions were replaced by point charge with $\pm e$, and the atomic functions were expanded in spherical harmonics around the center of the vacancy. For example, we write $\psi(\boldsymbol{r})$ in the form:

$$\psi(\boldsymbol{r}) = a_1 \sum_{lm} f_{lm}{}^{(1)}(r) Y_{lm}(\theta,\varphi) + a_2 \sum_{lm} f_{lm}{}^{(2)}(r) Y_{lm}(\theta,\varphi) \ , \tag{A3}$$

in which the first sum comes from the $2s$ functions, the second from the $2p$ functions. Then (9a) reduces to $\sum_n \sum_{n'} a_n a_{n'} U_{nn'}$, with

$$U_{nn'} = -e^2 \sum_{lm} \sum_{l'm'} \sum_{\nu} \varepsilon_\nu \int \frac{f_{lm}{}^{(n)}(r) f_{l'm'}{}^{(n')}(r)}{|\boldsymbol{r}-\boldsymbol{R}_\nu|} \times Y_{lm}(\theta,\varphi) Y_{l'm'}(\theta,\varphi) d\tau \ , \tag{A4}$$

where ε_ν takes $+1$ or -1 according to the sign of the ν-th ion. When $|\boldsymbol{r}-\boldsymbol{R}|^{-1}$ is also expanded in spherical harmonics, integrals appear which contain products of three spherical harmonics. These integrals were evaluated by using the formula

$$Y_{lm}(\theta,\varphi) Y_{l'm'}(\theta,\varphi) = \sum_{L=|l-l'|}^{l+l'} \sum_{M=-L}^{L} \left[\frac{(2l+1)(2l'+1)}{4\pi(2L+1)} \right]^{1/2} \times (ll'00|ll'L0)(ll'mm'|ll'LM) Y_{LM}(\theta,\varphi) \tag{A5}$$

for normalized Y_{lm}12); $(ll'mm|ll'LM)$ are the Clebsch-Gordan (vector addition) coefficients which are tabulated elsewhere13).

Integrals appearing below (10) were also computed with a similar method.

(b) Second, the values of the integrals of the type $\int u^2(\boldsymbol{r}-\boldsymbol{R}_k)|\boldsymbol{r}-\boldsymbol{R}_k|^{-1} d\tau$ (u is the $2s$ or $2p$ atomic function) were revised in accordance with the prescription described in § 4. For this purpose, we expand u as

$$u(\boldsymbol{r}-\boldsymbol{R}_k) = \sum_{lm} g_{lm}(r) Y_{lm}(\theta,\varphi) \ , \tag{A6}$$

and from (A4) subtract

$$-e^2 \sum_{lm} \sum_{l'm'} \int \frac{g_{lm}(r) g_{l'm'}(r)}{|\boldsymbol{r}-\boldsymbol{R}_k|} Y_{lm}(\theta,\varphi) Y_{l'm'}(\theta,\varphi) d\tau \ , \tag{A7}$$

and add to it

$$(\hbar^2/2m) \int u(\boldsymbol{r}-\boldsymbol{R}_k) \nabla^2 u(\boldsymbol{r}-\boldsymbol{R}_k) d\tau - I_u \ , \tag{A8}$$

in which I_u is the ionization energy of a free Li atom corresponding to this u orbital. The ionization energies employed were 5.391 ev for the $2s$ function and 3.544 ev for the $2p$ function. The revision of the integrals of the type $\int u(\boldsymbol{r}-\boldsymbol{R}_k) u'(\boldsymbol{r}-\boldsymbol{R}_{k'}) |\boldsymbol{r}-\boldsymbol{R}_k|^{-1} d\tau$, on the other hand, cannot be made in an unambiguous way. In the present calculation,

$$-e^2 \sum_{lm} \sum_{l'm'} \int \frac{g_{lm}(r) g'_{l'm'}(r)}{|\boldsymbol{r}-\boldsymbol{R}_k|} Y_{lm}(\theta,\varphi) \times Y_{l'm'}(\theta,\varphi) d\tau \tag{A9}$$

was subtracted from (A4) and

$$\frac{1}{2} \left[-e \int u(\boldsymbol{r}-\boldsymbol{R}_k) u'(\boldsymbol{r}-\boldsymbol{R}_{k'}) V_+(\boldsymbol{r}-\boldsymbol{R}_k) d\tau - e^2 \int \frac{u(\boldsymbol{r}-\boldsymbol{R}_k) u'(\boldsymbol{r}-\boldsymbol{R}_{k'})}{|\boldsymbol{r}-\boldsymbol{R}_k|} d\tau \right] \tag{A10}$$

was added, where by $V_+(\boldsymbol{r}-\boldsymbol{R}_k)$ means the Hartree-Fock potential due to a free Li$^+$ ion at $\boldsymbol{R}_k$. These integrals being two-center integrals, the integration can be performed in an analogous way to that of the kinetic energy integrals.

3. Summations over lattice points were carried out as follows:

(a) $\sum(\varepsilon_\nu/R_\nu)F(R_\nu)$ ($F(R)$ represents any function which tends monotonously to unity with increasing R, and $\varepsilon_+=1$, $\varepsilon_-=-1$). This type of summation is evaluated most conveniently by dividing the crystal into cubes of volume a^3 with centers at lattice points and placing a point charge of magnitude $-(\varepsilon_\nu/8)F(R_{\nu i})$ at the i-th corner $R_{\nu i}$ of the ν-th cube each. These point charges approximately cancel one another in each cube except in the cube which contains the vacant lattice point. The summation therefore converges very rapidly when first summed over nine point charges in each cube and then over ν.

(b) $\sum(M_\nu/R_\nu^4)F(R_\nu)$. If $F(R_\nu)$ were all equal to unity, the summation would have been[14)]

$$\frac{1}{a^4}(10.1977M_+ + 6.3346M_-) \qquad \text{(A11)}$$

Correction for $(M_\nu/R_\nu^4)[1-F(R_\nu)]$ was calculated for each lattice point and summed over ν.

(c) $\sum_v(\varepsilon_\nu/R_\nu^5)F(R_\nu)Y^4(\theta,\varphi)$. This was calculated one by one and added in a straightforward manner. This type of sum was found to be so small that it could be neglected in most cases.

4. Expansion in spherical harmonics was actually retained up to the fourth order, Y_4, in every case; the contributions of the Y_4 terms to the energy integrals were found to be certainly much smaller than those of the Y_0 terms. Also, a rapid convergence of the expansions was made sure by comparing the values of the normalization integrals calculated exactly by the method described in Appendix B. 1., and those calculated using the functions expanded in spherical harmonics up to the fourth order. The difference in values between two methods was below 1% for the ground state and below 3.5% for the excited state throughout the varied ranges of a_i and b_i.

5. Calculation of the integrals appearing in the expression for the g-factor could also be made similarly. But now it is expedient to expand the potential, V, in spherical harmonics around each lattice point and integrate within the sphere of volume a^3 surrounding it. This is because the contribution to the integrals comes mainly from the vicinity of each nucleus. Since the Hartree-Fock potential for a free Li atom does not give the correct value of the $2p$ doublet splitting of the atom, the potential was adjusted by multiplying a constant factor that makes the calculated doublet interval agree with the experimental value, 0.3366 cm^{-1}[15)]. A rough estimate was obtained by taking only the six spheres adjacent to the vacancy. When integrating within a given sphere, we employed the wave function modified as follows: those constituent atomic functions whose centers lie outside the sphere are omitted, and the wave function so simplified is renormalized within the sphere to the value which the initial wave function ψ gives in the same sphere.

Electronic States of the *F*-Center in Lithium Fluoride. II

By Tadanobu KOJIMA*

Department of Physics, Osaka University

(Received April 24, 1957)

The electronic structure of the *F*-center in LiF is investigated by making use of a variational wave function for the trapped electron which is orthogonal to all the ion-core functions. The variational parameters are so determined as to minimize the total energy of the whole crystal, including exchange interactions, polarization effects and van der Waals interactions. The equilibrium positions of the surrounding ions and the ion-core dipoles are determined in a self-consistent manner with the *F*-center wave functions. The resulting wave function shows correct oscillatory behaviors around each nucleus. The calculated first optical excitation energy is in excellent agreement with experiment. The associated oscillator strength is also evaluated. The line-width of the electron spin resonance is computed, yielding a value twice as large as the experimental value. A source of this discrepancy and other sources of errors which might have affected the energy levels are examined.

In the preceding paper¹⁾, we approximated the wave functions of a trapped electron in an *F*-center by linear combinations of atomic orbitals and calculated the energy levels. As mentioned there, an approach along this line is not very profitable to obtain better results by going to higher approximations, since the nonorthogonality of the wave functions with ion-core functions cannot practically be taken into account in any satisfactory way. Therefore it seems more profitable to start with another type of wave functions which is free from the above dismerit but still tractable. In this paper we shall make an attempt to find such wave functions and calculate with them the energy levels and the electron spin resonance line width, again for LiF.

§ 1. Polarization around a Negative Ion Vacancy

In I, the polarization around a vacancy was treated in Mott and Littleton's zeroth approximation, so that the deformations and displacements of the ions were assumed to be determined only by macroscopic quantities κ, κ_0 and ω_t, even for the ions in the immediate neighborhood of the vacancy. This assumption is actually not correct, because the electric field produced by a vacancy and a trapped electron is far from being uniform over a space large enough compared with the interatomic distance, and besides the dielectric constants must be different from those of the perfect crystal in a uniform field, as there is a lattice distortion caused by the lattice defect.

---

[*] Present address: Research Institute for Atomic Energy, Osaka City University, Awaza-Nakadori, Osaka.

Accordingly, in order to treat properly the polarization around the lattice defect, the polarizabilities of the ions in a strained lattice subjected to a nonuniform external field must be investigated. However, instead of doing this, we shall deal with the polarizations within the framework of Mott and Littleton's approximation²⁾, and proceed as follows.

In the first approximation, we take as unknowns the displacements $\xi_1 a$ and the ion-core dipoles $m_1 ea$ for the six ions adjacent to the vacancy, assuming that for all the other ions values given by the zeroth approximation are still valid. We assume also that the polarizability $\alpha_+{}^s$ of the (100) ions is unaffected by the presence of the vacancy and that the overlap repulsive potentials between ions of opposite signs have, as usual, the exponential form $Ae^{-r/\rho}$. The repulsive force exerted outwards on a (100) ion is then given by

$$F_r=\frac{A}{\rho}\left[-\exp\left\{\left(-1+\xi_1+\frac{M_-'}{4}\right)\frac{a}{\rho}\right\}\right.$$
$$\left.+\frac{4a}{d}\left(\xi_1+\frac{M_-'}{2\sqrt{2}}\right)e^{-d/\rho}\right], \qquad (1)$$

where

$$\left(\frac{d}{a}\right)^2=\left(1-\frac{M_-'}{2\sqrt{2}}\right)^2+\left(\xi_1+\frac{M_-'}{2\sqrt{2}}\right)^2,$$

and

$$M_\nu'=\frac{1}{4\pi}\left(1-\frac{1}{\kappa}\right)\frac{\alpha_d}{\alpha_+{}^s+\alpha_-{}^s+\alpha_d}\frac{\overline{M}}{M_\nu} \qquad (2)$$

is the displacement of the ion ($\nu=+$ or $-$) in units of a for the field of strength e/a^2, $\overline{M}$ being the reduced mass of the ions and $\overline{M}_\nu$ the mass of the ν-th ion. The constant A can be eliminated by making use of the equilibrium condition for the perfect crystal:

$$6Ae^{-a/\rho}/\rho=\alpha_M e^2/a^2\ ,$$

in which $\alpha_M=1.7476$ is the Madelung constant. The electrostatic force outward on the same ion is, aside from the Madelung field which is virtually zero for small displacements,

$$F_e=\frac{e^2}{a^2}\left[\frac{1+\sqrt{2}+0.25}{(1+\xi_1)^2}-\frac{4(1+\xi_1)}{(2+2\xi_1+\xi_1{}^2)^{3/2}}\right.$$
$$-\frac{1}{(2+\xi_1)^2}-\frac{2.3713\,m_1}{(1+\xi_1)^3}-0.3881\,M_+'$$
$$\left.-1.9652\,M_-'\right]. \qquad (3)$$

The unknowns m_1 and ξ_1 are determined from the conditions

$$F_r+F_e=0\ ,$$
$$m_1e^2a=\alpha_+{}^sF_e\ . \qquad (4)$$

In the second approximation, the displacements $\xi_2 a$ and ion-core dipoles $m_2 ea$ for the twelve (110) ions, as well as those for the (100) ions, are taken as unknowns which may be determined from additional conditions analogous to (4).

In order to practise the above calculations, it is necessary to know the value of ρ, which may be determined from the observed dielectric constant and reststrahl frequency as follows: When a uniform electrostatic field is impressed along the [100] direction of the perfect crystal, the overlap repulsive force exerted on a positive ion is given by

$$F_r=\frac{\alpha_M e^2}{6a^2}\left[e^{-x/\rho}-e^{x/\rho}\right.$$
$$\left.+\frac{4x}{\sqrt{a^2+x^2}}e^{-\surd(a^2+x^2-a)/\rho}\right], \qquad (5)$$

in which x denotes the relative displacements of the ions of unlike signs. The force due to the electrostatic field is $F_e=eE_{\text{loc}}$, where E_{loc} means the local field at the positive ion, which is related to x by $ex=\alpha_d E_{\text{loc}}$. Eliminating x from (5) with the use of the equilibrium condition, $F_r+F_e=0$, we have

$$\frac{1}{\alpha_d}=\frac{\alpha_M}{3a^2}\left(\frac{1}{\rho}-\frac{2}{a}\right). \qquad (6)$$

Inserting in this expression the value of α_d given in I, we finally obtain $\rho=0.253$ Å, which is employed throughout the present work.

Usually the value of ρ is determined from the observed compressibility, making use of a formula such as³⁾

$$\frac{1}{\beta}=\frac{\alpha_M e^2}{18a^3}\left(\frac{1}{\rho}-\frac{2}{a}\right), \qquad (7)$$

where β is the compressibility. Inserting the observed value 1.52×10^{-11}/barye for β into (7), we find $\rho=0.296$Å. The measered compressibility, however, is that for room temperature, whereas in fact we must use the value at 0°K. Since β decreases with decreasing temperature, the value of ρ should be lower than 0.296Å. Furthermore, a value of ρ obtained in this way corresponds to the repulsion between unpolarized ions and so would be larger than the value between the polarized ions with which we are actually concerned.

It is noted that our value of ρ, 0.253 Å, is valid for uniform electric field, and thus may not necessarily be satisfactory in applying to our problem of defect lattice. Fortunately, however, an accurate knowledge of ρ was found not very important when calculating the energy levels of the F-center, though it would be important in determining precisely the equilibrium positions of the surrounding ions.

The potential at a missing negative ion site due to the static polarization produced by it is given, in the zeroth, first and second approximations, by

$$V_0{}^s = -\frac{e}{a}(10.1977 M_+ + 6.3346 M_-)\,, \tag{8a}$$

$$V_1{}^s = -\frac{e}{a}\left[4.1977\, M_+ + 6.3346\, M_- + 6 - \frac{6}{1+\xi_1} + \frac{6m_1}{(1+\xi_1)^2}\right], \tag{8b}$$

$$V_2{}^s = -\frac{e}{a}\left[4.1977\, M_+ + 3.3346\, M_- + 6 - \frac{12}{\sqrt{2}} - \frac{6}{1+\xi_1} + \frac{12}{\sqrt{2}+\xi_2} + \frac{6m_1}{(1+\xi_1)^2} + \frac{12\, m_2}{(\sqrt{2}+\xi_2)^2}\right], \tag{8c}$$

respectively. In Table I are given our results of calculation. For reference, also the results of our similar calculation for optical polarization are included, *i. e.*, for the case where all the ions are held fixed to their own lattice points. In the latter calculation the optical polarizabilities of all the ions were assumed to be those for uniform electric field applied to the perfect crystal, and their values were taken from I.

Rittner *et al*⁴⁾ have made a similar calculation for the optical polarization of NaCl up to the tenth approximation. Considering the convergence in their calculation, it appears that our values of V^o converge to about -3.67 ± 0.02 ev. Therefore our second approximation seems to be satisfactory. On the other hand, the convergence of V^s seems rather poor. Rough evaluations were also made up to the fourth order in this case; it appears that V^s converges to a value between -9.2 ev and -9.7 ev⁵⁾. In spite of this poor convergence, the energy levels of the F-center can be computed fairly accurately, because the F-center is electrically neutral and the role of the polarization effects is not so important as in the case of a vacancy. In view of this and the uncertainty of the repulsive potential mentioned above, it was decided to make detailed calculations only to the *second* approximation.

§ 2. Wave Functions

Let us now take the wave function of the trapped electron in the form:

$$\psi(\boldsymbol{r}) = f(\boldsymbol{r}) - \sum_{\nu,j} C_{\nu j}\chi_{\nu j}(\boldsymbol{r})\,. \tag{9}$$

For the ground state, $f(\boldsymbol{r})$ is taken to be

$$f(\boldsymbol{r}) = C\frac{\sin kr}{kr} \quad (r<R)\,, \tag{10a}$$

$$f(\boldsymbol{r}) = C' e^{-\alpha r} \quad (r>R)\,, \tag{10b}$$

in which α is a variational parameter, and C, C' and k are determined from the condition that the two branches of $f(\boldsymbol{r})$ should join smoothly at $r=R$ and from the normalizing condition for $\psi(\boldsymbol{r})$. $\chi_{\nu j}$ denotes the j-th atomic function attached to the ν-th ion, and $c_{\nu j}$ are chosen so that $\psi(\boldsymbol{r})$ is orthogonal to all the core functions, *i.e.*, $c_{\nu j} = \int f(\boldsymbol{r})\chi_{\nu j}(\boldsymbol{r})d\tau$ neglecting the overlaps of different ions. For the first excited state, $f(\boldsymbol{r})$ is taken to be

$$f(\boldsymbol{r}) = C_e\left(\frac{\sin k_e r}{k_e{}^2 r^2} - \frac{\cos k_e r}{k_e r}\right)\cos\theta \quad (r<R), \tag{11a}$$

$$f(\boldsymbol{r}) = C_e' r e^{-\alpha_e r}\cos\theta \quad (r>R), \tag{11b}$$

where θ is the polar angle referred to a [100] axis. C_e, C_e' and k_e are determined similarly as mentioned above for the ground state. R may be taken as a variational parameter as well as α or α_e, but we fix its value, for simplicity, to $0.9\,a$ after Mott and Littleton. The final energy values were actually found to be rather insensitive to the value of R.

For $\chi_{\nu j}$ it is convenient to use simple analytic wave functions. We use therefore the approximate solutions of Hartree-Fock equations for the isolated lithium and fluorine ions⁶⁾:

$$\chi_{\mathrm{Li}^+,1\mathrm{s}}(r_i) = (2.69^3/\pi)^{1/2} e^{-2.69 r_i}\,,$$

$$\chi_{\mathrm{F}^-,2\mathrm{p}z}(r_i) = (2.35^5/\pi)^{1/2} r e^{-2.35 r_i}\cos\theta_i\,,\ \text{etc.},$$

$$\chi_{\mathrm{F}^-,2\mathrm{s}}(r_i) = (2.495^5/2.776\,\pi)^{1/2} \times (r_i e^{-2.495 r_i} - 0.8021 e^{-7.48 r_i})\,, \tag{12}$$

$$\chi_{\mathrm{F}^-,1\mathrm{s}}(r_i) = (8.75^3/\pi)^{1/2} e^{-8.75 r_i}\,, \qquad \text{(in a.u.)}$$

The wave functions of the core electrons may suffer slight changes when the ions aggregate to form a crystal, but we shall neglect such possible changes in our calculation. Furthermore, we shall ignore the effect of the displacements and deformations of the ions due to polarization in orthogonalizing $f(\boldsymbol{r})$ to the core functions. Both these approximations should be satisfactory for our purposes.

§3. Energy Levels

Among the various terms entering into the Hartree-Fock energy, the sum of the terms which are not related to polarization, (8a), (9a) and (13a) in I, can be rewritten by inserting (9) into them as follows, provided the overlaps of the core functions on different ions are ignored:

$$\int\psi(\mathscr{H}_1+\mathscr{H}_2+\mathscr{H}_5)\psi\, d\tau$$

$$=E_1+E_2+E_3+E_4+E_5\,, \tag{13}$$

$$E_1=-(\hbar^2/2m)\int f\nabla^2 f\, d\tau\,, \tag{13a}$$

$$E_2=\sum_{\nu,j}c_{\nu j}{}^2\left(-\frac{\varepsilon_\nu\alpha_M}{a}+\frac{1}{R_\nu}\right), \tag{13b}$$

$$E_3=\sum_{\nu,j}c_{\nu j}{}^2 I_{\nu j}\,, \tag{13c}$$

$$E_4=\int f^2\left[-e^2\sum_\nu\frac{Z_\nu}{|\boldsymbol{r}-\boldsymbol{R}_\nu|}+2e^2\sum_{\nu,j}\int\frac{\chi_{\nu j}{}^2(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|}d\tau'\right]d\tau, \tag{13d}$$

$$E_5=-e^2\sum_{\nu,j}\iint\frac{f(\boldsymbol{r})\chi_{\nu j}(\boldsymbol{r})f(\boldsymbol{r}')\chi_{\nu j}(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|}d\tau d\tau'. \tag{13e}$$

In (13b), ε_ν takes $+1$ or -1 according to the sign of the ν-th ion. $I_{\nu j}$, which appears in (13c), is the negative of the interaction energy between an electron in $\chi_{\nu j}$ and the rest of the ν-th ion, and may be put equal to the ionization energy of the orbital $\chi_{\nu j}$: $I_{\mathrm{Li}^+,1\mathrm{s}}=2.779$ a. u., $I_{\mathrm{F}^-,2\mathrm{p}}=0.131$ a. u., $I_{\mathrm{F}^-,2\mathrm{s}}=0.975$ a. u., $I_{\mathrm{F}^-,1\mathrm{s}}=26.15$ a. u. It is to be noted that, so far as experimental values or theoretical values calculated with much more accurate functions are employed for $I_{\nu j}$, detailed forms for $\chi_{\nu j}$ are of little importance in evaluating the energy levels. The methods of evaluating the overlap and exchange integrals are given in Appendix A.

Next we shall consider the terms associated with polarization. Although actual calculation was performed to the second approximation, we describe here, for simplicity, the method of calculation only to the first approximation, since the method can readily be extended to the second approximation. Setting

$$Q(r)=\int_{r'<r}\psi^2(\boldsymbol{r}')d\tau'\,, \tag{14}$$

we find for the term of $\mathscr{H}_3$, in terms of ξ_1 and m_1 which were worked out in §2,

$$\int\psi\mathscr{H}_3\psi d\tau$$

$$=\frac{6(\xi_1+m_1)e^2}{a}Q(a)+\sum_\nu{}'\frac{M_\nu e^2a^3}{R_\nu{}^4}Q(R_\nu)\,, \tag{15}$$

where the sum is taken over all the lattice points except the (100) set. In order to evaluate the term of $\mathscr{H}_4$, we take as unknowns the displacements $\xi_1'a$ and the ion-core dipoles $m_1'ea$ for the (100) ions, and assume for all other ions in the lattice the values in the zeroth approximation, namely, $-M_\nu'ea^3R_\nu{}^{-2}Q(R_\nu)$ for their displacements and $-(M_\nu-M_\nu')ea^3R_\nu{}^{-2}Q(R_\nu)$ for theirdeforma tions. Putting

$$q_n=1-Q(\sqrt{n}\,a)\,,$$

we find for the repulsive force exerted outward on a (100) ion,

$$F_r(\xi_1',\alpha)=\frac{\alpha_M e^2}{6a^2}\left[-\exp\left\{\left(\xi_1'+\frac{1}{4}\,q_4M_-'\right)\frac{a}{\rho}\right\}+\frac{4a}{d}\left(\xi_1'+\frac{q_2M_-'}{2\sqrt{2}}\right)\exp\left(\frac{a}{\rho}-\frac{d}{\rho}\right)\right], \tag{16}$$

where

$$\left(\frac{d}{a}\right)^3=\left(1-\frac{q_2M_-'}{2\sqrt{2}}\right)^2+\left(\xi_1'+\frac{q_2M_-'}{2\sqrt{2}}\right)^2,$$

and for the electrostatic force⁷⁾,

$$F_e(\xi_1',\alpha)=\frac{e^2}{a^2}\left[\frac{1+\sqrt{2}+0.25}{(1+\xi_1')^2}-\frac{4(1+\xi_1')}{(2+2\xi_1'+\xi_1'^2)^{3/2}}-\frac{1}{(2+\xi_1')^2}-\frac{2.3713m_1'}{(1+\xi_1')^3}-\frac{Q(a+\xi_1'a)}{(1+\xi_1')^2}\right.$$
$$\left.+\left(-1.2879\frac{q_3}{3}+0.22901\frac{q_5}{5}+\cdots\right)M_+ +\left(-4.5749\frac{q_2}{2}+1.4966\frac{q_4}{4}+\cdots\right)M_-\right]. \tag{17}$$

m_1' and ξ_1' are uniquely determined as functions of α from the conditions $F_r+F_e=0$ and

$m_1'e^2a=\alpha_+{}^sF_c$. Using the values of m_1' and ξ_1' so determined, we finally find for the term of $\mathscr{H}_4$,

$$\int\phi\mathscr{H}_4\phi d\tau=\frac{6(\xi_1'+m_1'-\xi_1-m_1)e^2}{a}Q(a)-\sum_\nu{}'\frac{M_\nu e^2a^3}{R_\nu{}^4}Q^2(R_\nu)\,. \tag{18}$$

For the first excited state, the situation is somewhat complicated because the charge distribution of the trapped electron has a lower symmetry (tetragonal); ions which lie at an equal distance from the vacancy do not always have an equal ion-core dipole strength, unlike the case of the ground state, and moreover, each ion-core dipole is not necessarily parallel to the vector joining the vacancy to that ion. It was estimated, however, that both these effects scarcely affect the final energy levels, so that we are justified to regard the induced optical polarization as if it were caused by a spherically symmetrical charge distribution which is obtained by averaging the true charge distribution of the trapped electron over solid angles. Therefore, denoting

$$Q_e(r)=\int_{r'<r}\psi_e{}^2(\boldsymbol{r}')d\tau,\quad q_{en}=1-Q_e(\sqrt{n}\ a)\,, \tag{19}$$

the term of $\mathscr{H}_{4a}{}^e$ can be evaluated as follows: Taking as an unknown the average of the optical dipole moments induced by the trapped electron on the six (100) ions, $m_{e1}{}^{o\prime}ea$, and assuming that for any other ion, ν, the induced optical dipole moment due to the trapped electron is still given by $-M_\nu{}^oea^3R_\nu{}^{-2}Q_e(R_\nu)$ and that it points toward the vacancy, $m_{e1}{}^{o\prime}$ is determined as a function of α_e from the equation:

$$m_{e1}{}^{o\prime}=\frac{\alpha_+{}^o}{\alpha^3}\Big[-Q_e(a+\xi_1'a)-\frac{2.3713\,m_{e1}{}^{o\prime}}{(1+\xi_1')^3}+\Big(0.3881-1.2879\frac{q_{e3}}{3}+0.22901\frac{q_{e5}}{5}+\cdots\Big)M_+{}^o$$
$$+\Big(1.9652-4.5749\frac{q_e{}^2}{2}+1.4966\frac{q_e{}^4}{4}+\cdots\Big)M_-{}^o\Big]\,, \tag{20}$$

We have then

$$\int\psi_e\mathscr{H}_{4a}{}^e\psi_e d\tau=\frac{6m_{e1}{}^{o\prime}e^2}{a}Q_e(a)-\sum_\nu{}'\frac{M_\nu{}^oe^2a^3}{R_\nu{}^4}Q_e{}^2(R_\nu)\,. \tag{21}$$

The term of $\mathscr{H}_{4b}$ is similarly expressed as

$$\int\phi_e\mathscr{H}_{4b}\psi d\tau=\frac{6(\xi_1'+m_1'-\xi_1-m_1-m_1{}^{o\prime})e^2}{a}Q_e(a)-\sum_\nu{}'\frac{(M_\nu-M_\nu{}^o)e^2a^3}{R_\nu{}^4}Q(R_\nu)Q_e(R_\nu)\,, \tag{22}$$

where $m_1{}^{o\prime}$ is given by the equation obtained by dropping the suffix e from Eq. (20). Expressions analogous to Eqs. (21) and (22) also hold, dropping the suffix e.

In the second approximation, we take as unknowns the displacements and the ion-core dipoles for the second neighbors, as well as for the first neighbors, and proceed in an entirely analogous way to the first approximation. Detailed expressions are omitted here because they are rather lengthy though it is easy to write them down.

So far we have approximated all the displacements of the ions by point dipoles. This might not be a good approximation if the displacements are large. We shall now briefly outline the method of calculation for this case though this effect was evetually found to be rather unimportant. These finite displacements can be taken into account without difficulty for the expressions of $\mathscr{H}_3$ and $\mathscr{H}_4$, in which one has only to replace $Q(a)$ and $Q_e(a)$ by other appropriate quantities according to circumstances. For example, the first term of Eq. (15) may be replaced by

$$\frac{6e^2}{a}\Big[\xi_1\Big(1+\frac{\xi_1}{2}\Big)^{-2}Q\Big(a+\frac{\xi_1}{2}a\Big)$$
$$+m_1(1+\xi_1)^{-2}Q(a+\xi_1a)\Big]\,.$$

On the other hand, the situation concerning the internal energy is much involved, for one can no longer use the relationship, $\mathscr{H}_6=-\mathscr{H}_4/2$, which has been derived under the approximation of point dipoles. To find the change of the internal energy, imagine a process in which the six first neighbors at $(1+\xi_1)$ a are removed to their new equilibrium positions $(1+\xi_1')$ a, and simultaneously an electron is brought into the vacancy from the outside of the crystal, then regard the accompanying change of charge density as a source of electric displactment $\boldsymbol{D}$, which would give rise to a polarization in the surrounding medium. More specifically, one can write in place of Eq. (A1) in I,

$$\boldsymbol{D}(\boldsymbol{r})=e\nabla\int\frac{\psi^2(\boldsymbol{r})'}{|\boldsymbol{r}-\boldsymbol{r}'|}d\tau' \\ -\sum_\nu\nabla V_+(\boldsymbol{r}-\boldsymbol{R}_\nu-\xi_1'\boldsymbol{R}_\nu)+\sum_\nu\nabla V_+(\boldsymbol{r}-\boldsymbol{R}_\nu-\xi_1\boldsymbol{R}_\nu),$$

where the sum is over the six (100) ions and V_+ stands for the Hartree-Fock potential due to a free Li$^+$ ion. Then, for the system composing the source of the electric displacement, the change in internal energy and of the interaction energy with the remaining part of the crystal can be calculated in a straightforward manner with the use of the known interatomic potentials. For the remaining part of the crystal, the change in internal energy may be put equal to $-1/2$ times the change of its interaction energy with the system composing the source of $\boldsymbol{D}$. An estimate shows, however, that these corrections for $\mathscr{H}_3$ and $\mathscr{H}_4$ nearly cancel with that for $\mathscr{H}_6$. Therefore, we conclude that the point-dipole approximation is effectively adequate even when the ionic displacements are not very small. All figures given in the next section are thus referred to the point-dipole approximation.

In calculating the energies related to polarization, we have entirely neglected the contributions from higher spherical harmonics, since they were expected to be negligibly small as in the case of the wave functions employed in I.

Next we shall consider the correction to the exchange energy E_5 which arises from the displacements of the ions; this was not considered in I. In the first approximation, this correction is made only for the first neighbors, in the second approximation, up to the second neighbors, and so on. The exchange integral between f and $\chi_{\nu j}$ will be nearly proportional to the value of f^2 at the nucleus of the ν-th ion if the displacement of the latter is small. Hence, for the ground state for instance, the correction will be given by

$$-e^2\sum_{\nu,j}\left[\frac{f^2(\boldsymbol{R}_\nu+\xi_\nu'\boldsymbol{R}_\nu)}{f^2(\boldsymbol{R}_\nu)}-1\right] \\ \times\iint\frac{f(\boldsymbol{r})\chi_{\nu j}(\boldsymbol{r})f(\boldsymbol{r}')\chi_{\nu j}(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|}d\tau d\tau' ,$$

where the sum is over only the first or up to the second neighbors according as the first or second approximation is used.

In the frame of the Hartree-Fock approximation, the correlation between the trapped electron and the core electrons is not taken into account. Unfortunately, no satisfactory method to deal with this correlation is known. We shall compute this correlation energy by expanding it into van der Waals (or multipole) interactions; of course this approach can not entirely be satisfactory. The van der Waals energies can be found by making use of a variational method (Appendix B), the result of which can be written,

$$E_{\text{v.d.w.}}=E^{(1)}_{\text{v.d.w.}}+E^{(2)}_{\text{v.d.w.}}+\cdots , \tag{23}$$

$$E^{(1)}_{\text{v.d.w.}}=-e^2\sum_\nu\frac{\alpha_\nu{}^0}{R_\nu{}^6}\left(\int_{r<R_\nu}r^2\psi^2d\tau\right)^2 \\ \Big/\left(\int r^2\psi^2d\tau+\sqrt{\frac{\alpha_\nu{}^0}{mn_\nu}}\frac{3\hbar}{2e}\right), \tag{23a}$$

$$E^{(2)}_{\text{v.d.w.}}=-e^2\sum_\nu\frac{3\alpha_\nu{}^0}{2R_\nu{}^8}\left(\int_{\nu<R\nu}r^4\psi^2d\tau\right)^2 \\ \Big/\int r^4\psi^2d\tau , \tag{23b}$$

where n_ν denotes the number of electrons in

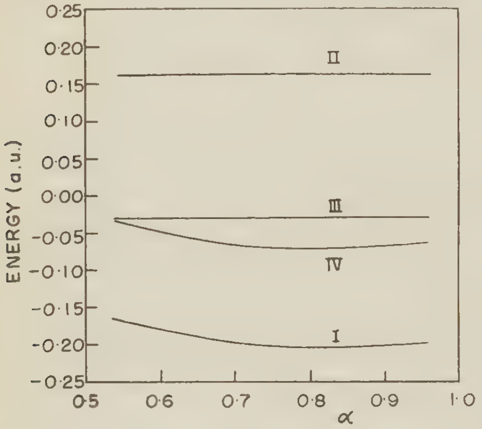
Table I. Comparison of the various approximations employed, for the static and optical polarizations around a negative ion vacancy.

Order of Approximation	Static Polarization					Optical Polarization		
	V^s(ev)	ξ_1	m_1	ξ_2	m_2	V^o(ev)	$m_1{}^o$	$m_2{}^o$
0	-8.92	0.086	0.003_5	-0.016	0.011	-3.55	0.003_4	0.036
1	-8.82	0.091	0.004_5	-0.016	0.011	-3.59	0.004_2	0.036
2	-9.62	0.087	0.004_2	-0.041	0.005_3	-3.69	0.003_9	0.039

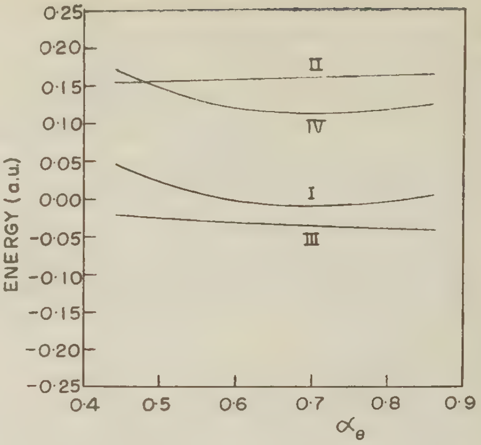
the outermost shell of the ion ν. In this expression, $E^{(1)}_{\text{v.d.w.}}$ corresponds to the dipole-dipole interaction, $E^{(2)}_{\text{v.d.w.}}$ the dipole-quadrupole interaction, and so on. We can show that the same expression with ψ_e in place of ψ also holds for the excited state.

§ 4. Results of Calculation

The energy values for the ground and the first excited states worked out to the second approximation are plotted in Figs. 1a and 1b, respectively, as functions of each variational parameter. The minimizing values of α and α_e, and the corresponding final energy levels are shown in Table II. The first optical excitation energy obtained is 4.96 ev. which is in close agreement with the observed value, 4.96 ev. Such an excellent agreement would, however, be somewhat fortuitous in view of our approximations made, as will be discussed in § 6.



(a) Ground State



(b) Excited State

Fig. 1. Energies of an *F*-center.

I. Energy not associated with polarization.
II. Energy associated with polarization.
III. Van der Waals energy.
IV. Total energy (I+II+III).

Table II. Energy levels and optimum values of variational parameters for various kinds of approximations, worked out to the second order. (Energies in a.u.)

Approximation	Ground State		First Excited State		Excitation Energy
	α	Energy	α_e	Energy	
Polarization neglected	0.818	−0.2054	0.704	−0.0126	0.1928
Quasi-adiabatic approx.	0.811	−0.0106	0.697	0.1624	0.1730
All terms included	0.809	−0.1053	0.720	0.0769	0.1822

In Table II are also included for comparison the values when the polarization and van der Waals interactions are entirely neglected and the values for quasi-adiabatic approximation. With the former approximation, the first excitation energy comes out to be higher by about 0.3 ev with no appeciable changes in α and α_e. The qnasi-adiabatic approximation is just what was

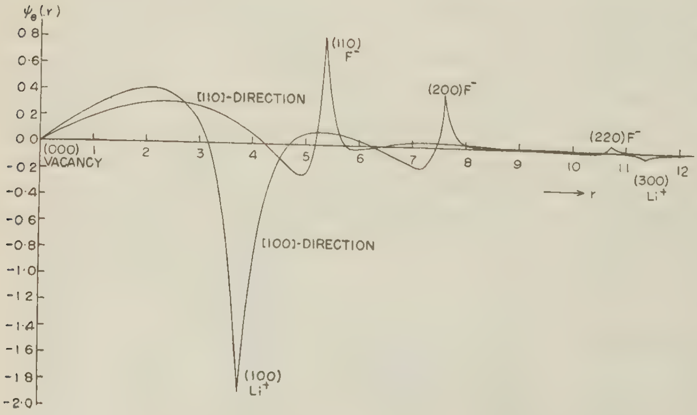


Fig. 2. (a) Ground State

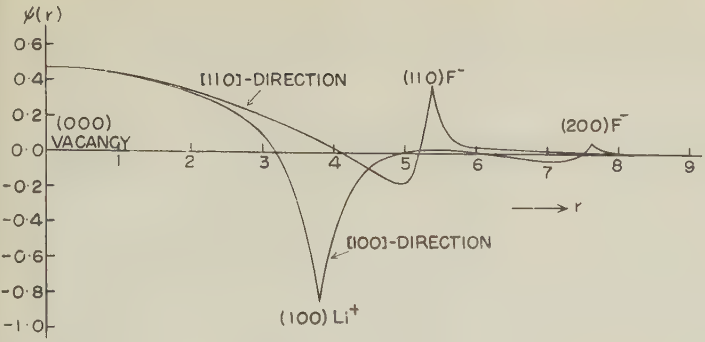

(b) Excited State

Fig. 2. Wave functions of a trapped electron along one of the [100]- and one of the [110]-directions.

employed in I and corresponds to neglecting $\mathscr{H}_{4\alpha}$ and the van der Waals interactions. Since both the neglected energies are rather insensitive to the variation of α or α_e, and besides this neglect lowers the first excitation energy by only 0.25 ev, we may conclude that the quasi-adiabatic approximation does not give appreciably different results compared with the Hartree-Fock approximation, as far as the excitation energy is concerned.

In Figs. 2a and 2b are depicted the wave functions along a [100] and a [110] direction for both the ground and excited states, and in Fig. 3, the charge distributions $Q(r)$ and $Q_e(r)$ defined by Eqs. (14) and (19). The mean orbital radii of the trapped electron turn out to be 2.4 a. u. for the ground state and 3.6 a. u. for the first excited state (note that a=3.8 a. u.). These figures indicate that the charge distributions are appreciably concentrated within the vacancy, as contrasted to earlier treatments. As Figs. 2a and 2b shows, our wave functions behave like a 2*s* function around each lithium nucleus and like a 3*s* function around each fluorine nucleus as might have been expected. The displacemets and ion-core dipole moments of the (100) and (110) ions for the ground state are listed in Table III.

Neighbors	ξ	m
(100)	-0.074	0.002
(110)	-0.026	0.006

The oscillator strength associated with the lowest optical excitation is given by the expression $(2m/\hbar)^2[(E_e-E)/h](\int\psi_e x\psi d\tau)^2$, which was evaluated using our wave functions to be 0.85. No measurements have so far been made for the oscillator strength in LiF. However, a value of 0.81 was obtained for KCl by Kleinschrod[8], and 0.85 and 0.87 for KCl and NaCl respectively (with an accuracy of ±5%) by paramagnetic experiments[9]; one might expect for LiF a value not much different from these values, inasmuch as the shape of the *F*-band of LiF closely resembles that of NaCl or KCl. The oscillator strength being a quantity rather sensitive to the values of the variational parameters, an accurate measurement of it for LiF is desired to test our calculation.

We have made estimates of the first excitation energy in the zeroth and first approximations to compare with the result of the second approximation. The first approximation yields a value about 0.1 ev higher and the zeroth approximation a value about 1/4 ev lower than the second approximation. Somewhat rough evaluations were made up to the fourth approximation in order to see the speed of convergence. The values of excitation energy in the third and fourth approximations agree with that the second approximation within about 0.06 ev. Our successive approximations thus appear to converge rapidly, and the *second* approximation is already satisfactory for our purposes.

§ 5. Electron Spin Resonance

Kip et al[10] have shown that the line-width of electron spin resonance in F-centers arises from the hyperfine interactions between the trapped electron and the nuclear magnetic moments on the surrounding nuclei:

$$\mathscr{H}_9=-\frac{16\pi\mu_B}{3}\sum_\nu\frac{\mu_\nu}{I_\nu}|\psi(\boldsymbol{R}_\nu)|^2, \tag{24}$$

in which μ_ν denotes the magnetic moment and I_ν the spin quantum number of the ν-th nucleus. These interactions lead us to the rms width:

$$\langle(\Delta H)^2\rangle_{\text{Av}}{}^{1/2}=\frac{8\pi}{3^{3/2}}\left[\sum_\nu\mu_\nu{}^2\frac{I_\nu+1}{I_\nu}|\psi(\boldsymbol{R}_\nu)|^4\right]^{1/2}. \tag{25}$$

Our wave function yields a value $|\psi(\text{Li})|^2=0.0485$ a. u. at a (100) lattice site, and $|\psi(\text{F})|^2=0.0083$ a. u. at a (110) site. Assuming a relative abundance of Li^6 and Li^7 to be 1:11.5[11] and neglecting small contributions from more distant nuclei, Eq. (24) gives 82 oersteds for the rms width[12], which is about twice as large as the observed value 39 oersteds by Lord[13]. Lord also obtained for the charge densities $|\psi(\text{Li})|^2=0.0228$ a. u. and $|\psi(\text{F})|^2=0.0031$ a. u. by analyzing their data of the line-width.

The principal reason for this discrepancy appears to lie in that we have constructed the wave functions by means of the Schmidt's method of orthogonalization, without solving exactly the wave equation around each nucleus. According to our oalculation performed on metallic lithium[14], the value $|\psi(0)|^2$ for the lowest conduction electrons ($\boldsymbol{k}=0$) computed with a single orthogonalized plane wave was found to be 2.0 times as large as the value obtained with a more elaborate variational method. Therefore, the discrepancy may substantially disappear if the wave equation is solved more accurately in the neighborhood of each atomic nucleus.

§ 6. Discussions

We shall enumerate several sources of errors which might have been introduced and estimate their order of magnitude wherever possible.

(1) We have made the wave functions orthogonal to the core functions by the Schmidt's process. Obviously this is not the only possible method of orthogonalization, therefore one can expect lower energy values by taking some better procedure. An estimate of this lowering can be made on the basis of the calculation on metallic lithium mentioned at the end of § 5. The result is as follows: a lowering of 0.010 to 0.015 ev is expected per (100)Li^+ atomic cell, therefore a total lowering of about 0.1 ev for the ground level and of 0.2 to 0.3 ev for the first excited level. It is noted that this point is intimately connected with the problem on electron resonance line-width, as discussed in § 5.

(2) We have consistently neglected the non-orthogonality between different core functions when constructing the wave functions and deriving expressions for the energy. To take account of this non-orthogonality would in principle be possible, but the corresponding computations would be impractical owing to the appearence of a large number of many-center integrals. Non-orthogonality integrals between core functions are small, as mentioned in I, and inclusion of them will scarcely affect the final energy levels.

(3) The choice of the joining radius R also can affect the energy levels. Recalculations with different joining radii showed that the ground state lowered by no more than about 0.1 ev. A similar magnitude of lowering may be expected for the excited state. We might thus conclude that the first excitation energy is virtually unaltered by choosing some better value of R.

Furthermore, choice of the repulsive potential between ions and the shape of the trial functions f and f_e would to some extent affect the final results. Our line of attack on the correlation effects between a trapped electron and core electrons, consisting of expansion of the Coulomb interactions into a series of van der Waals interactions, would not also be entirely satisfactory.

The method of approach presented in this paper is applicable to other alkali halides if more laborious practical calculations could be made. It will also be possible to construct a complete configuration coordinates diagram for an F-center by extending the present calculation, but we shall postpone this program to another occasion.

The author wishes to express his gratitude to Professor T. Nagamiya for his continued interest and encouragement throughout this work. The author is indebted also to Mrs.

K. Kojima for helpful discussions and valuable assistance in the numerical calculations.

Appendix A. Evaluation of Integrals

Evaluation of various integrals appeared in the text were carried out in the following way:

1. Overlap integrals $c_{\nu j}$.

If the branch of $f(\boldsymbol{r})$ going with $r>R$ were extended into the region $r<R$, the calculation of $c_{\nu j}$ could have been executed analytically with ease[15]. Actually $f(\boldsymbol{r})$ takes a different form in $r<R$, so that we must correct for this difference. For this purpose, $\chi_{\nu j}$ was expanded into spherical harmonics around the missing lattice point, and the overlap integrals between $\chi_{\nu j}$ and the two kinds of $f(\boldsymbol{r})$ were evaluated numerically within the sphere $r=R$. The difference between these overlap integrals gave the desired correction.

2. Coulomb integrals in Eq. (13d).

Coulomb integrals between f and $\chi_{\nu j}$ can also be calculated analytically[15] for each $\chi_{\nu j}$ if the outer branch of $f(\boldsymbol{r})$ could be extended into the region $r<R$. Correction for the deviation from this extended $f(\boldsymbol{r})$ was evaluated analytically by expanding the potential due to $\chi_{\nu j}^2$ into spherical harmonics around the missing lattice point. Summation over j was most conveniently performed by the method described in Appendix B. 3 of I.

3. Exchange integrals in Eq. (13e).

The exchange integrals associated with (100) and (110) ions were evaluated after Landshoff[16] by expanding $f(\boldsymbol{r})$ into spherical harmonics around the vacant lattice point. Contributions from those associated with more remote ions are less important, so that the following simplified method was employed to evaluate them: Exchange integrals were first calculated using Slater's free electron approximation[17], but since this method was found to give values not accurate enough for our purposes, a correction factor γ was introduced into Slater's approximation such that

$$\sum_j \int \frac{f(\boldsymbol{r})f(\boldsymbol{r}')\chi_{\nu j}(\boldsymbol{r})\chi_{\nu j}(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|}\,d\tau'$$

$$=3\gamma\left\{\frac{3}{8\pi}\sum_j \chi_{\nu j}^2(\boldsymbol{r})\right\}^{1/3} f^2(\boldsymbol{r})\,. \tag{A1}$$

γ can vary with α. It can also vary from ion to ion with which we are concerned, but we assumed a common value for all the positive ions and another common value for all the negative ions, and these values were determined at the (100) and (110) ions for each value of α.

It is needless to say that the above methods are also applicable to the excited state, provided some obvious modifications are made.

Appendix B. Van der Waals Energy

Let the total electronic wave function for the whole crystal containing an F-center be $\Psi=\psi(r)\prod_{\nu,j}\chi_{\nu j}(r_{\nu j})$, and let the deviation of the interaction between the trapped electron and core electrons from the Hartree-Fock Hamiltonian, $\mathscr{H}_{\mathrm{HF}}$,

$$\mathscr{H}_{\mathrm{corr}}=e^2\sum_{\nu,j}\left[\frac{1}{|\boldsymbol{r}-\boldsymbol{r}_{\nu j}|}-\iint\frac{\psi^2(\boldsymbol{r})\chi_{\nu j}^2(\boldsymbol{r}_{\nu j})}{|\boldsymbol{r}-\boldsymbol{r}_{\nu j}|}\,d\tau d\tau_{\nu j}\right]-e^2\sum_\nu Z_\nu\left[\frac{1}{|\boldsymbol{r}-\boldsymbol{R}_\nu|}-\int\frac{\psi^2(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{R}_\nu|}\,d\tau\right] \tag{A2}$$

be treated as a perturbation. We take as a trial function

$$\Phi=\left[1+\sum_{\nu,j}\lambda_{\nu j}{}^{(1)}u_{\nu j}{}^{(1)}(\boldsymbol{r},\boldsymbol{r}_{\nu j})+\sum_{\nu,j}\lambda_{\nu j}{}^{(2)}u_{\nu j}{}^{(2)}(\boldsymbol{r},\boldsymbol{r}_{\nu j})+\cdots\right]\Psi \tag{A3}$$

where $\lambda_{\nu j}{}^{(n)}$ are variational parameters and

$$u_{\nu j}{}^{(1)}=\frac{\boldsymbol{r}\cdot\overline{\boldsymbol{r}}_{\nu j}}{R_\nu{}^3}-\frac{3(\boldsymbol{r}\cdot\boldsymbol{R}_\nu)(\overline{\boldsymbol{r}}_{\nu j}\cdot\boldsymbol{R}_\nu)}{R_\nu{}^5}\,,$$

$$u_{\nu j}{}^{(2)}=\frac{3}{2}\left[\frac{r^2\overline{\boldsymbol{r}}_{\nu j}\cdot\boldsymbol{R}_\nu-\overline{r}_{\nu j}{}^2\boldsymbol{r}\cdot\boldsymbol{R}_\nu}{R_\nu{}^5}+\frac{\boldsymbol{r}\cdot\boldsymbol{R}_\nu-\overline{\boldsymbol{r}}_{\nu j}\cdot\boldsymbol{R}_\nu}{R_\nu{}^2}\left\{\frac{2\boldsymbol{r}\cdot\overline{\boldsymbol{r}}_{\nu j}}{R_\nu{}^3}-\frac{5(\boldsymbol{r}\cdot\boldsymbol{R}_\nu)(\overline{\boldsymbol{r}}_{\nu j}\cdot\boldsymbol{R}_\nu)}{R_\nu{}^5}\right\}\right], \tag{A4}$$

with an abbreviation $\overline{\boldsymbol{r}}_{\nu j}=\boldsymbol{r}_{\nu j}-\boldsymbol{R}_\nu$. $\lambda_{\nu j}{}^{(n)}$ are determined so as to minimize the variational integral:

$$\Delta E=\int\Phi(\mathscr{H}_{\mathrm{HF}}+\mathscr{H}_{\mathrm{corr}})\,\Phi d\tau\Big/\int\Phi^2 d\tau-\int\Psi\mathscr{H}_{\mathrm{HF}}\Psi d\tau\,. \tag{A5}$$

The result may be written

$$\begin{aligned}
\Delta E&=E^{(1)}_{\mathrm{v.d.w.}}+E^{(2)}_{\mathrm{v.d.w.}}+\cdots,\\
E^{(1)}_{\mathrm{v.d.w.}}&=-\sum_{\nu j}\frac{4me^4}{9\hbar^2}\langle\overline{r}_{\nu j}{}^2\rangle^2\frac{1}{R_\nu{}^6}\left(\int_{r<R_\nu}r^2\psi^2 d\tau\right)^2\Big/\left[\int r^2\psi^2 d\tau+\langle\overline{r}_{\nu j}{}^2\rangle\right],\\
E^{(2)}_{\mathrm{v.d.w.}}&=-\sum_{\nu j}\frac{2me^4}{3\hbar^2}\frac{1}{R_\nu{}^8}\left[\langle\overline{r}_{\nu j}{}^2\rangle\int_{r<R_\nu}r^4\psi^2 d\tau+\langle\overline{r}_{\nu j}{}^4\rangle\int_{r<R_\nu}r^2\psi^2 d\tau\right]^2\\
&\qquad\Big/\left[\int r^4\psi^2 d\tau+\frac{20}{3}\langle\overline{r}_{\nu j}{}^2\rangle\int r^2\psi^2 d\tau+\langle\overline{r}_{\nu j}{}^4\rangle\right],
\end{aligned} \tag{A6}$$

where $\langle\overline{r}_{\nu j}{}^2\rangle$ is an abbreviation for $\int\chi_{\nu j}(\boldsymbol{r})\times\overline{r}_{\nu j}{}^2\chi_{\nu j}(\boldsymbol{r})d\tau$. $E^{(1)}_{\mathrm{v.d.w.}}$ and $E^{(2)}_{\mathrm{v.d.w.}}$ correspond to instaneous dipole-dipole and dipole-quadrupole interactions, respectively. $\langle\overline{r}_{\nu j}{}^2\rangle$ can be expressed in terms of the polarizability $\alpha_\nu{}^0$ by means of the Kirkwood's formula[18]:

$$\alpha_\nu{}^0=\frac{4}{9}\sum_j\langle\overline{r}_{\nu j}{}^2\rangle^2\frac{me^2}{\hbar^2} \tag{A7}$$

Neglecting small terms in the expression of $E^{(2)}_{\mathrm{v.d.w.}}$ and assuming that only the electrons in the outermost shells contribute to the polarizabilities and van der Waals interactions, we arrive at Eq. (22).

The Magnetic Properties of Iron Selenide Single Crystals

By Kinshiro HIRAKAWA

Department of Physics, Kyushu University, Fukuoka, Japan

(Received September 22, 1956)

Large single crystals of Fe_7Se_8 and Fe_3Se_4 were prepared, and their magnetic properties below the Curie point were investigated by a torque magnetometer. The results obtained on Fe_7Se_8 at room temperature show similar characterics to that of natural pyrrhotite (Fe_7S_8), i.e. the crystals can be magnetized only in the *c*-plane. As the temperature is lowered, however, the *c*-axis becomes the direction of easy magnetization. This change in direction seems to occur gradually. In the case of Fe_3Se_4, such a change in direction of easy magnetization does not take place. The obtained saturation magnetizations for Fe_7Se_8 and Fe_3Se_4 are respectively 68 and 80 gauss at the liquid air temperature.

§ 1. Introduction

The original purpose of this investigation was to make clear the peculiar magnetic behavior of pyrrhotite.[1] In the course of an attack of this problem, it has been found that the properties of $FeSe_x$, which has selenium as an anion instead of surphur, have a close resemblance to those of pyrrhotite, because the anions in such a NiAs type crystal commonly have an important role in the super exchange interaction between iron atoms. We have already obtained an experimental evidence for the ordered arrangement of the lattice defects,[2] i.e. selectively missing iron ions in the alternating *c*-plane in the NiAs type structure. This may be a strong support for the occurence of ferrimagnetism in this substance. The magnetic properties of powdered $FeSe_x (x=1.00\sim1.35)$ have been studied by Hirone and his co-workers,[3] and they observed its ferrimagnetism-like behavior. After their experiments, $FeSe_{1.14}$ and $SeSe_{1.35}$ have Curie point at about 175°C and 40°C and the saturation magnetization at low temperature of about 35 and 15 gauss respectively. It is our purpose to obtain further informations about the anisotropy, saturation magnetization and their temperature dependence with the single crystals of Fe_7Se_8 and Fe_3Se_4.

§ 2. Preparation of Specimens

Single crystals were obtained by the following process: the electrolytic iron powder of about 50 mesh was fully reduced by electrolytic hydrogen gas at about 1000°C. A mixture of the proper proportion of this powder and redistilled selenium, which is more than 99.99% pure, was sealed into an evacuated thick silica tube. The inside of the tube was previously coated with thin carbon film by the decomposition of benzol gas. The tube was then put into the furnance horizontally so as to complete a full reaction and to avoid the cracking of the tube due to the anomalous contraction during the cooling. After keeping at 1100∼1150°C for 4∼5 days, it was cooled very slowly from one end of the container down to room temperature during about 7 days. The largest crystal thus obtained was a flat pole of hexagon of about $20\times20\times10$ mm. From each product, several circular disks were cut out. Crystallographic orientations of them are listed in Table I.

The compositions of specimens have been ascertained by chemical analysis of a small piece of the disks (about 15 mg), the results being listed in Table II. In each case, both selenium content and total weight are lower than the values expected. These disagreements may come from the situation that some amounts of selenium had been lost during the process of analysis, although it is not yet certified. The composition calculated from the iron weight is also listed in the last column of the table. No. 1∼3 show a good agreement to the expected composition of Fe_7Se_8, whereas No. 4 and No. 5 have surely excess content of iron. The remainder of the product, from which the specimens No. 4 and No. 5 were cut out, has also been examined and it proved to show a poor content of iron, as can be seen in the last row in that table. It has the Curie point of about −10°C which is lower than that of No. 4 and No. 5, although

Table I. The dimention and the planes of specimens.

In this table, a, c and V mean respectively the diameter, thickness and volume. The volume was determined from the weight of the disk and the density calculated from the X-ray data. N is the demagnetization factor with respect to the direction of applied field parallel to the plane of the disk, which is approximated to an oblate spheroid. In the last column of the table the indices of plane of the disks are listed, the possible error of which being within 2°.

Specimens number	Composition	a(mm)	c(mm)	V(cm^3)	N	Plane of the disk
No. 1	Fe_7Se_8	8.2	1.1_7	0.0603	1.2_0	$\{10\bar{1}0\}$

*	34.1_4(34.66)	65.1_6(65.34)	99.30	$Fe_3Se_{4.09}$

the details are not yet studied.

§ 3. Experimental Procedure

The measurements were carried out by means of the torque magnetometer which was the same type as that used by Kaya and Miyahara.[4] In order to see the saturation effect, we measured the normal component of magnetization $\boldsymbol{I}_\perp$ to the external field $\boldsymbol{H}$, because it should vanish for the field strength of complete saturation. Here $\boldsymbol{I}_\perp$ is given by

$$\boldsymbol{I}_\perp = \boldsymbol{D}/\boldsymbol{VH}\,, \qquad (1)$$

in which $\boldsymbol{D}$ denotes the exerted torque, which is measured by setting the disk horizontally in the uniform horizontal field as shown in Fig. 1 (a). From the amplitude of the torque curves which was obtained under a field strength sufficient to saturate, we can directly obtain the anisotropy constants.

As the crystals are hexagonal and expected to be strongly anisotropic, the following process may be applicable to obtain the saturation magnetization: first, we set the disk vertically and one of the directions of easy magnetization, which is in the plane of the disk, parallel to the direction of the external field. Next, the plane of the disk is turned through a small angle δ from the original position (Fig. 1 (b)). Then the torque in this case is given by

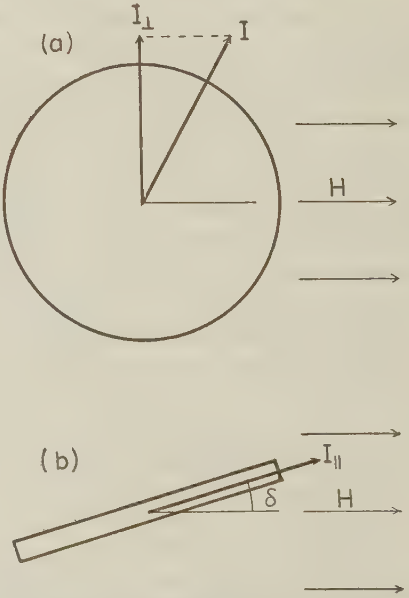

Fig. 1. Method of holding the specimen disk in the magnetic field. The torque is exerted in the plane of the paper. (a) for the measurement of the normal component and (b) of the saturation magnetization.

$$D = VI_{\parallel}H\sin\delta - \frac{\chi_{\perp}}{1+4\pi\chi_{\perp}}VH^2\sin\delta\cos\delta\ , \tag{2}$$

where $I_{\parallel}$ is the induced magnetization in the direction of easy magnetization, and $\chi_{\perp}$ the susceptibility in the direction normal to the plane of the disk when the crystal is regarded as paramagnetic in this direction. For small angle δ, Eq. (2) can be written as

$$D/VH\sin\delta = I_{\parallel} - \frac{\chi_{\perp}}{1+4\pi\chi_{\perp}}H\ , \tag{3}$$

which decreases with increasing H in the region of saturation. We can therefore obtain the saturation magnetization I_s by plotting the measured values of $D/VH\sin\delta$ as a function of H and by extrapolating it to $H=0$. Practically δ was taken as ±5° around the original position of $D=0$. The torque constant of the phosphorbronze string was determined by the method of oscillation. Magnetic field was produced by a rotatable electromagnet, and the field was measured by a search coil calibrated by proton resonance. The damping bath was not used, because the eddy current induced in the specimen holder played a role in damping-actions. The temperature was measured by a very fine copper-constantan thermocouple, which was attached very closely to the specimen.

§ 4. Experimental Results on Fe_7Se_8

a) Torque curves in the plane $\{10\bar{1}0\}$. (Specimen No. 1)

As the crystal of Fe_7Se_8 has a hexagonal symmetry, the anisotropy energy E, in the

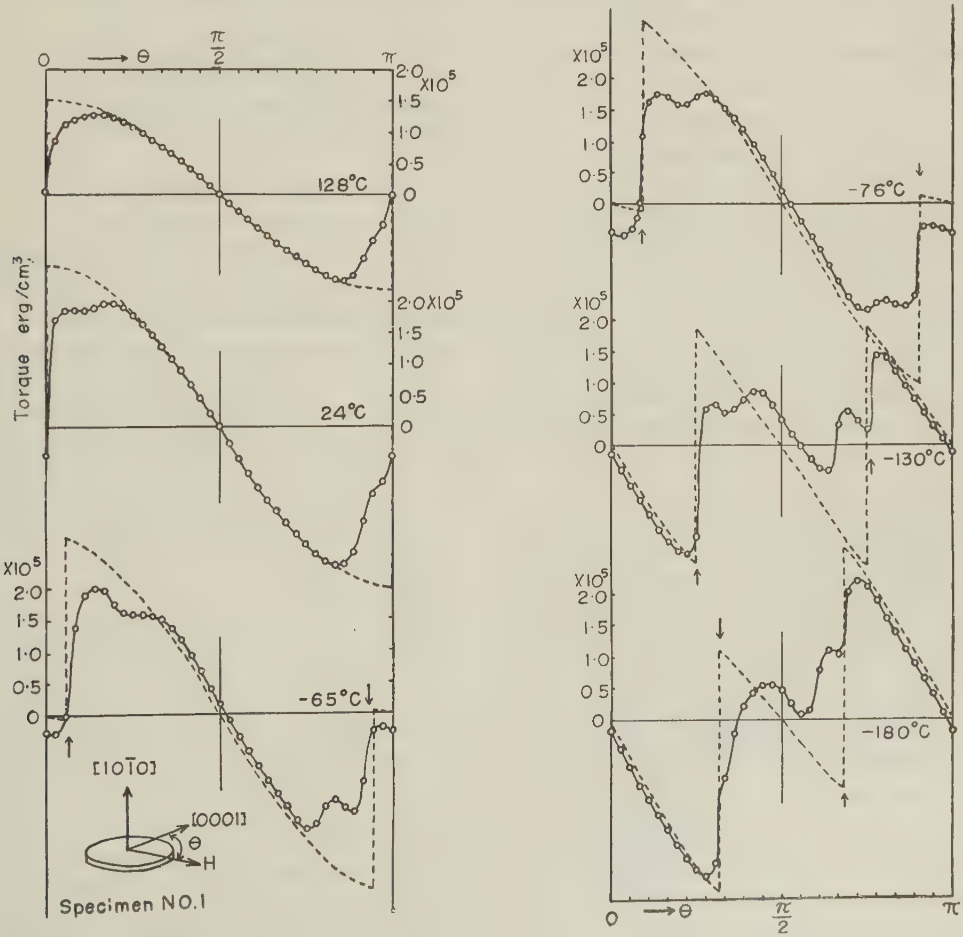

Fig. 2. Temperature variation of the torque curves of Fe_7Se_8 in the plane $\{10\bar{1}0\}$ under a constant field of 5650 Oe. The white circles are the observed points. The anomalous dents are marked by the arrows. The dotted curves are the suggested curves under the simple assumptions described in § 7 (i).

case when the crystal is magnetized, is given by

$$E=K_1\sin^2\theta+K_2\sin^4\theta+K_3\sin^6\theta$$
$$+K_3'\sin^6\theta\cdot\sin^2 3\varphi+\cdots\,, \qquad (4)$$

where $K_1, K_2, \cdots$ are the anisotropy constants and θ is the angle between the direction of magnetization and the c-axis. For the field strength higher than for saturation, the torque per unit volume in the plane $\{10\bar{1}0\}$ is

$$D/V=-\frac{\partial E}{\partial\theta}=-K_1\sin 2\theta$$
$$-2K_2\sin 2\theta\cdot\sin^2\theta-\cdots\,. \qquad (5)$$

At first, we examined the normal component of magnetization $I_\perp$ in this plane for the various field strength up to 11500 Oe. Up to this field strength, any decrements of $I_\perp$ was not observed at all. This fact means that the used field is too weak to analyse the torque curves quantitatively by means of Eq. (5).

Fig. 2 shows the temperature variation of the torque curves in this plane $\{10\bar{1}0\}$ which was obtained under the constant field of 5650 Oe. The direction of easy magnetization can be found out from the stable equilibrium position of $D=0$. At higher temperatures this is in the c-plane, but in the c-axis at lower temperatures. The torque curves thus obtained show a gradual change in their form. We suppose therefore that the direction of easy magnetization changes gradually with decreasing temperature as will be discussed in § 7.

b) *Torque curve in the plane {0001}.* (Specimen No.2)

The temperature variation of the torque curves in the c-plane under a constant field strength of 5650 Oe. can be seen in Fig. 3, where φ denotes the angle between the direction of external field and the axis $[10\bar{1}0]$. From the stable equilibrium positions of $D=0$, it seems that the directions of easy magnetization in the c-plane are parallel to the axis $[1\bar{1}20]$ or its equivalents. As expected from the hexagonal symmetry, all these curves have a six-fold symmetry, although a small component with two-fold symmetry is also contained. This fraction of two-fold symmetry is too large to come from the probable errors in cutting the specimen, so that there may be a small deformation from the hexagonal symmetry of an undetected order. As the temperature is lowered, a continuous decreasing of the amplitude of the torque curves can be seen. This decreasing of the amplitude is considered to have a close connection to the curves in Fig. 2 as will be discussed in § 7.

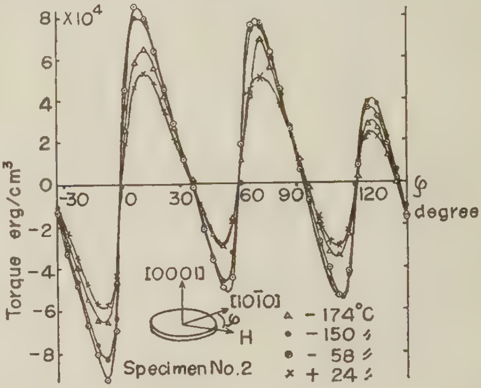

Fig. 3. Temperature variation of the torque curves in the plane {0001} obtained at a constant field strength of 5650 Oe.

c) *Saturation magnetization of Fe_7Se_8* (Specimen No. 1 and No. 3)

According to the method described in § 3, the saturation magnetization I_s of Fe_7Se_8 at various temperatures was measured. The specimen No. 3 was used at higher temperatures than −120°C and No. 1 at the lower temperatures, because below this temperature the specimen No. 3 is forced to rotate by 90°

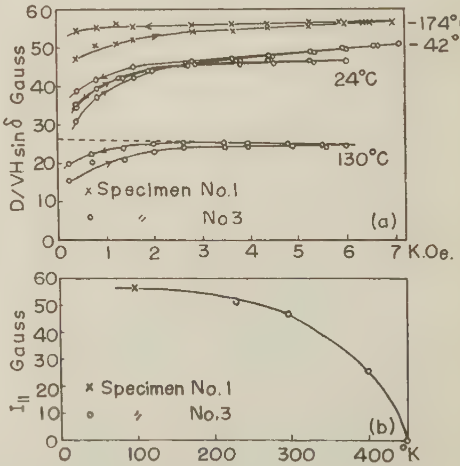

Fig. 4. (a) $D/VH\sin\delta$ and (b) the parallel component of magnetization in the directions of the $[11\bar{2}0]$ axis (○) and of the [0001] axis (×) as the functions of temperature.

to orient so as to make its surface normal to the direction of the field. Fig. 4 (*a*) shows the measured values of $D/VH \sin\delta$ as a function of H. As described in § **3**, the value of $D/VH \sin\delta$ decreases linearly in the region of high field at 128°C. At lower temperatures, however, it tends to increase with field strength, as if the crystal were not saturated. In such a case, we can not obtain the correct value of I_s. Neglecting the second term in Eq. (3), we took up, therefore, the maximum values of $D/VH \sin\delta$ as a value of $I_{\|}$ at 7000 Oe., which is shown in Fig. 4 (*b*). Thus, these values may somewhat, but not too much, be smaller than the saturation magnetization.

§ 5. X-ray Measurements

In order to examine any structural change in Fe_7Se_8, the X-ray diffraction study on the single crystal was carried out at liquid air temperature by the method of Lonsdale and Smith.[5)] But we could not find any marked change in the crystal structure and in the ordered arrangement of the lattice defects. Only a small contraction of the lattice parameters was observed as shown in Table III.

Table III. Lattice parameters of Fe_7Se_8

	Room temp.	Liq. air temp.	Fraction of contraction
B(2*a*)*	7.23_4	7.17_0	0.88%
C(3*c*)*	17.65	17.62	0.17%
c/*a*	1.62_5	1.63_8	

* The capital and small letters designate the unit cell lengths of the super and fundamental lattices, respectively.

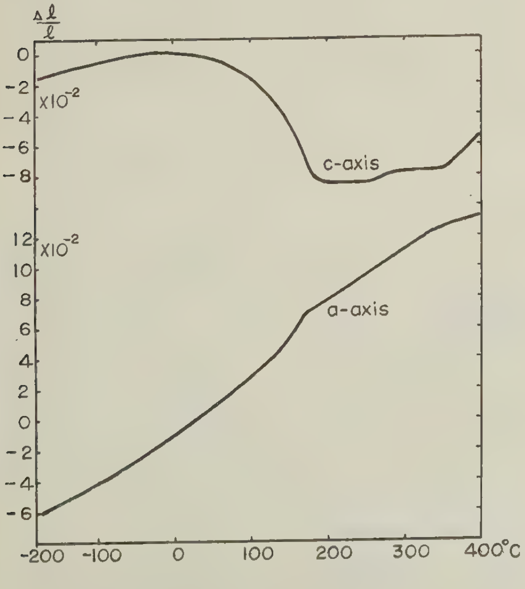

Fig. 5. Thermal expansion of Fe_7Se_8 along the direction parallel to the a- and c-axes.

The thermal expansion of Fe_7Se_8 was measured by a dilatometer and the results are shown in Fig. 5. There is no discontinuous change at low temperatures, but an anomalous change was observed at 170°C, which is a ferrimagnetic Curie point. Immediately below this temperature, on heating, the crystal expands along the *a*-axis while contracts along the *c*-axis.

At about 350°C there is an anomalous kink in both curves, suggesting the existence of a crystal transformation.*

§ 6. Experimental Results on Fe_3Se_4 (Specimen No. 4 and 5)

Fig. 6 shows the measured torque curves in the plane {0001} of the NiAs type structure under the various field strengths and temperatures. These curves show a strong two-fold symmetry besides the symmetry having a period of 60°. This may be possible, because Fe_3Se_4 has a pseudo- NiAs type structure or correctly monoclinic structure with $A = 6.16_7$ Å ($\approx\sqrt{3}\,B$), $B = 3.53_7$ Å, $C = 11.1_7$ Å ($\approx 2c$) and $\beta = 92.0°$.[2)] After the torque and X-ray studies, it was found that the direction of easy magnetization was in the *c*-plane. Contrary to the case of Fe_7Se_8, the saturation effect in this plane was not observed up to 11000 Oe. as well as in the plane $\{11\bar{2}0\}$. In the present case, the change of the direction of easy magnetization was not observed at all. In Fig. 7 are shown the measured values of $D/VH \sin\delta$ and of the saturation magnetization obtained by the method described in § **3**.

---

* The temperatures of 170°C and 350°C at which the anomalies occur agree well with those observed in thermal analysis by Hirone and Chiba[3)].

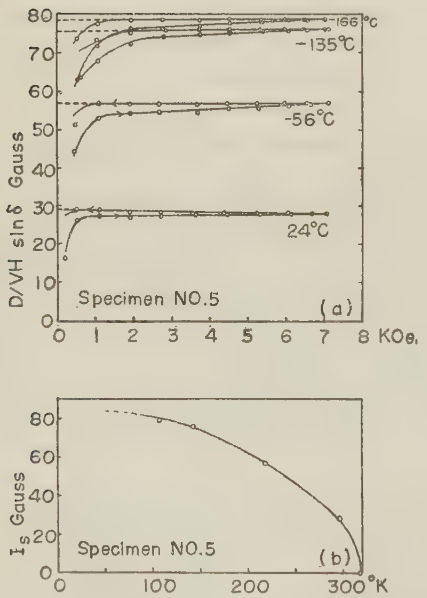

Fig. 7. $D/VH \sin\delta$ and I_S of Fe_3Se_4 as functions of temperature.

§ 7. Discussions of the Results

From the results described above, it seems that Fe_3Se_4 does not show any peculiar property and the obtained thermo-magnetic curve is similar to that of usual ferrimagnetic materials, while Fe_7Se_8 shows a change in direction of the easy magnetization at about −120°C. But the change is not likely to be simple. In the common case, when the contribution of the first term in the anisotropy expression (4) is dominant, the sudden change of the direction of easy magnetization occurs at a definite temperature at which K_1 changes its sign, and consequently the phase of the torque curve in the plane {10$\bar{1}$0} abruptly changes by an amount of $\pi/2$.* At the same temperature, the abrupt change in the torque amplitude in the plane {0001} may also be expected if the applied field were not so strong. Our results show, however, that the changes of the torque curves in both plane {10$\bar{1}$0} and {0001} are continuous over a wide temperature range.

We propose here that the direction of easy magnetization rotates progressively from one direction to another with decreasing temperature. Now, from this standpoint, we shall give an interpretation of the observed torque curves as follows:

(i) *Interpretation of the torque curves in Fig. 2.*

The torque curves in the plane {10$\bar{1}$0} change their forms according to the various field strengths. As an example, the torque curves of the crystal in which the direction of easy magnetization is in the *c*-plane and for the cases where the terms other than that of K_1 in Eq. (4) are negligible are shown schematically in Fig. 8. (a) is the case for the field strengths higher than for saturation. This curve can be expressed by $-\partial E/\partial\theta = -K_1 \sin 2\theta$. (c) is the case for a sufficiently weak field. In such a case where the field is very weak,

---

[*] See Fig. 9 (a) and (e).

the direction of magnetization remains in the c-plane, when the angle θ between the direction of the external field and the c-axis is varied.

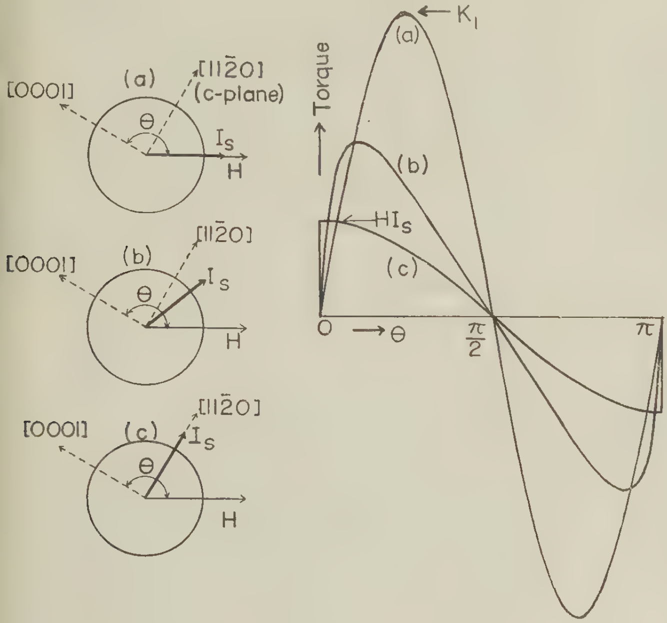

Fig. 8. The torque curves in the plane $\{10\bar{1}0\}$ of the crystal in which the direction of easy magnetization is in the c-plane.

(a) is the case for the field strength higher than for saturation. This torque can be expressed by $-K_1 \sin 2\theta$.

(c) is the case for the field fur weaker than the anisotropy field. The curve can be expressed by $HI_s \cos\theta$. At $\theta=0$, π a reversal of the sense of magnetization occurs, resulting a sudden change in torque.

(b) is the case for the intermediate field strength.

(b) is the case for an intermediate field strength. The torque curves observed at 128°C and 24°C in Fig. 2 resemble to the cases of (b) or (c). Regarding these two observed curves as the case of (c) ....as shown by the dotted curves in Fig. 2 ...., we can obtain the values of I_s, which are shown in Fig. 11. The values of I_s thus obtained agree well with the values those obtained in § 4 (**c**). As the temperature is lowered, however, a couple of anomalous dents appears in the vicinity of $\theta=0, \pi$ and it moves toward the position of $\theta=\pi/2$ with further decreasing temperatures. These dents are marked by the arrows in Fig. 2.

As an interpretation of these anomalous dents, we propose that the direction of easy magnetization rotates progressively from the direction in the c-plane at high temperatures towards the direction of c-axis at low temperatures. Such a progressive change is possible when the K_2 term plays a considerable contribution to the anisotropy expression of Eq. (4).* The torque curves for the various magnitude of K_1 and K_2 are shown schematically in Fig. 9 (the case of strong field). Now, let the polar angles which denote the direction of easy magnetization be θ_0 and $\pi-\theta_0$, which are the functions of temperature, then the torque becomes zero at the directions of $\theta=0$, θ_0, $\pi/2$, $\pi-\theta_0$, π, $\cdots$, as can be seen in Fig. 9.

Under a weak field, however, the forms of the torque curves in Fig. 9 will not immediately give those of the obtained curves, because the latter would greatly be modified, especially in the cases when the domain structures remain as yet. We shall set up, therefore, the forms of the torque curves which would be observed under a weak field and compare them with those observed.

In an actual crystal there exists, perhaps in equal proportions, two kinds of domains, one is magnetized in θ_0 direction and the other in $\pi-\theta_0$ direction. When such a crystal is rotated in a weak field, we assume that the transfer of the domains (domain $(\theta_0)\rightleftarrows$domain $(\pi-\theta_0)$ does not occur,** but the reversal of the sense of magnetization in each domain is permitted. Then the torque for the whole crystal can be expressed by a superposition of the two torque curves of the type of Fig. 8 (c), each of which corresponding respectively to the domain (θ_0) and the domain $(\pi-\theta_0)$, as shown in Fig. 10 (b). As can be seen in Fig. 10 (b), the torque decreases abruptly at $\theta=\pi/2\pm\theta_0$, where the direction of easy magnetization is just perpendicular to the external field.

---

* The direction of easy magnetization is neither in the c-plane nor in the c-axis, when the conditions $\frac{1}{2}|K_1|<|K_2|$ and $K_1K_2<0$ are satisfied. The possibility of these conditions from the atomic theory will not be discussed at present.

** The transfer of the domain will cause a change in the elastic deformation, resulting the increase in crystalline energy.

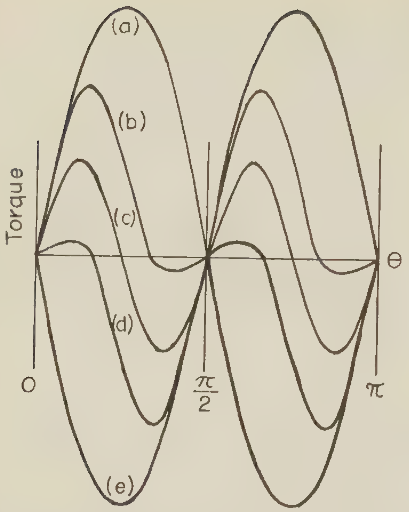

Fig. 9. The forms of the torque curves for the various values of K_1 and K_2 represented by Eq. (5).

(a) $|K_1| \gg |K_2|$, $K_1 < 0$
(b) $1/2|K_1| < |K_2| < |K_1|$, $K_1K_2 < 0$
(c) $K_1 = -K_2$
(d) $|K_1| < |K_2|$, $K_1K_2 < 0$
(e) $|K_1| \gg |K_2|$, $K_1 > 0$

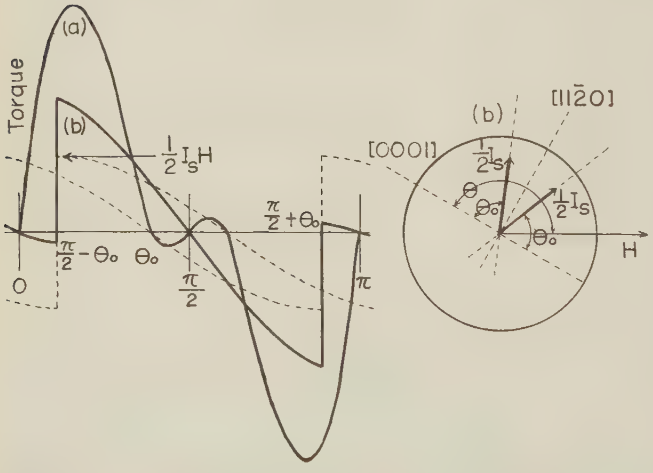

Fig. 10. An example of the forms of the torque curves for the crystal in which the directions of easy magnetization θ_0 and $\pi-\theta_0$ are not in the crystal axes. (a) is the case for a strong field. (b) is the supposed torque curve for a weak field, assuming that a half of the volume of the specimen is magnetized in the direction of θ_0 and the other half in the direction of $\pi-\theta_0$. This torque curve is composed by the superposition of two torque curves (dotted lines) of the type Fig. 8 (c).

The supposed torque curve in Fig. 10 (b) is very different from the curve of Fig. 10 (a) which is the case for a strong field, but Fig. 10 (b) gives the forms which resemble to the observed at −65°C. As can be seen in Fig. 10 (b), the positions of the anomalous dents appeared in Fig. 2 can be expressed by θ_0, while the magnitude of the observed torque, can be fit by a suitable choise of the magnitude of $\boldsymbol{I}_s$. The supposed torque curves thus obtained are represented by the dotted curves in Fig. 2. The used values of θ_0 and $\boldsymbol{I}_s$ are shown in Fig. 11 as functions of temperature.

At low temperatures the value of $\boldsymbol{I}_s$ thus chosen are larger than $\boldsymbol{I}_{\parallel}$ which was obtained in § 4. As $\boldsymbol{I}_{\parallel}$ is the component of $\boldsymbol{I}_s$ in the direction of the *c*-plane or the *c*-axis, $\boldsymbol{I}_s$ can be obtained by using $\boldsymbol{I}_{\parallel}$ and θ_0. At −180°C, for instance, $\boldsymbol{I}_s$ calculated from $\boldsymbol{I}_{\parallel}$ and θ_0 is

$$\boldsymbol{I}_s = \boldsymbol{I}_{\parallel}/\cos\theta_0 = 57 \text{ gauss}/\cos(33°) = 68 \text{ gauss},$$

which is in good agreement with the value of 68 Gauss at −180°C in Fig. 11.

The supposed and the observed torque curves, as can be seen in Fig. 2, deviate from each other in the neighbourhood of the maximum torque. These deviations may come from the fact that the model used (Fig. 8 (c) and the dotted curves in Fig. 10) is not adequate in the vicinity of the maximum torque. The appearence of the other small dents in the observed curves is not understood at present. Some orders of asymmetries in the observed curves can not be understood either, although a small order of lower crystal symmetry, as suggested in § 4 (b), may be the origin of the observed phenomenon.

Although any numerical evaluation of $\boldsymbol{K}_1$ and $\boldsymbol{K}_2$ can not be made under the field strengths lower than 10^4 Oe., $\boldsymbol{K}_1+\boldsymbol{K}_2$ will change from a large negative aluev at room temperature into a positive value with decreasing temperature. For the numerical evaluation of the anisotropy energy, a sufficiently strong field such as to bring the crystal into saturation is required. If $\boldsymbol{K}_1$ of the crystal is the same order of magnitude as that of MnBi[6] ($10^6 \sim 10^7$ erg/cm^3), the orders of 10^5 Oe. will be necessary to saturate Fe_7Se_8 with a small value of saturation magnetization of about 70 gauss.

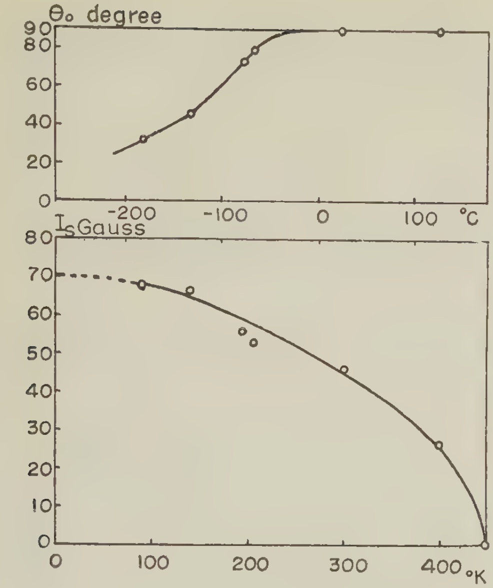

Fig. 11. The direction of easy magnetization and the saturation magnetization I_s in the direction θ_0 as the functions of temperature obtained by taking the observed torque curves in Fig. 2 as the supposed one in Fig. 10 (b).

(ii) *Interpretation of the torque curves in Fig. 3.*

The amplitude of the torque curve in the plane {0001} is proportional to $K_3' \sin^6 \theta$ in Eq. (4). As discussed in the previous case (i), the direction of magnetization θ induced by the weak field (5650 Oe.) is supposed to be nearly in the direction of easy magnetization θ_0. Thus if the change in the direction of easy magnetization takes place abruptly at a definite temperature, the torque amplitude would become zero abruptly at that temperature. The gradual decrement of our torque amplitude towards the lower temperatures (Fig. 3) may mainly depend upon the change of the direction of magnetization θ rather than that of K_3'. Thus the gradual decrement of our torque amplitude in the plane {0001} agrees qualitatively with the fact discussed in the previous case (i).

Pauthenet⁷⁾ has also observed a similar phenomenon on the natural crystal of Fe_7S_8, i.e. the c-axis, which is the direction of difficult magnetization at room temperature, becomes progressively the direction of easy magnetization at lower temperatures. As a change of the direction of easy magnetization commonly takes place suddenly, Néel¹⁾ has pointed out that the origin of the observed phenomenon in Fe_7S_8 may possibly be the local inhomogeneties of the specimen which contains many impurities. We took up, therefore, the measurements again on Fe_7Se_8 of high purity*, but the results was the same as before.

Next, we shall discuss the saturation magnetization of Fe_7Se_8 and Fe_3Se_4. Let us tentatively divide the lattice made of cations into two sublattices⁸⁾ consisting of layers parallel to the c-plane alternatively along the c-axis. One of them contains lattice defects, ferric and ferrous ions, and the other ferrous ions only. By assuming further that the magnetic moments in one sublattice are all antiparallel to those of the other, we obtain the resultant magnetization of Fe_7Se_8 of 69 gauss. This value is in good agreement with the extrapolated value of 70 gauss at 0°K in Fig. 11. Fe_3Se_4 can not be explained by such a model, because the calculated value becomes too large to give the experimental value of 80 gauss.

On the Electronic Structure of the BH Molecule

By Kimio OHNO*

Department of Physics, Faculty of Science,
University of Tokyo, Tokyo

(Received March 20, 1957)

A nonempirical calculation of the electronic structure of the BH molecule based on a simple Heitler-London method is attempted. It is found that the results are in rather poor agreement with experiment and configuration interaction (CI) must be invoked. In the CI calculation we take into account all the configurations in which two electrons are retained in the 1*s* orbital of the boron atom. Thus we get $13\,{}^1\Sigma^+$, $12\,{}^3\Pi$, $11\,{}^1\Pi$, $9\,{}^3\Sigma^-$, $6\,{}^3\Sigma^+$, $6\,{}^1\Delta$, $3\,{}^5\Sigma^-$, $3\,{}^3\Delta$, $3\,{}^1\Sigma^-$ and $1\,{}^5\Pi$ configurations. In constructing the energy matrices, the orthogonalized atomic orbitals are used and we get the eigenvalue and eigenfunction of the lowest energy state of each symmetry by solving the secular equation. The results show marked improvements on those of the single configuration calculation.

A new nonempirical modification, in which intra-atomic energies are evaluated with atomic orbitals whose orbital exponents are adjusted according to an ionicity of the atom, is tried and leads to satisfactory results.

§1. Introduction

About twenty years ago, Stehn[1)] and King[2)] applied the conventional, extremely simplified form of the Heitler-London theory to the energy levels of the molecules BH, CH, NH, OH and FH. The authors made use of the Hamiltonian of the form

$$\mathscr{H}=\sum_{j>i} J_{ij}-\sum_{j>i}\tfrac{1}{2}\langle 1+4\boldsymbol{s}_i\cdot\boldsymbol{s}_j\rangle K_{ij}\,, \quad (1)$$

which is usually derived by neglecting overlaps between atomic orbitals. They determined the Coulomb (J_{ij}) and exchange (K_{ij}) integrals empirically to make the theory fit the known levels and found these values were smooth functions of the atomic numbers. Moreover, the empirically determined values for $K_{\pi h}$ were close to the calculated values. From these facts, Stehn and King concluded that the success of their theory was not entirely due to the fact that they had adjusted parameters to get the best fit.

It now seems clear that one cannot neglect overlaps between atomic orbitals at least in quantitative arguments and so we can hardly justify the Hamiltonian (1) in the usual way. However, it has been used often not only in the theory of molecules but also in the theory of solids. Recently Carr[3)] made an interesting analysis to determine under what conditions, and with what modifications, the Hamiltonian of the form (1) could be used.

It is of some interest, therefore, to choose one simple hydride molecule as an example and carry out a nonempirical calculation in order to compare its results with those of the semiempirical theory so as to get some insight into the validity of the Hamiltonian (1).

Thus we take up the BH molecule here and start from a calculation based on a simple Heitler-London scheme (§2). It is found, however, that the calculated dissociation and excitation energies are in rather poor agreement with experiment and we cannot rely upon the single configuration theory, so we are forced to proceed to a more refined treatment in which configuration interaction (CI) is included (§ 3).

---

* Present address: Department of Chemistry, University College of North Staffordshire, keel, Staffordshire, England.

The results of the CI calculation are much better than those of the single configuration calculation but still give a somewhat unsatisfactory dissociation energy. In view of this, a new modified nonempirical calculation is proposed and applied to the BH molecule (§ 4). The gist of the modified calculation is to use intra-atomic energies evaluated with the atomic orbitals whose orbital exponents are adjusted according to an ionicity of the atom. The results of our calculations are discussed and compared with experiment (§ 5).

§ 2. Single Configuration Calculation

In this section, a simple form of the Heitler-London or the valence-bond method is applied to the four states $^1\Sigma^+, {}^3\Pi, {}^1\Pi, {}^3\Sigma^+$ of the BH molecule, which were considered also by Stehn and King. The simple form means that we take only one electron configuration to represent each state and neglect all other electron configurations including ionic ones. In order to save computational labour, we calculate the energies of all states at the equilibrium internuclear distance, 1.2325 A, of the ground state, that is, the calculated energy differences are the vertical excitation energies.

In almost all quantum mechanical treatments of molecules, the building bricks are atomic orbitals. The following Slater type atomic orbitals are used for the $1s, 2s, 2p\sigma, 2p\pi$ orbitals of the boron atom and the $1s$ orbital of the hydrogen atom respectively:

$$\left.\begin{aligned}
u&=\sqrt{\frac{Z^3}{\pi}}e^{-Zr}\,,\\
s&=\sqrt{\frac{\delta^5}{3\pi}}re^{-\delta r}\,,\\
\sigma&=\sqrt{\frac{\delta^5}{\pi}}r\cos\theta\, e^{-\delta r}\,,\\
\pi_+&=\sqrt{\frac{\delta^5}{2\pi}}r\sin\theta\, e^{i\phi}e^{-\delta r}\,,\\
\pi_-&=\sqrt{\frac{\delta^5}{2\pi}}r\sin\theta\, e^{-i\phi}e^{-\delta r}\,,\\
\text{or}\quad \pi_x&=\sqrt{\frac{\delta^5}{\pi}}r\sin\theta\cos\phi\, e^{-\delta r}\,,\\
\pi_y&=\sqrt{\frac{\delta^5}{\pi}}r\sin\theta\sin\phi e^{-\delta r}\,,\\
h&=\sqrt{\frac{Z'^3}{\pi}}e^{-Z'r}\,.
\end{aligned}\right\}\qquad (2)$$

The polar axis is taken to coincide with the internuclear axis. Throughout this paper the unit of length is the first Bohr radius of the hydrogen atom: $a_0=0.529172\times10^{-8}$ cm[4]; the unit of energy is e^2/a_0: 1 a. u. $=27.20976$ eV[4] unless otherwise noted. These forms of atomic orbitals are chosen because they are most convenient for evaluation of molecular integrals.

In actual construction of molecular wave functions, instead of s, we make use of the orbital v which is orthogonalized to u,

$$v=\frac{1}{\sqrt{1-S^2}}[s-Su]\,,$$

where S is the overlap integral between s and u: $S=\int u(1)s(1)dv_1$. The reason for this is that v is not only expedient for the computation of energy because of its orthogonality to $1s$, but also v can be considered to be nearer to the best atomic $2s$-like orbital function. In fact, Fischer concluded from her calculation on LiH[5] that, if all the electrons of the molecule are represented explicitly in the wave function, the $2s$ orbit must have a node; while if the inner shells are accounted for by suitable screening constants only, the s-orbits of the valence shell should be nodeless.

The values of the orbital exponents Z, δ have to be determined, in principle, to make the total energy of the boron atom a minimum, but are chosen here to be 4.7 and 1.3 respectively as Slater rules indicate. Using these values, we get -666.503 eV as the total energy of boron atom in its ground state, while the more refined treatment of Tubis[6] gives -666.707 eV by varying these parameters. This means we adopt the suggestion made by Fischer that the wisest course consists in choosing the same screening constants as those obtained for the atomic problem.

We assume almost the same type of wave functions as Stehn and King assumed;

$$\left.\begin{aligned}
\varPhi(^1\Sigma^+)&=\frac{1}{\sqrt{6!}}\sum_P(-1)^P Pu(1)\alpha_1u(2)\beta_2l(3)\alpha_3l(4)\beta_4b(5)h(6)\frac{\alpha_5\beta_6-\beta_5\alpha_6}{\sqrt{2}}\\
&=|u\bar{u}l\bar{l}\,[bh]|\,,
\end{aligned}\right.$$

$$\left.\begin{aligned}\varPhi({}^3\Pi)&=\frac{1}{\sqrt{6!}}\sum_P(-1)^P P u(1)\alpha_1 u(2)\beta_2 v(3)\alpha_3 v(4)\beta_4 \pi(5)\alpha_5 h(6)\alpha_6\\&=|u\bar{u}v\bar{v}\pi h|\ ,\\ \varPhi({}^1\Pi)&=\frac{1}{\sqrt{6!}}\sum_P(-1)^P P u(1)\alpha_1 u(2)\beta_2 v(3)\alpha_3 v(4)\beta_4 \pi(5)h(6)\frac{\alpha_5\beta_6-\beta_5\alpha_6}{\sqrt{2}}\\&=|u\bar{u}v\bar{v}[\pi h]|\ ,\\ \varPhi({}^3\Sigma^+)&=\frac{1}{\sqrt{6!}}\sum_P(-1)^P P u(1)\alpha_1 u(2)\beta_2 v(3)\alpha_3 v(4)\beta_4 \sigma(5)\alpha_5 h(6)\alpha_6\\&=|u\bar{u}v\bar{v}\sigma h|\ .\end{aligned}\right\}\quad(3)$$

Here, b and l are the *s-p* hybridized orbitals of the following form,

$$\left.\begin{aligned}b&=\mu v+(1-\mu^2)^{1/2}\sigma\ ,\\ l&=(1-\mu^2)^{1/2}v-\mu\sigma\ .\end{aligned}\right\}\quad(4)$$

The u orbital is included in (3) explicitly because the calculation of Kotani[7] on simple hydride molecules, which treated the 1*s* electrons as point charges coinciding with the nuclei, led to negative binding energies, a result which is very unsatisfactory.

The only difference between the wave functions (3) and those of Stehn and King is that *s-p* hybridization is allowed in $\varPhi({}^1\Sigma^+)$ of (3) in order to get a good single determinant wave function.

The next step is to evaluate the expectation values of the Hamiltonian

$$\mathscr{H}=\sum_{i=1}^{6}\left(-\frac{1}{2}\varDelta-\frac{5}{r_{Bi}}-\frac{1}{r_H}\right)+\sum_{j>i}^{6}\frac{1}{r_{ij}}+\frac{1}{R_{BH}}\qquad(5)$$

with the use of the wave functions (3).

This is carried out for the ground state by three different methods in order to compare their usefulness. The first method is to enumerate all the permutations which make contributions to the expectation values. Although there is only one non-orthogonal orbital h, we have to consider 50 such permutations of 17 different types, so it is not easy to list all the necessary permutations. The second one is to make use of the orthogonalized orbit h' instead of h. h' is defined as

$$h'=\frac{1}{\sqrt{1-S_u^2-S_l^2-S_b^2}}[h-S_u u-S_l l-S_b b]\,,$$

where S_u, S_l, S_b are the overlap integrals between h and u, l, b, respectively.

Then we see

$$\begin{aligned}\varPhi({}^1\Sigma^+)&=|u\bar{u}\,l\,\bar{l}[bh]|\\&=|u\bar{u}\,l\,\bar{l}[bh']|+\sqrt{2}S_b|u\bar{u}\,l\,\bar{l}\,b\bar{b}|\\&=A+\sqrt{2}S_b B\end{aligned}$$

and

$$\begin{aligned}H({}^1\Sigma^+)&=\int\varPhi({}^1\Sigma^+)^*\mathscr{H}\varPhi({}^1\Sigma^+)d\tau\\&=H_{AA}+2\sqrt{2}S_b H_{AB}+2S_b^2H_{BB}\ .\end{aligned}$$

H_{AA}, H_{AB}, H_{BB} can be expressed in terms of molecular integrals more easily because they contain the orthogonal orbits only. The molecular integrals which involve h' can be decomposed into the normal ones; for example

$$\begin{aligned}(bh'|h'b)=(1-S_u^2-S_l^2-S_b^2)^{-1}\{&(bh|hb)\\&+S_u^2(bu|ub)+S_l^2(bl|lb)+S_b^2(bb|bb)\\&-2S_u(bh|ub)-2S_l(bh|lb)-2S_b(bh|bb)\\&+2S_uS_l(bu|lb)+2S_uS_b(bu|bb)\\&+2S_lS_b(bl|bb)\}\ .\end{aligned}$$

Here $(ab|cd)$ is the electron repulsion integral:

$$(ab|cd)=\int a^*(1)b(1)\frac{1}{r_{12}}c^*(2)d(2)dv_1dv_2\ .$$

The second method is compared favourably with the first one because of its simplicity but is still rather cumbersome, since it is necessary to calculate the molecular integrals involving b and/or l for various values of the parameter μ.

In order to avoid this difficulty, the third method was devised. We can transform and decompose the wave functions as follows:

$$\begin{aligned}\varPhi({}^1\Sigma^+)&=\sqrt{1-\mu^2}\,|u\bar{u}v\bar{v}[\sigma h]|+\mu|u\bar{u}\sigma\bar{\sigma}[vh]|\\&=\sqrt{1-\mu^2}\,\varPhi_\alpha+\mu\varPhi_\beta\ ,\\ \varPhi_\alpha&=|u\bar{u}v\bar{v}[\sigma h_0]|+\sqrt{2}S_\sigma|u\bar{u}v\bar{v}\sigma\bar{\sigma}|\\&=\varPhi_a+\sqrt{2}S_\sigma\varPhi_b\ ,\\ \varPhi_\beta&=|u\bar{u}\sigma\bar{\sigma}[vh_0]|+\sqrt{2}S_v|u\bar{u}\sigma\bar{\sigma}v\bar{v}|\\&=\varPhi_c+\sqrt{2}S_v\varPhi_b\ ,\\ H({}^1\Sigma^+)&=(1-\mu^2)H_{\alpha\alpha}+2\mu\sqrt{1-\mu^2}\,H_{\alpha\beta}\\&\quad+\mu^2H_{\rho\beta}\ ,\\ H_{\alpha\alpha}&=H_{aa}+2\sqrt{2}S_\sigma H_{ab}+2S_\sigma^2H_{bb}\ ,\\ H_{\beta\beta}&=H_{cc}+2\sqrt{2}S_vH_{bc}+2S_v^2H_{bb}\ ,\end{aligned}$$

$$H_{\alpha\beta}=H_{ac}+\sqrt{2}\,S_\sigma H_{bc}+\sqrt{2}\,S_v H_{ab}+2S_\sigma S_v H_{bb}\ ,$$

where

$$h_0=\frac{1}{\sqrt{1-S_u{}^2-S_v{}^2-S_\sigma{}^2}}\,[h-S_u u-S_v v-S_\sigma \sigma]\ . \qquad (6)$$

After some manipulation H_{aa}, H_{ab}, H_{bb}, H_{cc}, H_{bc}, and H_{ac} can be expressed as linear combinations of molecular integrals which involve neither b nor l.

We have neglected the *s*-*p* hybridization in the wave functions $\Phi(^3\Pi)$, $\Phi(^1\Pi)$, and $\Phi(^3\Sigma^+)$, so that the energies of these states can be calculated most easily by the second method.

All molecular integrals are evaluated exactly by means of the method developed by Roothaan, Ruedenberg and Jauzemis[8-10]. Details of the computation and the values of integrals are given in Appendix I.

The electronic energy of the $^1\Sigma^+$ state for various values of the hybridization parameter μ is given in Table I and illustrated in Fig. 1. We can see that the effect of *s*-*p* hybridization is rather small. In fact, even for the optimum value of μ^2 (0.060), the energy gain compared with the case of a pure $p\sigma$ bond is only 0.485 ev.

In Table II, the calculated binding and excitation energies are compared with those of the semiempirical theory and experiment[11]. The order of levels is in agreement between two calculations but quantitatively they show very poor agreement. For the $^1\Pi$ state, the semiempirical value is correct undoubtedly, but there are no detinite grounds for trusting the value predicted by the semiempirical theory for the $^3\Pi$ and $^3\Sigma^+$ states. On the other hand, for the nonempirical calculation, a question arises about whether the choice of the wave functions (3) is at all suitable or not. Therefore we try to find another wave functions which seem to have lower energies. The following wave functions are possibilities, since they preserve the σ-h bond although one $2s$ electron is promoted to the $2p\pi$ state:

$$\Phi(^3\Pi)'=|u\bar{u}v\pi\,[\sigma h]|\ ,$$
$$\Phi(^1\Pi)'=|u\bar{u}\,[v\pi]\,[\sigma h]|\ . \qquad (7)$$

The calculation of the energies with the use of these functions is straightforward but again somewhat tedious and details are not given here*.

We find the new $^3\Pi$ and $^1\Pi$ levels to be 2.93 ev and 8.35 eV above the $^1\Sigma^+$ state respectively. Thus the new $^3\Pi$ level is lower than the old one, while the new $^1\Pi$ is higher. If we adhere to the single configuration theory, we had better choose the new wave function to represent the $^3\Pi$ state, and Stehn and King's theory loses ground at least for the $^3\Pi$ state.

Table I. Electronic energy of the $^1\Sigma^+$ state of BH (in eV).

---

* All the results obtained in this section can also be obtained by transforming the energy matrices of the next section into the non-orthogonal basis.

The results of the present nonempirical calculation are very unsatisfactory as there are still marked discrepancies between the theory and experiment in the $^1\Sigma^+-{}^1\Pi$ energy interval and in the dissociation energy.

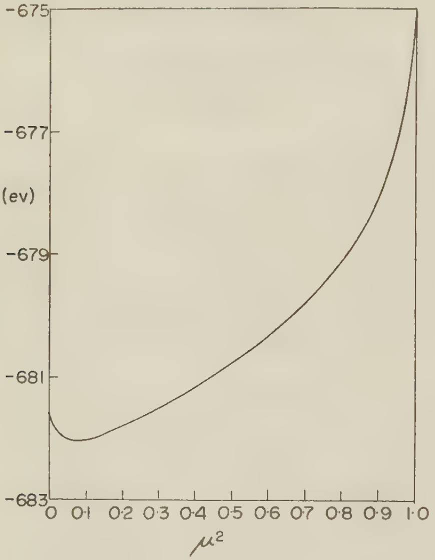

Fig. 1. Electronic energy of the $^1\Sigma^+$ state of the BH molecule.

If we want to improve on these points, we have to make more precise calculation and take account of configuration interaction. In the next section we digress from our primary aim of investigating the basis of the semiempirical single configuration theory and proceed to a many configuration calculation in order to get the most reliable result within the limits imposed by the available computational facilities*.

§ 3. Configuration Interaction Calculation

In this section, we take into account all the configurations in which two electrons are retained in the 1*s* orbital of the born atom. This limitation is imposed in order to reduce the number of configurations. However, from the results of the MO CI study of O_2[12] and the LCAO SCF study of N_2[13] and BH[14], we may suppose it has little influence on the final result.

Thus distributing 4 electrons among the 10 spin orbitals, $v\alpha$, $v\beta$, $\sigma\alpha$, $\sigma\beta$, $\pi_+\alpha$, $\pi_+\beta$, $\pi_-\alpha$, $\pi_-\beta$, (or sometimes $\pi_x\alpha$, $\pi_x\beta$, $\pi_y\alpha$, $\pi_y\beta$) $h\alpha$,

* Spins of two orbitals in square brackets and in parenthesis are coupled to form a singlet and a triplet respectively. Similarly $[(h\sigma)(\pi_x v)]$ (or $((h\sigma)(\pi_x v))$) means that a singlet (triplet) should be made from the two triplet $(h\sigma)$ and $(\pi_x v)$; actually in these cases we should use spin functions

$$\{\alpha\alpha\beta\beta-(\alpha\beta+\beta\alpha)(\alpha\beta+\beta\alpha)/2+\beta\beta\alpha\alpha\}/\sqrt{3}$$

for a singlet and

$$\{\alpha\alpha\alpha\beta+\alpha\alpha\beta\alpha-\alpha\beta\alpha\alpha-\beta\alpha\alpha\alpha\}/2$$

for a triplet.

---

* Actually all the calculations were made using desk machines.

$h\beta$, we obtain 13 $^1\Sigma^+$, 12 $^3\Pi$, 11 $^1\Pi$, 6 $\Delta^3\Sigma^+$ configurations and further 9 $^3\Sigma^-$, 6 $^1\Delta$, 3 $^5\Sigma^-$, 3 $^3\Delta$, 3 $^1\Sigma^-$ and 1 $^5\Pi$ configurations. Summing up the number of independent states, which is the number of configurations times their degeneracy, we get $210={}_{10}C_4$, thus we can see there is no other independent state. These wave functions are explicitly given in Table III. We use π_+ and π_- in Σ and Δ states and π_x and π_y in Π states. This choice makes the energy matrices a little simpler. Throughout this paper π without any suffix can be replaced by any one of π_+, π_-, π_x, and π_y.

In constructing the energy matrices, we make use of the orthogonalized orbital h_0 defined in § 2 (6), instead of h. We need not here transform or reduce the wave functions, all we need to do is replace the orbital h wherever it appears by the orbital h_0. This corresponds to the transformation from the non-orthogonal basic wave functions to the orthogonal ones and the eigenvalue E and the state function Ψ are invariant under such a transformation. If we denote the non-orthogonal and orthogonal basic wave functions by the row vector Φ and Φ_0, the following equations hold:

$$\left.\begin{aligned}(H_0-E)\Gamma_0=(H-EM)\Gamma=0\ ,\\ \Psi=\Phi_0\Gamma_0=\Phi\Gamma\ ,\\ \Gamma_0{}^\dagger\Gamma_0=l\ ,\quad \Gamma^\dagger M\Gamma=l\ ,\\ \Phi_0=\Phi T,\quad \Phi=\Phi_0 S\ ,\\ H=S^\dagger H_0 S\ ,\\ M=S^\dagger S\ .\end{aligned}\right\}\qquad(8)$$

By this replacement, we can make the CI calculation very much easier, in fact it seems to be almost impossible to set up many energy matrices by using non-orthogonal orbits. calculation of the matrix elements of the energy matrices H_0 are straightforward. The results are available in mimeographed form and will be sent on request to those interested in this problem.

Solving the secular equation of each symmetry by the iteration method, we can get its lowest eigenvalue and the corresponding eigenfunction.

The results will be discussed in § 5, together with those of the modified treatment which will be explained in the next section.

§ 4. Modified CI Calculation with an Intra-Atomic Correction

The importance of a correct estimate of intra-atomic energy in the molecular energy calculation was pointed out by Moffitt, who, has developed the method of atoms in molecules (AIM)$^{15)}$ from his experience of the calculation on the oxygen molecule. He recommended the use of the Hamiltonian

$$H(\mathrm{AIM})=H+\tfrac{1}{2}[M(W_e-W)+(W_e-W)M]\ ,\qquad(9)$$

where H and M are the usual energy and overlap matrix, W is an asymptotic form of H for large nuclear separations, and W_e is also a diagonal matrix formed from the energy of dissociation products in their valence states estimated by an appeal to the spectroscopic atomic term values.

For large nuclear separations, H tends to W and M tends to unity, and therefore H (AIM) tends to W_e. Thus use of the Hamiltonian (9) separates the whole energy into that of atoms and interactions between them and replaces the atomic energy W by the corresponding empirical value W_e: in effect, only the interactions are calculated from the usual wave function. Applying this method to the π-electron states of oxygen, ethylene, cyclobutadiene and benzene, Moffitt and Scanlan$^{15-16)}$ obtained much better agreement with experiment than in the case of the usual ASMO method. On the other hand, it must be noted that, in their application to the excitation energies of Li_2 and the ground state energy of H_2, Rahman$^{17)}$ and Hurley$^{18)}$ did not get reasonable results.

Recently Hurley$^{19)}$ and Arai$^{20)}$ criticized Moffitt's method and proposed the method of intra-atomic correlation correction and the method of deformed atoms in molecules respectively.

All these methods have a semiempirical character as they make use of the experimental term values. In an earlier paper, Itoh and the author$^{21)}$ proposed a modification of the nonempirical atomic orbital method, in which the use of different atomic orbitals for covalent and ionic structure of molecules is suggested in order to assess more correctly the energies of ionic structures. We applied this modified form to the lower excitation energies of $C_2H_4$$^{21)}$ and $O_2$$^{22)}$ with considerable success. In this section we try another modification within the scope of nonempirical calculation, namely the use of the Hamiltonian of the following form:

$$H(\text{modified})=H+\tfrac{1}{2}[M(W'-W)+(W-W)M], \tag{10}$$

where W' is a diagonal matrix formed from the energy of dissociation products in their valence states calculated with the use of different orbital exponents in atomic orbitals for polar and homopolar states. The purpose of using the Hamiltonian (10) is to replace the energy of the intra-atomic part by the more precise estimates W'. Thus applying this modification, we follow the general idea of Moffitt and are able to introduce it into the nonempirical theory.

In actual calculation, it is convenient to represent the Hamiltonian (10) in the orthogonal basis Φ_0;

$$H_0(\text{modified}) =H_0+\tfrac{1}{2}[S(W'-W)T+\{S(W'-W)T\}^{\dagger}]\,, \tag{11}$$

where $\{S(W'-W)T\}^{\dagger}$ is the Hermitian conjugate of $S(W'-W)T$. In calculating W', we use the same values of the orbital exponents for all states of a given atom with the same ionicity and determine these values from Slater rules. Accordingly, we take, for the BH molecule,

$$\delta^-=1.125, \quad \delta^+=1.475, \quad Z'^-=0.7,$$

while Z is considered to be unchanged.

Comparing this modification with our previous modified AO method, we may say the merits of the present modification are the simplicity of calculation and the circumvention of somewhat arbitrary approximations in calculating the complicated heteropolar integrals. On the other hand, the present modification has something dubious in its nature, because the calculated energy is not gained as an expectation value of the original Hamiltonian (5) with a given wave function. Therefore, the calculated energy may go below the true value in this treatment while this cannot occur with the previous method.

The present modification aims to assess properly the relative locations of covalent and ionic structures, but we can see from the result of the CI calculation that the state functions are essentially of covalent character for almost all levels of BH. Therefore we cannot expect a much improved result by this modification in BH. Nevertheless, we performed numerical calculations in order to see what it turns out to be. The necessary integrals are given in Appendix II and the resulting energy levels are illustrated in Figs. 2 and 3, with those of the preceding section. In Fig. 2, the zero of energy is shifted to −683.248 eV, which is the total energy of BH in its ground state calculated by the CI method. In Fig. 2 and Fig. 3 the energy of the lowest configuration of each symmetry is shown under the column (a).

§ 5. Discussion of Results

Carrying out nonempirical calculation based on the assignment of electron wave functions by Stehn and King, we found that assignment was not necessarily suitable. Therefore, we can say the basis of their semiempirical theory is open to question. In addition, the predicted value of the $^3\Sigma^+$ state by the theory seems to be too low, as is seen from the comparison with the results of these more detailed calculation.

From Table V, we see that by including configuration interaction the agreement with experiment is much improved as to the excitation energies but still rather unsatisfactory as to the dissociation energy and the $^1\Sigma^{+\prime}-{}^1\Pi$ separation. With the intra-atomic correction the calculated dissociation energy becomes very close to the observed value but the $^1\Sigma^{+\prime}-{}^1\Pi$ separation shows only a little improvement.

When the s–p hybridization is allowed, the single configuration calculation gave −682.042 eV as the total energy of the molecule, the figure already compares favourably with Sahni's LCAO SCF value −681.899 eV* and we get −683.248 eV by the CI calculation. On the other hand, the single configuration $(1s)^2(2s)^2(2p)$ P' of the boron atom gives -666.497 eV as its energy, while by the inclusion of the configuration $(1s)^2(2p)^3$ ^2P, the energy becomes −667.426 eV. Therefore, the calculated dissociation or binding energy increases only by 0.762 eV** when CI is applied consistently, i.e. to atom and molecule alike.

With the intra-atomic energy correction, the energy of the molecule goes down 1.075 eV further and the energy of the separated atoms remains unchanged, so that the resulting gain of dissociation energy, 1.075 eV, makes the agreement with experiment much better as was mentioned above.

Table V. Dissociation and excitation energies of the BH molecule (in eV)

c. The CI calculation with the intra-atomic correction.
d. See reference 11. As for the total energy of the boron atom, see Atomic Energy Levels (the United State Department of Commerce, National Bureau of Standards, 1949) p 16.
e. $^1\Sigma^{+\prime}$ means the second lowest state among 13 $^1\Sigma^+$ eigenfunctions.

The electronic level scheme illustrated in Figs. 2 and 3 shows also there are marked differences between the results of the single configuration and the CI calculation, for example, the location of $^3\Pi$, the order of $^1\Pi$ and $^3\Sigma^-$ but small differences between those of CI and the modified CI except for the order of $^1\Sigma^-$ and $^5\Pi$. We can seen from Tables III and IV that the state function $^1\Sigma^-$ has a large contribution from ionic structure, while $^5\Pi$ is of purely covalent character, so that the reversal of the order of these two levels is not unreasonable.

Next we will try to interprete the coefficient of each state function given in Table IV. This is more easily done in the case of the non-orthogonal representation, because we can make use of our chemical intuition. Let us take the ground state $^1\Sigma^+$ for example. Configuration 4 was taken in the single configuration calculation (§ 2) and is the most important. Configuration 12 is the only one which interacts with 4 in the atomic problem and the coefficient of which is the second largest. The coefficient of 5 is the third largest and this represents the degree of *s–p* hybridization whose amount is about the same as was found in § 2. The coefficient of 2 is the fourth largest and represents the contribution of the ionic structure B $(1s)^2(2s)^2$+H $(1s)^2$. Comparing the coefficients in the column (b) and (d) in Table IV, however, we can see clearly that the coefficient in the non-orthogonal representation are very unstable with respect to the intra-atomic correction. Judging from the change of (a) and (c), we know that the difference of the direction of the vector Ψ in Hilbert space is not so large, but it looks large in the non-orthogonal representation, because the basis vectors are not mutually orthogonal. Another point in favour of the orthogonal representation is that the simple relation $\Gamma_0{}^*\Gamma_0=\sum_i c_i{}^2=1$ holds in this representation and this makes the importance of each configuration very clear.

---

* This is slightly different from the original value given in reference 14, as the conversion factor from the atmic unit to eV used in this paper is not the same as one used by Sahni.

** Relative to the $vv\,[\sigma h]$ ground state. This increase is 0.277 eV relative to the single configuration with hybridization.

Calculated dissociation energies of some simple molecules are given in Table VI, from which we can see evidence of a very difficult situation arising in this type of nonempirical molecular calculation: the dissociation energy is the difference between two large figures, and the errors of our calculation are of the same order as the binding energy. Consequently the much more refined treatments do not necessarily show greatly improved results.

Table VI. Dissociation energy of some simple molecules (in eV)

Method / Molecule	S.S.[a] AO	S.S.[a] MO	LCAO SCF MO	CI[b] AO	CI[b] AO	CI[b] MO	CI[b] MO	obs.

Acknowledgements

The author would like to express his hearty thanks to Dr. T. Itoh, with whom the work was originally begun and who kindly checked almost all the formulae used in this paper. He is very grateful to Prof. M. Kotani for his valuable discussions and continual encouragement throughout this work. He also wishes to thank members of Kotani Laboratory for their discussions and economical help, Prof. K. Kambe, Dr. R. McWeeny and Mr. J. Eve for reading the manuscript and

making valuable comments. He is indebted greatly to Mrs. H. Komuro and Miss K. Murata for their help in numerical calculations.

Appendix I. Evaluation of Moleculars Integral

The atomic orbital functions used in the calculation were given in § 2, (2). We take, for the sake of computational convenience, the following values for parameter ZR, δR, $Z'R$

$$ZR=10.95\ ,\quad \delta R=3.03\ ,$$
$$Z'R=2.33\ .$$

As all integrals are calculated at the equilibrium internuclear distance for the ground state:

$$R=1.2325\ \mathrm{A}$$
$$=2.329114785\ \mathrm{a.u.}^{11)}\ ,$$

the above choice of parameters means we choose the orbital exponents

$$Z=4.701356958\ ,$$
$$\delta=1.300923432\ ,$$
$$Z'=1.00038006\bar{5}\ .$$

One electron, one centre and Coulomb integrals are evaluated using the formulae of Roothaan[8], to seven decimal places.

Exchange integrals are calculated by the formulae, of Ruedenberg[9]. Taking 5 or 6 terms in the expansion, we can get the value accurate to six decimal places. The convergence is slow for the integrals containing the u orbital.

For the computation of hybrid integrals, we find Ruedenberg and others' formulae, especially those given in the unabridged paper in the Technical Report of the Chicago group, are very convenient. This type of integral is also calculated accurately to seven decimal places.

The numerical values obtain-

ed are compared with the values of Sahni[14] who calculated almost all the integrals used here, except for those involving the π orbital, at the same R but took $Z=4.7$, $\delta=1.3$, $Z'=1$. The agreement is generally quite satisfactory but for the five hybrid integrals, $(u\sigma|uh)$, $(u\sigma|\sigma h)$, $(u\sigma|sh)$, $(s\sigma|uh)$ and $(\sigma\sigma|uh)$, we could not get reasonable agreement. These five are common in that they involve a factor $\sigma(1)h(2)$ and at least one u orbital. We therefore took as an example $(u\sigma|sh)$ and calculated this using Barnett and Coulson's formulae[23], getting a result identical with the previous value to 10 decimal places. It seems to us, therefore, that there may be a systematic error in Sahni's evaluation of this type of hybrid integral.

Our values are also compared with those, when available, interpolated from the table of Kotani and others[24], they coinside to three decimal places. Computed numerical values are given in Table AI.

Appendix II. Atomic Integrals for the Positive and Negative Ions of Boron

The orbital exponents

$$\delta^-=1.124890889$$

$$\delta^+=1.474809237$$

are used for the negative and positive ions of boron so as to make the parameters δ^-R and δ^+R round numbers for the equilibrium internuclear distance of the ground state:

$$\delta^-R=2.62\ ,\quad \delta^+R=3.435\ .$$

As we need only the integrals of atomic nature, the evaluation is very simple and the numerical values are given in Table AII,

where the one electron operator

$$F'=-\frac{1}{2}\Delta-\frac{5}{r_B}$$

is used.

On Some Transition Phenomena in Aqueous Solution of Polyvinylalcohol

By Teruko SOEYA and Ryusuke KŌNO

Department of Applied Physics, Defence Academy

(Received April 6, 1957)

In order to obtain an information about the configurational state of molecule in an aqueous solution of P.V.A., the measurements of the specific volume, the ultrasonic velocity and the dielectric constant were carried out over a certain range of the concentration and the temperature, and the experimental result was discussed from a view point of transition phenomena.

The result seems to show that in a region of concentration higher than a certain critical value (C_m) the configurational state of molecule in the solution is similar to that in solid P.V.A. plasticized by a solvent type plasticizer possessing no transition point, while in the region of concentration lower than C_m, only above a certain critical temperature T_β, a model of spherical coiled molecule is applicable. The heat of cross-linking estimated experimentally by making use of Eldridge and Ferry's formula with respect to an apparent melting temperature of gel is about 12 k.cal./mol.

§1. Introduction

At present, it is allowed to consider that[1] the configurational states of long chain polymer molecules in the solution take two different types depending on the concentration of high polymer, that is to say: in a very dilute solution, each molecule coils independently and behaves as if a small isolated particle in a suspension, while in the case of relatively large concentration, the molecules form a loose irregular network structure by random cross-linking of each other. On the other hand, these configurational shapes of molecules are also affected by temperature changes. Accordingly, the changes in the configurational state of molecules will probably be detected in the concentration and temperature dependences of various physical properties of the solution through the changes of segmental motion.

From such a view point, the measurements of the specific volume, the ultrasonic velocity and the dielectric constant of the solution were carried out over a certain range of the concentration and the temperature.

The results of the experiment are regarded to show that if the concentration is higher than a certain critical value (C_m), in the solution there also takes place the change of segmental motion similar to the one which occurs at the second order transition point of solid P.V.A. plasticized by a solvent type plasticizer and there exist not only the critical concentration (C_m) but also the critical temperature (T_β) to the validity of the model of suspending coiled molecules. That is to say: if temperature is lower than T_β, even in the case of concentration lower than C_m, the weak inter-molecular cross-linkings exist between the segments belonging to different molecules, and the solution rather takes a network structure. Furthermore, in this paper, heat of cross-linking was estimated experimentally.

§ 2. Method of Experiment

The density of the solution was measured by a pycnometer. For the measurement of the ultrasonic velocity, the method of acoustic interferometer of Hubbard type[2)] was used. The frequency of the ultrasonic waves was 1000 k.c./sec. The measurement of the dielectric constant was carried out by means of the exchange method using a quartz oscillator. The used specimens were the aqueous solutions of P.V.A. (the average value of the degree of polymerization was about 4550).

§ 3. Experimental Results

(1) *Specific volume*

The specific volume (v) obtained from the density measurements of the solution is plotted against temperature as shown in Fig. 1. These curves have a look of the typical volume-temperature curve which is obtained in the experiment for the second order transition phenomena of high polymers in solid state. Each curve consists of two straight line portions connected by a curved part. Now, if we denote the temperature corresponding to the point of intersection of two straight lines by T_v, T_v increases linearly with the concentration of P.V.A. as shown in Fig. 2.

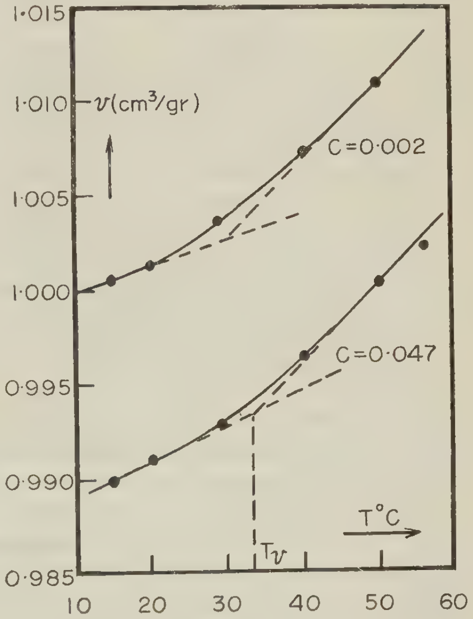

Fig. 1. Typical relations between specific volume and temperature.

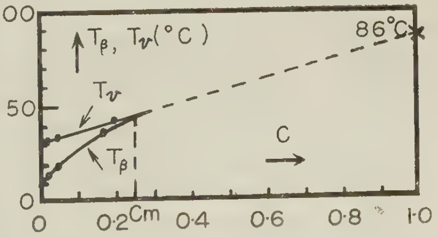

Fig. 2. Concentration dependence of T_β and T_v.

(2) *Ultrasonic velocity*

In Fig. 3, the ultrasonic velocity (V) and the adiabatic compressibility (β), which is obtained from $V=\sqrt{1/\rho\beta}$ using the experimental data of V and ρ (density), are plotted as the functions of temperature. As it will be seen from Fig. 3, there appears a certain anomalous range of temperature where the variation of V or β for temperature is especially distinguished. Now, let us denote the temperature at the middle point of the above anomalous range by T_β. In that case, as shown in Fig. 2, T_β depends upon the concentration of P.V.A. and the curve of $(T_\beta - C)$ relation coincides with the line of $(T_v - C)$ at the concentration about $C=0.25$.

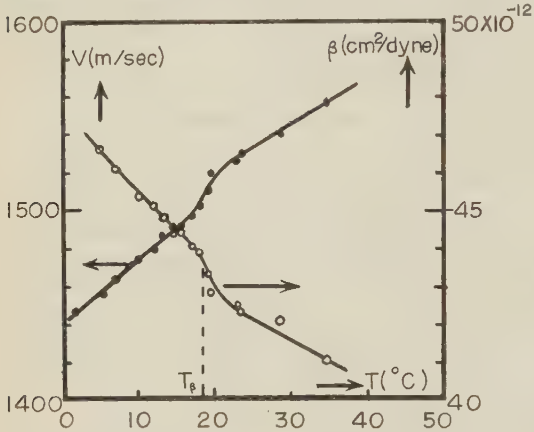

Fig. 3. Temperature dependence of ultrasonic velocity and adiabatic compressibility.

(3) *Dielectric constant*

The relations between the dielectric constant (ε) and temperature are shown in Fig. 4 and Fig. 5. Each curve in Fig. 4 has an obvious flexion point at a certain temperature. Now if we denote the temperature corresponding to the flexion point by T_ε, $T_\varepsilon = T_\beta$ is approximately satisfied. As shown in Fig. 5, however, the flexion point becomes indistinct with decreasing of frequency and seems to disappear almost entirely in the case of frequency 364 k.c./sec.

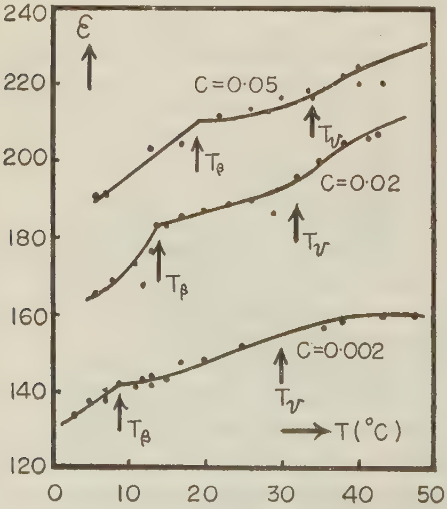

Fig. 4. Temperature dependence of dielectric constant. Frequency=1000 *k.c./sec.*

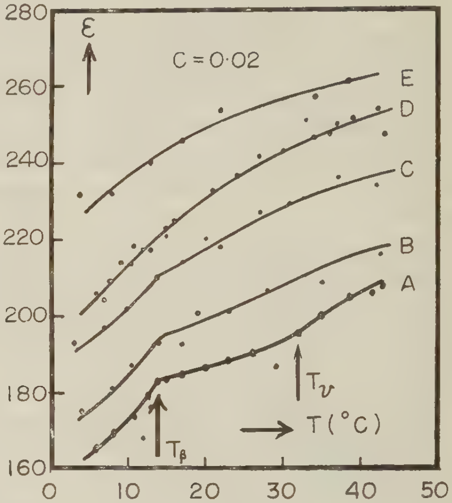

Fig. 5. Temperature dependence of dielectric constant. Concentration of P.V.A.=0.02. Curve A (1000 *k.c./sec*), B (700 *k.c./sec*), C (600 *k.c./sce*), D (364 *k.c./sec*), E (150 *k.c./sec*).

§4. Discussion of Results

As already described, T_β and T_v depend upon the concentration. Now, if the experimental curves $(T_\beta - C)$ and $(T_v - C)$ are extended to $C=1$, they coincide with each other at about $C=0.25$ and intersect the ordinate of $C=1$ at $T_\beta = T_v = 86°\text{C}$. This roughly extrapolated value $(T_\beta = T_v = 86°\text{C})$ is considered to be fairly close to the second order transition temperature[3] of pure solid P.V.A. (=85°C). This fact seems to suggest that the phenomena characterized by T_β or T_v may probably be caused by the molecular process which is similar to that of ordinary second order transition of solid P.V.A.

On the other hand, as it has been already known, the second order transition temperature of high polymer is much affected by the addition of the plasticizer and especially, if the solvent type plasticizer possessing no transition point is added, the second order transition temperature becomes lower. Accordingly, it seems to be reasonable to consider that in our solution water probably plays the same role as the solvent type plasticizer.

Next, in Fig. 1, we write as follows;

$$\Delta\gamma = \left(\frac{\Delta v}{\Delta T}\right)_{T>T_v} - \left(\frac{\Delta v}{\Delta T}\right)_{T<T_v} .$$

Then, the value of $\Delta\gamma$ obtained in this experiment is shown by solid curve in Fig. 6.

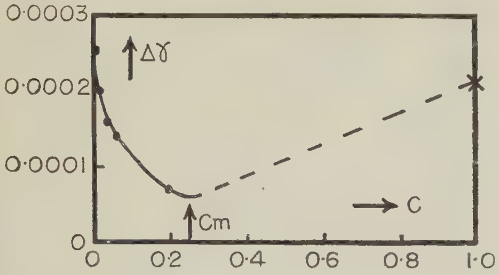

Fig. 6. Relation between $\Delta\gamma$ and concentration. Solid curve: experimental.

So far as concerns the concentration used in this experiment, $\Delta\gamma$ decreases with increasing concentration of P.V.A.. The value of $\Delta\gamma$ for the pure solid P.V.A., however, is in the neighbourhood of 0.0002. Consequently, it is natural to consider that the solid curve in Fig. 6 will rise for further increasing of C through a minimum point and approach to the corresponding value of solid P.V.A. at $C=1$ (dotted line in Fig. 6). In regard to this problem, it has been already found experimentally that[4] $\Delta\gamma$ for the molecular mixture of high polymer and solvent type plasticizer possessing no transition point approaches zero linearly with the amount of plasticizer added. On the other hand, our experimental result shows that, in the case of concentration lower than C_m $(=0.25)$, two anomalous points (T_β and T_v) are observed but in the case of concentration higher than C_m, one anomalous point only observed ($T_\beta=T_v$). These facts seem to support a presumption that in the region of concentration higher than C_m the aqueous solution of P.V.A. has a structure, as it were, of the molecular mixture of long chain polymer and solvent type plasticizer possessing no transition point. In consequence, the change of segmental motion at T_v $(=T_\beta)$ would probably be the same kind with that of the second order transition of solid P.V.A. plasticized by solvent type plasticizer.

In the next place, we describe with phenomena in the region of concentration lower than C_m $(=0.25)$. In this case, it is expected that the changes of segmental motion at T_β and T_v will be reflected sensitively in the dielectric properties of the solution because P.V.A. is polar polymer. Actually, the curves of $(\varepsilon-T)$ relation indicate the anomalies at T_β and T_v as shown in Figs. 4 and 5. In this case, if we make a presumption that even in the case of concentration lower than C_m if $T<T_\beta$, the solution has a network structure (i.e., so-called gel structure), we can interpret the result shown in Figs. 4 and 5 as follows. If temperature rises and approaches to T_β, the liberations of inter-molecular cross-linkings between the segments belonging to different polymer molecules would begin to take place and at the temperature T_β almost all inter-molecular cross-linkings would be liberated. As the result of this liberation each molecule would coil up independently to be regarded as a small spherical particle. This coiling up of molecules would bring on an increase of the number of intra-molecular cross-linkings and as a matter of course, the segmental motion would rather be suppressed to some extent. That is to say: as the result of the change in the configurational state of molecules at T_g $(=T_\beta)$, the activation energy for the segmental rotation would increase, and this means the increase of a relaxation time for the segmental rotation.

In regard to this problem, it was experimentally confirmed that while there is a distinct flexion point in the case of frequency $=1000$ k.c./sec, the flexion point becomes gradually indistinct with decreasing of frequency and disappears almost entirely in the case of frequency $=364$ k.c./sec. This experimental fact seems to allow to estimate the relaxation time (τ) for the segmental rotation as follows; i.e., in the region $T_\beta<T<T_v$, τ is in the neighbourhood of 2×10^{-6} sec, while in the region $T<T_\beta$, $\tau<10^{6}$ sec. Furthermore, if temperature rises beyond T_v, then in each coiled molecule, the liberation of the intra-molecular cross-linkings would take place and the hindered rotation of segments would again become active. This would cause the relatively rapid increase of ε at about T_v.

On the other hand, with respect to the relation between the apparent melting temperature of gel and the concentration, the following formula has been derived theoretically by Eldridge and Ferry[5]

$$\log C=\frac{\Delta H}{RT_m}+\text{constant}$$

where ΔH is heat of cross-linking. Making use of our experimental data, $\log_{10}C$ was plotted against $1/2.303RT_\beta$ as shown in Fig. 7

and from the linear part of the relation ΔH was estimated. The obtained value of ΔH is about 12 k.cal./mol. This value of ΔH is roughly close to the value obtained by Kawai[6] and co-workers. This fact is considered to support our previous presumption that even $C < C_m$, if $T < T_\beta$, the solution takes the network structure (gel structure).

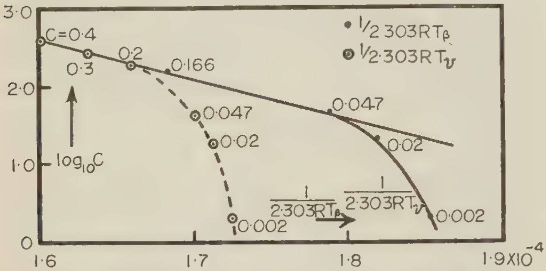

Fig. 7. Relation between $\log_{10} C$ and $1/2.303\,RT_\beta$ or $1/2.303\,RT_v$.

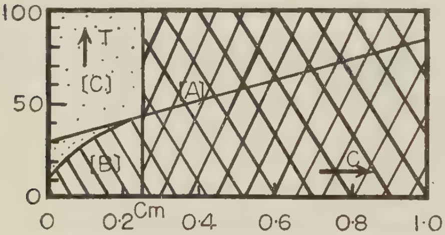

Fig. 8. Diagram illustrating the configurational state of molecules in aqueous solution of P.V.A.

Finally, we can summarize briefly the consequences of this experiment as follows.

(*1*) A diagram with respect to the configurational state of molecules in the aqueous solution of P.V.A. is obtained as shown in Fig. 8. In this temperature-concentration diagram, [*A*] represents the domain where the solution takes the irregular network structure which will be similar to that of solid P.V.A. plasticized by the solvent type plasticizer possessing no transition point, [***B***] represents the domain of network structure (i.e., so-called thermal recovery gel) and [*C*] represents the domain where the model of spherical coiled molecule is applicable.

(*2*) In the domain [*A*], for temperature variation, the change of molecular motion takes place only once at T_v $(=T_\beta)$. This is considered to take place in like manner with the second order transition of solid P.V.A. plasticized by the solvent type plasticizer possessing no transition point. On the contrary, in the region of concentration $C < C_m$, the changes of molecular motion occur twice at T_β and T_v. The one at T_β would be ascribed to the separation of inter-molecular cross-linkings and T_β is considered to represent the melting temperature of gel, while the another at T_v would be related with the separation of intra-molecular cross-linkings in the coiled molecules. This molecular process in each coiled molecule would also occur in like manner with the second order transition.

(*3*) Eldridge and Ferry's formula on the apparent melting temperature of gel is approximately satisfied in the range of concentration from $C=0.047$ to $C=0.4$. The obtained value of ΔH is about 12 k.cal./mol.

In conclusion, we wish to express our sincere thanks to Prof. Y. Ikeda for his continuous encouragement throughout this work.

On the Magnetic Aging of Commercial Pure Iron

By Mitsuru ASANUMA
Department of Physics, Faculty of Science, University of Hokkaido
and Shinji OGAWA
Research Institute of Applied Electricity, University of Hokkaido

(Received April 10, 1957)

The origin of magnetic aging in commercial pure iron is clarified by means of magnetic initial susceptibility and internal friction. It is due to very small amounts of carbon and nitrogen in iron, and the effect of nitrogen is more remarkable than that of carbon and it is dominant especially in the period of formation of intermediate nitride. Some possiblities that the different effect of nitrogen and carbon can be interpreted are suggested.

§ 1. Introduction

It has been known that the magnetic initial susceptibility of commercial pure iron decreases remarkably on tempering in the vicinity of 130°C, but the origin has not yet been clarified.

In the past Y. Shimizu[1] explained that small amounts of sulphur in iron was responsible for the decrease. According to him, sulphur has little solubility to iron, and forms the inclusion of iron-sulphide, therefore, when iron is heated up to about 130°C, the lattice parameter in C axis of FeS varies and this might cause the decrease of magnetic initial susceptibility. Moreover he concluded that this decrease was hindered by quenching.

However his explanation is unsuitable, because the transformation of lattice parameter in FeS is of the second kind, and is not generally hindered by quenching. In his experiment, he added FeS to pure iron and measured the thermal expansion and magnetic initial susceptibility in each step of rising the temperature to 130°C. But his experiment does not provide a direct proof about its origin, because it may be natural that the specimen which contains much FeS than commercial pure iron shows the decrease of magnetic initial susceptibility, and it does not provide any proof on the assertion that in pure iron FeS is main cause of the decrease of the susceptibility.

Then one must study in the new view point about this problem. The commercial pure iron contains always very small amounts of carbon and nitrogen in interstitial position of iron crystal. The precipitation of carbon and nitrogen from solid solution is accompanied by change in many physical properties. The effects of the precipitation of carbon and nitrogen in α-iron on physical properties, for example, elastic after effect, magnetic after effect, etc. were investigated by Snoek[2]. The change in coercive force during aging was also measured by Köster[3] in order to investigate the kinetics of precipitation. The same measurement was also made by Wert[4]. The structure sensitive magnetic properties, for example, the coercive force and the initial susceptibility may depend on the particle size or the shape of precipitates. The investigation along this problem was partly investigated by Néel[5].

In order to discuss the decrease of magnetic initial susceptibility or coercive force of these alloys during aging, the knowledge of the structure of the produced precipitates is necessary. Dijkstra[6] has demonstrated that the aging of N_2 in α-iron takes place by two stage process: metastable precipitation are first formed, then they dissolve and reprecipitate as Fe_4N. Jack[7] has shown the metastable precipitates to be $Fe_{16}N_2$.

In the investigation of the precipitation of carbon and nitrogen from solid solution, Wert[8] has pointed out that the volume of precipitates is proportional to $t^{3/2}$, $t^{5/2}$ and $t^{1/2}$, where t is aging time, for sphere-, diske- and cylinder-like shape, respectively. He also showed that the intermediate phase $Fe_{16}N_2$ is of the disk-like shape and Fe_3C is of the sphere-like shape.

The effect of the carbide or the nitride itself on the magnetic aging, however, has not yet been investigated in detail.

In the present paper the origin of the aging of magnetic, initial susceptibility will be clarified and the difference of the effect on aging between nitride and carbide will be discussed.

§ 2. Experimental Details

The iron which was supplied by Research Institute of the Mitsubishi Minning Co. Ltd. was used as specimen. The amounts of carbon and nitrogen in solid solution was determined by the measurement of internal friction and sulphur contents of specimen was determined by chemical analysis. The apparatus for measuring the internal friction was well known torsion pendulum, and the frequency used was about 1.0 c.p.s. The background damping Q^{-1} of the pendulum was 0.001. The strain on the surface of specimen at maximum deflection was 4×10^{-5}. The size of specimen was 1.0 mm in diameter and 300 mm in length. The magnetic initial susceptibility was measured by balistic galvanometer.

In order to separate the effect of carbon and nitrogen on the magnetic aging, the specimens were first purified by heating in a wet hydrogen atmosphere at 720°C for several hours and then carbon or nitrogen was separately dissolved into the specimens.

The carbon was dissolved into the purified specimens by heating at appropriate temperature in the mixing gases of carbon dioxide and monoxide, and nitrogen was added to the specimens by heating in the mixture of hydrogen and ammonia gases.

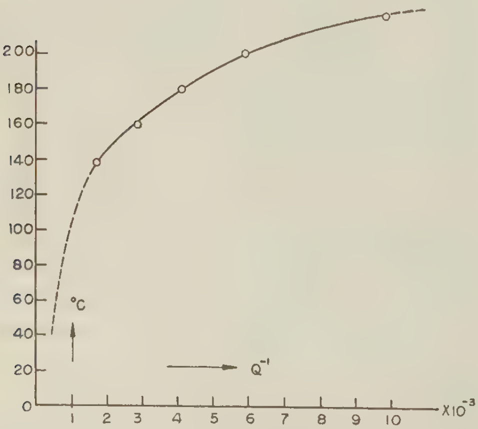

Fig. 1. The phase diagram of *Fe–N* system.

The phase diagram of Fe-N system was determined in our specimens by internal friction, although this had been investigated by Dijkstra[9] and Paranjpe[10]. This result was shown in Fig. 1.

§ 3. Experimental Results and Discussions

The specimens of the commercial pure iron which contain the amount of nitrogen corresponding to $Q^{-1}=0.0037$, less carbon and 0.003 wt % sulphur were annealed at 950°C for an hour and cooled down in the furnace to 750°C and then quenched in water. Thereafter the magnetic initial susceptibilities were measured for these specimens at every 10°C from 80°C to 200°C in the course of tempering. These results were shown in Figs. 2 and 3.

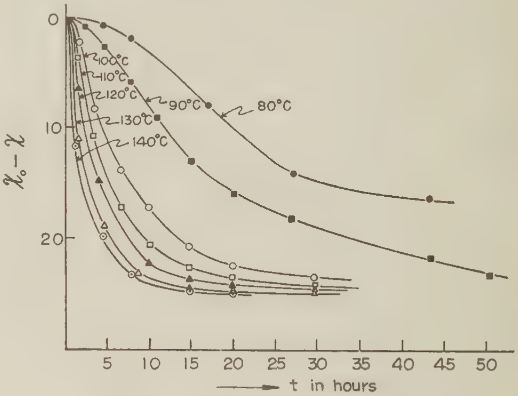

Fig. 2. The decrease of magnetic initial susceptibility *vs* tempering time.

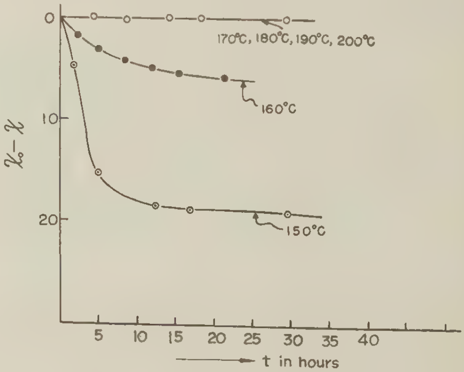

Fig. 3. The decrease of magnetic initial susceptibility *vs* tempering time.

The effect of the tempering on the magnetic initial susceptibility was most remarkable at 140°C, while it was not found above 170°C. In the specimen which was annealed in a wet hydrogen atmosphere to remove the impurities, the decrease of magnetic initial susceptibility was not observed during the tempering at 140°C where the magnetic aging would be the most effective. Fig. 4 (a) shows this result.

The specimen before and after hydrogen treatment contains 0.003 wt % and 0.002 wt % sulphur, respectively, which shows that the sulphur contents of this specimen was hardly changed. These facts mean that the small amounts of sulphur are not responsible for the decrease of magnetic initial susceptibility. Therefore, the interstitial impurities such as carbon and nitrogen is considered to be the possible origin.

In Fig. 1, the temperature corresponding the value $Q^{-1}=0.0037$ is about 170°C, and it seems that the interstitial impurity, nitrogen does not precipitate from the matrix above this temperature. On the basis of this fact, together with the facts that are showed in Figs. 2 and 3, it may be concluded that the magnetic aging of commercial pure iron is accompanied by the precipitation of carbide and nitride from solid solution, or segregation of carbon and nitrogen.

In order to investigate the effect of carbon separately, the initial susceptibilities of carbrized specimen was measured in the course of aging treatment at 140°C. This result is shown in Fig. 4 (b), where carbon contents correspond to $Q^{-1}=0.0022$. Fig. 4 (c) shows the result of nitride specimen, where nitrogen contents correspond to $Q^{-1}=0.0060$.

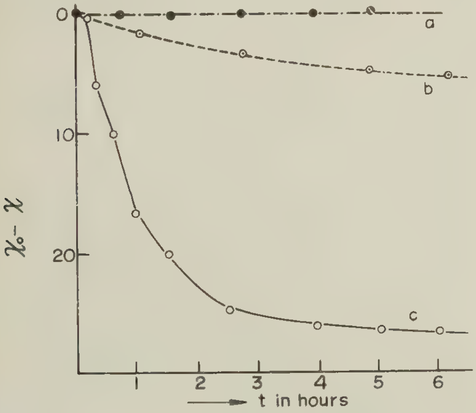

Fig. 4. The decrease of magnetic initial susceptibility *vs* tempering time.
a: the specimen after hydrogen treatment
b: the specimen to which was added the carbon after hydrogen treatment
c: the specimen to which was added the nitrogen after hydrogen treatment
Aging temperatures are 140°C.

According to Pitch and Lücke[11], carbon contents corresponding to $Q^{-1}=0.0033$ is about 0.005 wt % and according to Åstrom and Borelius[12] the Q^{-1} value of damping by nitrogen in α-iron is nearly equal to the contents of nitrogen in α-iron in weight per cent, in the region of small amounts of nitrogen. Therefore, in our both specimens carbon contents and nitrogen contents are considered to be 0.005 wt % and 0.006 wt % respectively. In Fig. 4, it is shown that the magnetic againg of nitrided specimen is more remarkable than that of carbrized specimen, although they have nearly the same amount of impurity. In other word, the effect of nitrogen on magnetic aging is more remarkable than that of carbon.

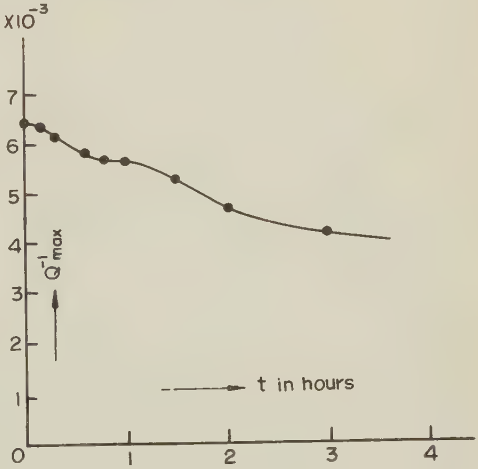

Fig. 5. International friction during precipitation of nitrogen at 140°C.

On the other hand, the aging of nitrided specimen was investigated at 140°C by means of internal friction method as shown in Fig. 5. It is noticed that the precipitation from supersaturated solid solution takes place according to different successive process. This result agrees with that of Dijkstra[6]. Fig. 6 is the curve of transformed fraction vs. growth time obtained from Fig. 5. The transformed fraction q is represented in terms of Q^{-1} as follows:

$$q=(Q_0^{-1}-Q^{-1})/(Q_0^{-1}-Q_f^{-1}),$$

where Q_0^{-1} and Q_f^{-1} are initial and final values of Q^{-1}, respectively and Q^{-1} corresponds to the cocentration of the solute at any time. The power of t, n, is determined according the equation[13]

$$q=1-\exp[-kt^n]$$

by the slope of the curve in Fig. 6. Thus the value of n obtained is 2.4 in the first stage and 1.1 in the second stage. If there is some stage before first stage, the value of n in it would be about 2/3, which means a formation of Cottrell atmospheres[14] in dislocations, though it is not quite accurate because of the difficulty of the measurement.

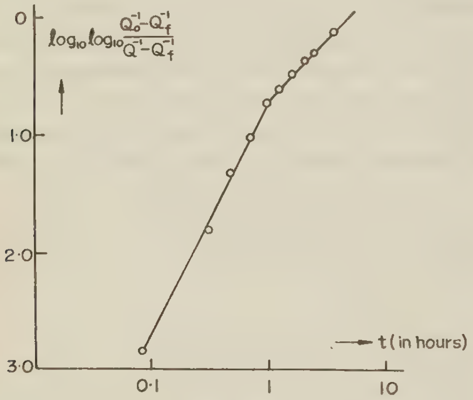

Fig. 6. $\log_{10}\log_{10}\frac{Q_0^{-1}-Q_f^{-1}}{Q^{-1}-Q_f^{-1}}$ vs log t curve. The nitrogen contents of the specimen is 0.0060%. From the slope of this curve n is determined. The aging time is 140°C.

Considering the aging of the magnetic initial susceptibility of the specimen which containg the same amount of nitrogen as that used for internal friction measurement, the following conclusions are obtained by comparing Figs. 4 (c) and 6. The process of precipitation which is proportional to t have completely accomplished during an hour after the aging treatment at 140°C, while in the same period, the decrease of the magnetic initial susceptibility was about three-fifth of total change. So that it would be concluded that the precipitation of the intermediate phase $Fe_{16}N_2$ is rather dominantly responsible for the decrease of magnetic initial susceptibility and Fe_4N more or less have also an influence on it. Moreover, even if the stage of $n=2/3$ takes place in present precipitation process, which corresponds to from 0 to about 5 minutes, the decrease of magnetic initial susceptibility would be insensitive in this stage.

It is not yet satisfactory clarified why the effect of nitrogen on the magnetic aging is more remarkable than that of carbon, but there are a few possibilities for the interpretation of this problem. That is (a) the difference of the shape between the precipitates of carbide and nitride, (b) the difference of the solubility limit of nitrogen and carbon in α-iron, and (c) the difference of the saturation magnetization of these.

§ 4. Conclussion

The magnetic aging in the commercial pure iron is due to very small amounts of carbon and nitrogen, and the effet of nitrogen is more remarkable than that of carbon. Though the reason of different effect of nitrogen and carbon is not clear, some possibilities are considered for these phenomenon, that is, the difference of the shape, the saturation magnetization of carbide and nitride and the difference of the solubility limit of carbon and nitrogen in α-iron.

Acknowledgements

The authors wish to express their thanks to Professor S. Miyahara for valuable advice during the course of present work. They also wish to acknowledge their indebtedness to Dr. E. Watanabe in the Research Institute of the Mitsubishi Minning Co. Ltd. for supply of the specimen. A part of the expenses of this research has been defrayed from the Scientific Research Expenditure of the Educational Ministry.

Application of the Thin-Wing-Expansion Method to the Compressible Flow past Profiles of Arbitrary Shape

By Humio NARUSE

Department of Physics, Faculty of Science,
Tokyo Metropolitan University

(Received May 10, 1957)

The formulae for the velocity distribution over the surface of an obstacle of arbitrary shape are given to the transonic third approximation by the use of Imai's thin-wing-expansion method. These formulae are applied to the flow past an elliptic cylinder and it has been found that the results are in accord with the other authors's results within the order of the approximation used. Further, these formulae, together with the Ψ- and the $\Phi\Psi$-procedures, are applied to the flow past Tomotika-Tamada's profiles. Calculated velocity distributions are compared with Tomotika-Tamada's exact solutions as well as with Takami's numerical results obtained by various approximate methods.

These formulae seem to be very useful, because their convergency and accuracy are very good up to considerably high Mach numbers.

§ 1. Introduction

A great many investigations have been made so far about the thin-wing-expansion method by which the compressible flow past a two-dimensional thin aerofoil can be treated successfully. Namely, Kaplan has calculated the flow past a cusped symmetrical aerofoil which is called the Kaplan bump[1)], a circular arc aerofoil[2)] and an elliptic cylinder[3)], taking account of the effects of their thickness or camber up to the third order.

On the other hand, more than ten years ago Imai established independently his thin-wing-expansion method, by which he gave the analytical expressions for the velocity and the pressure distributions, the lift and the moment of an aerofoil placed in the flow of a compressible fluid up to the second approximation[4)], and investigated in detail the characteristics of general Joukowski profiles[5)]. By that method, we can easily calculate the influences of an obstacle on the flow, even when its shape cannot be given in an analytical form. Later, Imai and Ōyama have given the formulae for the third approximation.[6)]

On the basis of these formulae, several examples have been treated up to the third approximation: the flow along a sinusoidal wall by Imai and Ōyama[7)], the flow past an elliptic cylinder by Hasimoto[8)], the flow past a Kaplan bump by Matunobu[9)], and the flow past a symmetrical circular arc aerofoil by Asaka in a somewhat modified and extended form[10)].

Recently, as an extension of von Kármán's transonic similarity rule, Imai developed a method called transonic thin-wing-expansion method[11)]. Matunobu has applied it to the compressible flow past a Kaplan bump and has calculated the velocity distribution over the profile up to the fourth approximation[12)].

In this paper, the formulae for the velocity distribution over the surface, which are convenient for both the analytical and the numerical calculations for an obstacle of arbitrary shape, have been given to the transonic third approximation by the use of Imai's method. These formulae are applied to the flow past an elliptic cylinder as an example of the analytical calculations and also to the flows past Tomotika-Tamada's profiles[13)], for which the exact solutions are known, as examples of the numerical calculations. The calculated velocity distributions are compared with Tomotika-Tamada's exact solutions as well as with Takami's numerical results obtained by various approximate methods[14)], in order to investigate the limitation of the validity of the thin-wing-expansion method. Further, the Ψ- and the $\Phi\Psi$-procedures associated with the thin-wing-expansion method are applied to the flow past these profiles.

§ 2. Basic Formulae of the Thin-Wing-Expansion Method

For the sake of convenience, a brief account of Imai's thin-wing-expansion method for a symmetrical profile will be given here.

The two-dimensional irrotational flow of a compressible fluid which obeys the adiabatic law is governed by the equations:

$$u=\frac{\partial \Phi}{\partial x}=\frac{\rho_\infty}{\rho}\frac{\partial \Psi}{\partial y}, \qquad v=\frac{\partial \Phi}{\partial y}=-\frac{\rho_\infty}{\rho}\frac{\partial \Psi}{\partial x}, \tag{2.1}$$

$$\frac{\rho}{\rho_\infty}=\left[1-\frac{\gamma-1}{2}M^2\left(\frac{q^2}{U^2}-1\right)\right]^{1/(\gamma-1)}, \tag{2.2}$$

where (u, v) are the component velocities in the x- and the y- directions respectively, q the magnitude of the velocity, ρ the density, ρ_∞ that of the undisturbed fluid, Φ the velocity potential, Ψ the stream function, U and M the magnitude of the velocity and the Mach number of the undisturbed flow respectively, and γ is the ratio of the specific heats.

Then the undisturbed flow will be given as

$$\Phi=x, \quad \Psi=y.$$

On the assumption of the small disturbance, Φ and Ψ can be expanded as follows:

$$\begin{aligned}\Phi&=x+\phi_1+\phi_2+\phi_3+\cdots,\\ \Psi&=y+\psi_1+\psi_2+\psi_3+\cdots,\end{aligned} \tag{2.3}$$

where ϕ_1, ψ_1; ϕ_2, ψ_2; ϕ_2, ψ_3; $\cdots$ are quantities of the order $t, t^2, t^3, \cdots$ respectixely ,t being a small parameter representing the thickness-ratio of the profile. Substituting from (2.2) and (2.3) into (2.1) and comparing terms of the same powers of t, we obtain a set of differential equations for ϕ_m and ψ_m $(m=1, 2, \cdots)$ suitable for the iterative method.

Here let us introduce the following quantities:

$$\xi=x, \quad \eta=\mu y, \quad \psi_m=\mu\chi_m, \quad \mu=\sqrt{1-M^2}, \tag{2.4}$$

$$\zeta=\xi+i\eta, \quad \overline{\zeta}=\xi-i\eta; \quad G_n=\phi_n+i\chi_n, \tag{2.5}$$

and transform the differential equations for ϕ_m and ψ_m in terms of complex quantities.

As the solutions of the transformed differential equations, we have the following expressions for G_1 and G_2:

$$G_1(\zeta)=f(\zeta), \tag{2.6}$$

$$G_2(\zeta, \overline{\zeta})=H_2(\zeta, \overline{\zeta})+g_2(\zeta), \tag{2.7}$$

$$H_2(\zeta, \zeta)=\frac{M^2}{4}\left[\lambda f'^2\overline{\zeta}+(1+\lambda)\{2f'\overline{f}+\int\overline{f}'^2d\overline{\zeta}\}\right]. \tag{2.8}$$

If we neglect those terms smaller than $O(t^3/\mu^5)$, as in Imai's transonic thin-wing-expansion method[11)], we have the following expression for G_3:

$$G_3(\zeta, \overline{\zeta})=H_3(\zeta, \overline{\zeta})+g_3(\zeta), \tag{2.9}$$

$$\begin{aligned}H_3(\zeta, \overline{\zeta})=\left\{\frac{M^2}{4}(1+\lambda)\right\}^2\Big\{&12f'^2\overline{f}+4ff'\overline{f'}+2f''\overline{f}^2+2f\overline{f'^2}+14f'\int\overline{f}'^2d\overline{\zeta}\\ &+\frac{16}{3}\int\overline{f}'^3d\overline{\zeta}+2f'g_2(\zeta)+2g_2'(\zeta)\overline{f}+2\int\overline{f}'\,\overline{g_2'(\zeta)}\,d\overline{\zeta}\Big\}+g_3(\zeta),\end{aligned} \tag{2.10}$$

where $f(\zeta)$, $g_2(\zeta)$ and $g_3(\zeta)$ are analytic functions of ζ, which must be determined by the boundary conditions, and $\overline{f}$ and f' are the complex conjugate and the derivative with respect to ζ of f respectively and $\lambda=(\gamma+1)M^2/4(1-M^2)$.

§ 3. Boundary Conditions

The region outside profile: $(\xi_p, \eta_p)=(x_p, \mu y_p)$ in the ζ-plane may be mapped conformally onto the region outside the unit circle: $Z=e^{i\theta}$ in fhe Z-plane by means of an analytic function of the form:

$$\zeta=C_{-1}Z+C_0+C_1/Z+\cdots, \quad |Z|>1. \tag{3.1}$$

The boundary conditions by which f, g_2 and g_3 are to be determined are as follows:

(i) $\partial G_m/\partial\zeta$ is one-valued and continuous throughout the flow field,

(ii) as $\zeta\to\infty$, $\partial G_m/\partial\zeta\to 0$, and

(iii) on the surface of the profile, $\mathfrak{J}(\zeta/\mu^2+G)=0$, where $\mathfrak{J}$ means "the imaginary part of". This condition is equivalent to the statement that $\Psi=0$ on the surface.

Then, it can easily be shown that $f=-(1/\mu^2)(\zeta-C_0-C_1Z-\overline{C}_{-1}/Z)$ satisfies the conditions (i), (ii) and (iii), and that dg_n/dZ is regular and one-valued for $|Z|>1$ and tends to 0 as $Z\to\infty$, if we consider the above-mentioned conditions and the behaviour of

$\partial H_n/\partial Z$ as $Z\to\infty$. Since the flow is symmetrical, the circulation is absent, and f and g_n may be expanded in the form:

$$\frac{b_1}{Z}+\frac{b_2}{Z^2}+\cdots . \tag{3.2}$$

Hereafter, let us confine ourselves to the boundary of the profiles where G_n, H_n and g_n may be decomposed as

$$G_n(e^{i\theta}, e^{-i\theta})=\phi_n(\theta)+i\chi_n(\theta)\ , \tag{3.3}$$

$$H_n(e^{i\theta}, e^{-i\theta})=P_n(\theta)+iQ_n(\theta)\ , \tag{3.4}$$

$$g_n(e^{i\theta})=R_n(\theta)+iI_n(\theta)\ . \tag{3.5}$$

Referring to the theory of the conjugate Fourier series and (3.2), we have

$$\phi_1(\theta)=\chi_1{}^*(\theta), \tag{3.6}$$

$$R_n(\theta)=I_n{}^*(\theta), \tag{3.7}$$

where asterisk denotes the conjugate Fourier series. Since $\chi_n(\theta)$ can be determined by taking account of the boundary condition (iii), $\phi_n(\theta)$ and $g_n(\theta)$ are determined as follows:

$$\phi_1(\theta)=\chi_1{}^*(\theta)\ , \tag{3.8}$$

$$\left.\begin{aligned} &\phi_n(\theta)=P_n(\theta)-Q_n{}^*(\theta)+\chi_n{}^*(\theta)\ , && (3.9)\\ &g_n(\theta)=\chi_n{}^*(\theta)+i\chi_n(\theta)\\ &\qquad-\{Q_n{}^*(\theta)+iQ_n(\theta)\}\ , && (3.10)\end{aligned}\right\} n\geqq 2\ .$$

§ 4. Approximate Boundary Conditions

An arbitrary aerofoil P can be parametrically represented by

$$x_p=\cos\vartheta\ ,\quad y_p=g(\vartheta)\ , \tag{4.1}$$

$\vartheta=0$, π corresponding to the leading and the trailing edges respectively.

The region outside the profile P′ in the ζ-plane may be mapped onto the region outside the unit circle in the Z-plane by an analytic function:

$$\zeta=\tfrac{1}{2}(Z+1/Z)+C(Z)\ , \tag{4.2}$$

where

$$C(Z)=C_{-1}Z+C_0+C_1/Z+\cdots\ ,\quad C_n=A_n+iB_n\ , \tag{4.3}$$

$C(Z)$ and hence C_n being $O(t)$.

Putting $C(e^{i\theta})=A(\theta)+iB(\theta)$, we have from (4.2)

$$\xi_p=\cos\theta+A(\theta)\ ,\quad \eta_p=B(\theta)\ . \tag{4.4}$$

Since the function: $C(Z)-C_{-1}Z-C_0$ is regular for $|Z|>1$ and tends to 0 as $Z\to\infty$, we have on the unit circle: $Z=e^{i\theta}$

$$A(\theta)=B^*(\theta)+2(A_{-1}\cos\theta-B_{-1}\sin\theta)+A_0\ , \tag{4.5}$$

taking account of the theory of the conjugate Fourier series. Further, from (2.4), (4.1) and (4.4), we have

$$A(\theta)=\cos\vartheta-\cos\theta=-\sin\theta(\vartheta-\theta)-\tfrac{1}{2}\cos\theta(\vartheta-\theta)^2+O(t^3)\ , \tag{4.6}$$

$$B(\theta)=\mu g(\vartheta)=\mu\{g(\theta)+g'(\theta)(\vartheta-\theta)+\tfrac{1}{2}g''(\theta)(\vartheta-\theta)^2\}+O(t^4)\ . \tag{4.7}$$

Considering that $A(0)=0$, $A(\pi)=0$ and $A'(0)=0$, $A(\theta)$, $B(\theta)$ and $(\vartheta-\theta)$ are determined from (4.5), (4.6) and (4.7) by the iterative method as follows:

$$A(\theta)=\mu h(\theta)+\mu k(\theta)+O(t^3)\ , \tag{4.8}$$

$$B(\theta)=\mu g(\theta)-\mu^2\frac{h(\theta)}{\sin\theta}g'(\theta)-\mu^2\left[\frac{g'(\theta)k(\theta)}{\sin\theta}+\frac{\mu}{2}\,\frac{h^2(\theta)}{\sin^2\theta}\left\{\cot\theta g'(\theta)-g''(\theta)\right\}\right]+O(t^4)\ , \tag{4.9}$$

$$\vartheta-\theta=-\frac{\mu}{\sin\theta}h(\theta)-\frac{\mu}{\sin\theta}\left\{k(\theta)+\frac{1}{2}\mu\,\frac{\cos\theta}{\sin^2\theta}h^2(\theta)\right\}+O(t^3)\ , \tag{4.10}$$

$$\cos\vartheta=\cos\theta+\mu h(\theta)+\mu k(\theta)+O(t^3)\ , \tag{4.11}$$

where

$$h(\theta)=g^*(\theta)-\tfrac{1}{2}\{g^*(0)-g^*(\pi)\}\cos\theta-g^{*\prime}(0)\sin\theta-\tfrac{1}{2}\{g^*(0)+g^*(\pi)\}\ , \tag{4.12}$$

$$k(\theta)=H^*(\theta)-\tfrac{1}{2}\{H^*(0)-H^*(\pi)\}\cos\theta-H^{*\prime}(0)\sin\theta-\tfrac{1}{2}\{H^*(0)+H^*(\pi)\}\ , \tag{4.13}$$

$$H(\theta)=-\mu\frac{h(\theta)}{\sin\theta}g'(\theta)\ . \tag{4.14}$$

§ 5. Velocity Potential

From (4.4), (4.9) and the boundary condition (iii) in § 3, $\chi_n(\theta)$ can be determind as follows:

$$\chi_1(\theta)=-g(\theta)/\mu\ , \tag{5.1}$$

$$\chi_2(\theta)=\frac{h(\theta)}{\sin\theta}g'(\theta)\ , \tag{5.2}$$

$$\chi_3(\theta)=\frac{g'(\theta)k(\theta)}{\sin\theta}+\frac{\mu}{2}\frac{h^2(\theta)}{\sin^2\theta}\{\cot\theta g'(\theta)-g''(\theta)\}\,. \tag{5.3}$$

Thus we have from (2.6), (3.3), (3.8) and (5.1) as the first approximation:

$$\phi_1(\theta)=-g^*(\theta)/\mu\,, \tag{5.4}$$

$$f(e^{i\theta})=f_0/\mu,\quad f_0=-\{g^*(\theta)+ig(\theta)\}\,. \tag{5.5}$$

Further, from (2.7), (2.8), (4.3), (3.9) and (5.2), we have

$$\phi_2(\theta)=\frac{M^2(1+\lambda)}{2\mu^2}\left\{\Re\int\left(\frac{df_0}{d\theta}\right)^2\frac{d\theta}{d\sigma}e^{-i\omega}\,d\theta+p_2(\theta)-q_2{}^*(\theta)\right\}+\chi_2{}^*\,, \tag{5.6}$$

where

$$e^{i\omega}\,d\sigma=d\zeta_p\,, \tag{5.7}$$

$$p_2(\theta)+iq_2(\theta)=2ig\frac{df_0}{d\theta}\frac{d\theta}{d\sigma}e^{-i\omega}\,, \tag{5.8}$$

and $\Re$ means "the real part of."

Neglecting terms smaller than $O(t^3/\mu^5)$, we have from (2.9), (2.10), (3.4), (3.9), (3.10) (5.3) and (5.7).

$$\phi_3(\theta)=\frac{M^4(1+\lambda)^2}{16\mu^3}\left[\frac{32}{3}\Re\int\left(\frac{df_0}{d\theta}\right)^3\left(\frac{d\theta}{d\sigma}\right)^2e^{-2i\omega}\,d\theta+8\Re\int\frac{df_0}{d\theta}\frac{dF}{d\theta}\frac{d\theta}{d\sigma}e^{-i\omega}d\theta+p_3'(\theta)-q_3'(\theta)\right], \tag{5.9}$$

where

$$\begin{aligned}p_3(\theta)+iq_3(\theta)=&12\bar{f}_0\left(\frac{df_0}{d\theta}\right)^2\left(\frac{d\theta}{d\sigma}\right)^2e^{-2i\omega}+4f_0\left|\frac{df_0}{d\theta}\frac{d\theta}{d\sigma}e^{-i\omega}\right|^2+2\bar{f}^2\left\{\frac{d^2f_0}{d\theta^2}\left(\frac{d\theta}{d\sigma}\right)^2e^{-2i\omega}\right.\\&\left.-\frac{df_0}{d\theta}\frac{d^2\zeta_p}{d\theta^2}\left(\frac{d\theta}{d\sigma}\right)^3e^{-3i\omega}\right\}+2f\overline{\left(\frac{df_0}{d\theta}\right)^2\left(\frac{d\theta}{d\sigma}\right)^2e^{-2i\omega}}+14\frac{df_0}{d\theta}\frac{d\theta}{d\sigma}e^{-i\omega}\overline{\int\left(\frac{df_0}{d\theta}\right)^2\frac{d\theta}{d\sigma}e^{-i\omega}\,d\theta}\\&+4\frac{df_0}{d\theta}\frac{d\theta}{d\sigma}e^{-i\omega}\bar{F}+4\bar{f}\frac{dF}{d\theta}\frac{d\theta}{d\sigma}e^{-i\omega}\,,\end{aligned} \tag{5.10}$$

and

$$F(\theta)=-\{q_2{}^*(\theta)+iq_2(\theta)\}\,. \tag{5.11}$$

§ 6. Velocity Distributions

The velocity distribution over the surface of the aerofoil is given by

$$q=\frac{d\phi}{ds}=\frac{d\phi}{d\vartheta}\frac{d\vartheta}{ds}=\left\{\frac{dx_p}{d\vartheta}+\left(\frac{d\phi_1}{d\theta}+\frac{d\phi_2}{d\theta}+\frac{d\phi_3}{d\theta}\right)\frac{d\theta}{d\vartheta}\right\}\frac{d\vartheta}{ds}\,, \tag{6.1}$$

where

$$\frac{ds}{d\vartheta}=\sqrt{\left(\frac{dx_p}{d\vartheta}\right)^2+\left(\frac{dy_p}{d\vartheta}\right)^2}=\sqrt{\sin^2\vartheta+\{g'(\vartheta)\}^2}\,,$$

$$\frac{dx_p}{d\vartheta}=-\sin\vartheta\,,\qquad \frac{d\vartheta}{d\theta}=1-\left\{\frac{\mu}{\sin\theta}h(\theta)\right\}'$$

and $d\phi_1/d\theta$, $d\phi_2/d\theta$ and $d\phi_3/d\theta$ are given by (5.4)~(5.11).

For the simplicity of the calculation, it is convenient to use the following formulae. Neglecting terms smaller than $O(t^3/\mu^5)$, we have from (4.10) and (6.1)

$$q=\{\sin\vartheta+g^{*\prime}(\vartheta)/\mu+S'(\vartheta)+\nu T(\vartheta)+\tfrac{1}{4}\mu\nu^2R(\vartheta)\}[\sin^2\vartheta+\{g'(\vartheta)\}^2]^{-1/2}\,, \tag{6.2}$$

where

$$S(\theta)=g^{*\prime}(\theta)\frac{h(\theta)}{\sin\theta}-\left\{g^{*\prime}(\theta)\frac{h(\theta)}{\sin\theta}\right\}^*\,, \tag{6.3}$$

$$T(\theta)=-\left[\Re\left\{\left(\frac{df_0}{d\theta}\right)^2\frac{d\theta}{d\sigma}e^{-i\omega}\right\}+p_2'(\theta)-q_2{}^{*\prime}(\theta)\right], \tag{6.4}$$

$$R(\theta)=-\left[\frac{32}{3}\Re\left\{\left(\frac{df_0}{d\theta}\right)^3\left(\frac{d\theta}{d\sigma}\right)^2 e^{-2i\omega}\right\}+8\Re\frac{df_0}{d\theta}\frac{dF}{d\theta}\frac{d\theta}{d\sigma}e^{-i\omega}+p_3'(\theta)-q_3^{*\prime}(\theta)\right], \tag{6.5}$$

$$\nu=\frac{1}{2}\frac{M^2}{(1-M^2)}\left\{1+\frac{(\gamma+1)M^2}{4(1-M^2)}\right\}, \tag{6.6}$$

and $h(\theta)$, $f_0(\theta)$, $p_2(\theta)+iq_2(\theta)$, $p_3(\theta)+iq_3(\theta)$ and $F(\theta)$ are given in (4.12), (5.5), (5.8), (5.10) and (5.11).

§ 7. The Ψ-Procedure and the $\Phi\Psi$-Procedure

The Ψ-procedure and the $\Phi\Psi$-procedure in which the velocity is obtained from the stream function or the combination of the velocity potential and the stream function respectively, were developed by Imai[15]. These procedures were applied, together with the M^2-expansion method, to the cases of a circular cylinder and a circular arc aerofoil by Imai himself and to the cases of Cherry's profile and Tomotika-Tamada's profile by Takami[16],[14] and it has been shown that the $\Phi\Psi$-procedure may give the most adequats results within the order of the approximation employed.

Now these procedures can be applied also to the thin-wing-expansion method as well as to the M^2-expansion method as follows. Let the velocity q, the stream function Ψ and the density ρ be expanded as

$$q=1+q_1+q_2+q_3+\cdots,$$

$$\Psi=\psi_0+\psi_1+\psi_2+\psi_3+\cdots,$$

$$1-\frac{\rho}{\rho_\infty}=\rho_1+\rho_2+\rho_3+\cdots, \tag{7.1}$$

where

$$\rho_1=M^2q_1,$$

$$\rho_2=M^2(\tfrac{1}{2}q_1^2+q_2)-\tfrac{1}{2}(2-\gamma)M^4q_1^2,$$

$$\rho_3=M^2(q_3+q_1q_2)-\tfrac{1}{2}(2-\gamma)M^4q_1(q_1^2+2q_2)$$
$$+\tfrac{1}{6}(2-\gamma)(3-2\gamma)M^6q_1^3. \tag{7.2}$$

Then, inserting (7.1) into the relation

$$\frac{\partial\Psi}{\partial n}=-\frac{\rho}{\rho_\infty}\frac{\partial\Phi}{\partial s}, \tag{7.3}$$

we get

$$\frac{\partial\psi_0}{\partial n}=1, \qquad \frac{\partial\psi_1}{\partial n}=q_1-\rho_1,$$

$$\frac{\partial\psi_2}{\partial n}=q_2-\rho_1q_1-\rho_2,$$

$$\frac{\partial\psi_3}{\partial n}=q_3-\rho_1q_2-\rho_2q_1-\rho_3. \tag{7.4}$$

From (7.2) and (7.4), $\partial\psi_n/\partial n$ can easily be calculated if we know q_1, q_2, $q_3\cdots$ in the Φ-procedure by the method of § 6. When $\partial\Psi/\partial n$ is known, we get the values of q in the Ψ-procedure by using the following relation:

$$\frac{\rho q}{\rho_\infty}=q\left\{1+\frac{\gamma-1}{2}M^2(1-q^2)\right\}^{1/(\gamma-1)}=\frac{\partial\Psi}{\partial n},$$

and in the $\Phi\Psi$-procedure by the relation: $q=(\rho_\infty/\rho)\partial\Psi/\partial n$, where the values from the Φ-procedure are substituted for q in ρ_∞/ρ.

In this paper these procedures are applied to Tomotika-Tamada's profiles and the results will be given in § 9.

§ 8. Flow past an Elliptic Cylinder

The formula (6.2) can be applied to the analytical and the numerical calculations for an obstacle of an arbitrary shape, and here, as an example of the analytical one, we consider the flow past an elliptic cylinder with its major axis parallel to the undisturbed flow.

Let the ellipse be given by

$$x_p=\cos\vartheta, \quad y_p=t\sin\vartheta. \tag{8.1}$$

Then we have from (4.1)

$$g(\vartheta)=t\sin\vartheta \quad \text{and} \quad g^{*\prime}(\vartheta)=t\sin\vartheta,$$

from (5.11)

$$f_0(\vartheta)=t(\cos\vartheta-i\sin\vartheta),$$

from (4.12) and (6.3)

$$h(\vartheta)=0 \quad \text{and} \quad S(\vartheta)=0,$$

from (5.8) and (6.4)

$$T(\vartheta)=t^2\frac{2\sin^3\vartheta-\sin\vartheta}{\sin^2\vartheta+\mu^2t^2\cos^2\vartheta}$$

and from (5.10) and (6.5)

$$R(\vartheta)=-t^3\left\{-\frac{128}{3}\sin\vartheta+64\frac{\sin\vartheta}{\sin^2\vartheta+\mu^2t^2\cos^2\vartheta}\right.$$
$$\left.-28\frac{\tan^{-1}\left(\frac{\sqrt{1-\mu^2t^2}}{\mu t}\sin\vartheta\right)}{\sin^2\vartheta+\mu^2t^2\cos^2\vartheta}\right\}.$$

Then from (6.2)

$$q=\left\{\sin\vartheta+\frac{t}{\mu}\sin\vartheta+\nu t^2\frac{2\sin^3\vartheta-\sin\vartheta}{\sin^2\vartheta+\mu^2t^2\cos^2\vartheta}\right.$$
$$+\mu\nu^2t^3\left[\frac{32}{3}\sin\vartheta-\frac{1}{\sin^2\vartheta+\mu^2t^2\cos^2\vartheta}\right.$$

$$\times\left\{16\sin\vartheta-7\tan^{-1}\left(\frac{\sqrt{1-\mu^2t^2}}{\mu t}\sin\vartheta\right)\right\}\Bigg]\Bigg\}$$

$$\times(\sin^2\vartheta+\mu^2t^2\cos^2\vartheta)^{-1/2}\,.$$

Further simplification can be achieved for $\vartheta\neq 0$ and π,

$$q=\left\{1+\frac{t}{\mu}+\nu t^2\left(2-\frac{1}{\sin^2\vartheta}\right)+\mu\nu^2t^3\right.$$

$$\left.\times\left(\frac{32}{3}-\frac{1}{\sin^2\vartheta}+\frac{7\pi}{2}\frac{1}{\sin^3\vartheta}\right)\right\}(1+\mu^2t^2\cot^2\vartheta)^{-1/2}\,.$$

This result is in accord with Imai's11) and Hasimoto's8) results based on Imai's thin-wing-expansion method and Kawaguti's results based on the M^2-expansion method.17)

§ 9. The Flow past Tomotika-Tamada's Profiles

As an example of the numerical calculations, we consider the flow past Tomotika-Tamada's profiles, for which the exact solutions have already been obtained by the hodograph method for a certain hypothetical gas satisfying the adiabatic gas relation approximately13). The shapes of these profiles, which have been calculated for the Mach numbers of the undisturbed flow equal to 0.717, 0.745 and 0.752, are slightly different from each other, and are symmetrical with respect to the direction of the oncoming flow

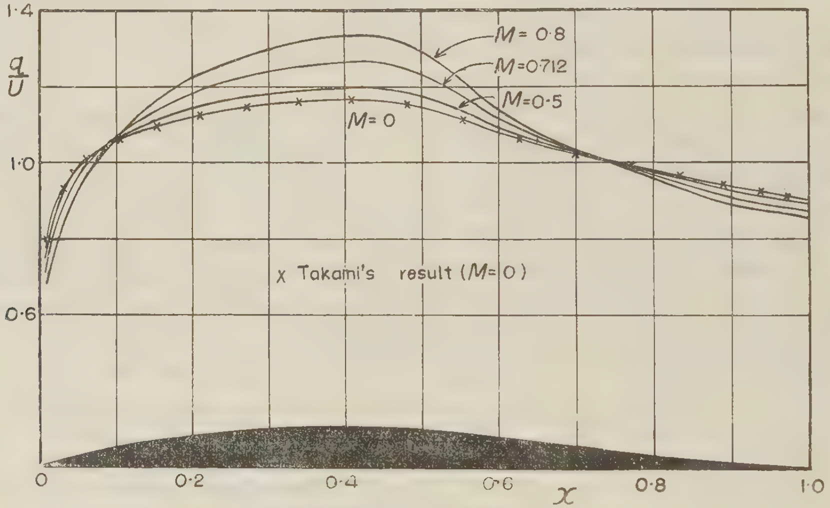

Fig. 1. The velocity distributions over the surface of the profile I for various Mach numbers (2nd approx.).

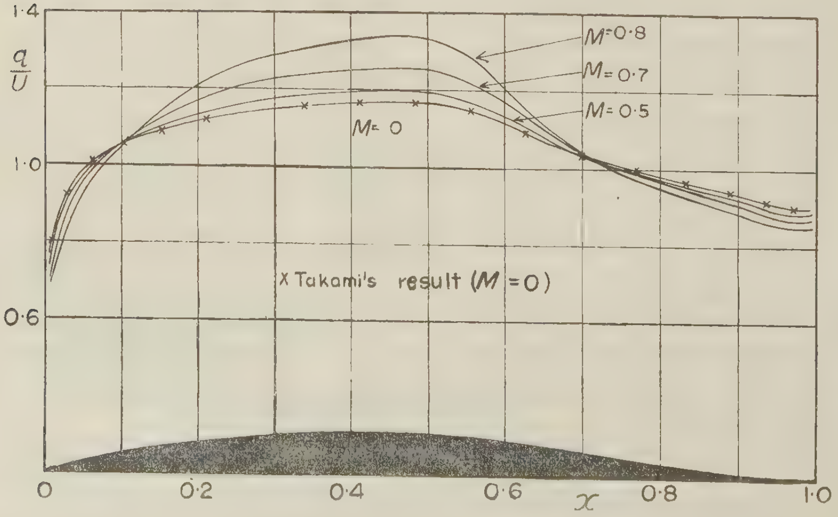

Fig. 2. The velocity distributions over the surface of the profile II for various Mach numbers (2nd approx.).

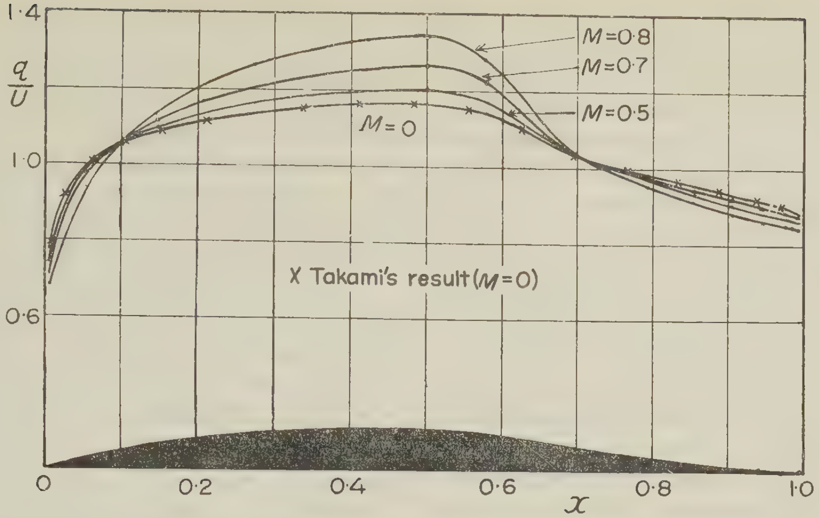

Fig. 3. The velocity distributions over the surface of the profile III for various Mach numbers (2nd approx.).

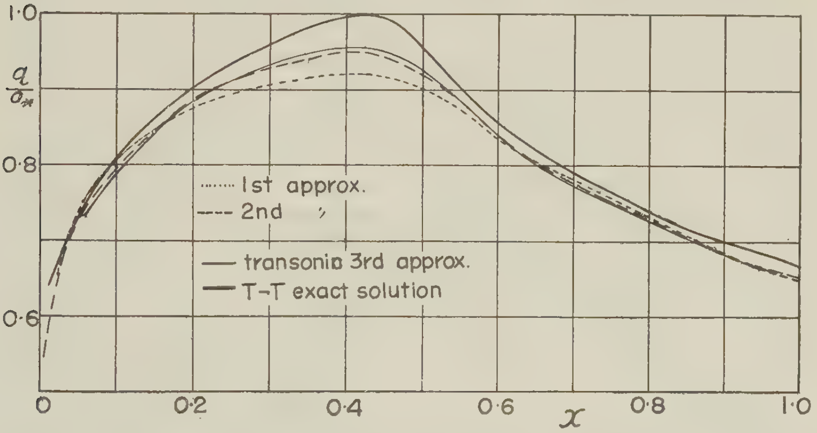

Fig. 4. The velocity distribution over the surface of the profile I ($M=0.717$).

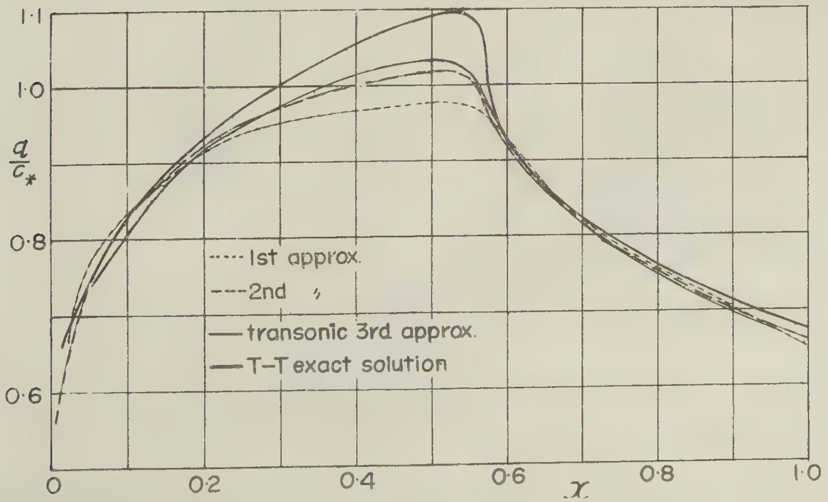

Fig. 5. The velocity distribution over the surface of the profile III ($M=0.752$).

and have a finite angle at the leading edge and a cusp at the trailing edge. It should be noticed that the flow past profile I with $M=0.717$ has the sonic speed at the point of the maximum velocity on the surface and the flow past profile III with $M=0.752$ has the infinite velocity gradient at a point of the surface.

Numerical calulations have been performed with 20 equipartitions of ϑ (the interval being 9°) for the three following cases:

(I) In order to investigate the change of the velocity distributions with the change of the Mach number, the velocity distributions over the surface of the profiles I, II, and III have been calculated to the second approximation by using (6.2) and taking $\gamma=1.4$ for various Mach numbers. These results are given in Figs. 1–3.

(II) In order to investigate the range of the validity of the thin-wing-expansion method, the velocity distributions over the surfaces of the profiles I and III have been calculated to the transonic third approximation by using (6.2) and taking as before $\gamma=1.4$ for the same Mach numbers as for the exact solutions. These results are given in Figs. 4 and 5.

(III) In order to investigate the validity of the Ψ- and the $\Phi\Psi$-procedures the velocity distribution over the surface of profile I has been calculated to the third approximation by using the method of § 7 and taking $\gamma=1.4$ for the same Mach number as for the exact solution. These results are given in Fig. 6.

The following may be concluded from Figs. 1–3. The velocity distributions over these

━━━ Tomotika-Tamada's exact solution.

profiles are fairly different from each other even for the same Mach number, and the higher the Mach number of the undisturbed flow becomes, the more the difference becomes conspicuous. In the case of $M=0$, the values from the second approximation agree very well with the exact ones calculated numerically by Takami and thus it follows that the calculation for the incompressible flow is sufficient with the second approximation.

From Figs. 4–5 it may be inferred that these solutions converge in the range of the local Mach number less than 1, but diverge in the range of the local Mach number larger than 1. Although the values to which the velocity seems to converge are generally somewhat lower than that of Tomotika-Tamada's exact solutions, the difference may be, due chiefly to the fact that the characteristics assumed in the exact solutions deviate from those of the adiabatic gas with $\gamma=1.4$. In fact, when the differences of the characteristics of the both gases are calibrated, it can be shown that our solutions are in very good agreement with the exact ones except for the neighbourhood of the sonic point.* Generally speaking, the convergency is very good in the range of the local Mach number lower than 0.9 where both the results calculated by (6.2) and Takami's numerical ones obtained by various approximate methods seem to be sufficiently reliable.

From Fig. 6 it is concluded that the behaviours of the solutions in the Ψ- and the $\Phi\Psi$-procedures agree very well with that by the M^2-expansion method. In fact it is worth noticing that in the $\Phi\Psi$-procedure the convergency is remarkably well even for a high subsonic velocity and the second approximation in the $\Phi\Psi$-procedure gives very good results in almost entire flow region (naturally except for the neighbourhood of the tip) in spite of the simplicity of the calculation.

§ 10. Conclusion

The formulae for the velocity distribution over the surface of an obstacle of arbitrary shape have been given to the transonic third approximation by the use of Imai's thin-wing-expansion method. As an example of the analytical calculations, these formulae are applied to the flow past an elliptic cylinder and it has been found that the results are in accord with the other authors's results within the approximation used. Further, as an example of the numerical calculations, these formulae, together with the Ψ- and the $\Phi\Psi$-procedures, are applied to the flow past Tomotika-Tamada's profiles. Although the calculated values are generally somewhat lower than those of Tomotika-Tamada's exact solutions, their convergency and accuracy are very good up to considerably high Mach numbers. Consequently, these formulae, particularly the second approximation in the $\Phi\Psi$-procedure, seem to be very useful, because of their good accuracy and simplicity of the calculation.

Acknowledgements

The writer would like to express his hearty thanks to Professor Isao Imai who suggested the problem and has guided and encouraged him throughout this study. The writer's thanks are also due to Professor Toshimitu Nagakura, Professor Saburo Asaka, Dr. Mitutosi Kawaguti and Dr. Hidenori Hasimoto for their advice and kind inspection of the manuscript, and to Mr. Hideo Takami who kindly showed him the numerical data and gave him much advice.

Notes on the Calculation of Electrophoresis of Polyelectrolytes with Partial Free-Drainage

By Hiroshi FUJITA

Physical Chemistry Laboratory, Department of Fisheries, University of Kyoto, Maizuru

(Received May 4, 1957)

This paper presents detailed numerical evaluation of the Hermans-Fujita's general equation for the electrophoretic mobility of a coiled polyelectrolyte molecule in salt solution. Values of the electrophoretic mobility u_p are obtained as functions of values of two basic parameters σ and β; here σ is Debye's "shielding ratio," and β is the radius of the polymer coil relative to the thickness of the diffuse double layer. It is shown that the criticism offered recently by Overbeek and Stigter for the validity of Hermans-Fujita's u_p equation is doubtlessly incorrect. A procedure is demonstrated by means of which u_p *vs.* β curves for different fixed values of σ can be reduced approximately to a single curve. The approximate solution for the same problem obtained by Overbeek and Stigter is discussed and compared with the rigorous treatment in relation to this reduction procedure.

§ 1. Introduction

Hermans and Fujita[1] extended the theory of Brinkman[2] and of Debye and Bueche[3] for the sedimentation of uncharged polymer molecules to the calculation of electrophoretic mobility of polyelectrolyte molecules in simple salt solutions. The model used was a porous sphere in which the density of polymer segments, and therefore also that of the fixed charges, is constant. For the charge density due to mobile ions an expression was used which had been derived for this model by Hermans and Overbeek[4] on the assumption that the approximation of Debye and Hückel is applicable. Relaxation effects were ignored. The calculation was made without any mathematical approximations. The final expression for the electrophoretic mobility, u_p, was obtained as a function of two dimensionless parameters, β and σ. Here β is the ratio of the molecular radius to the thickness of the diffuse electric double layer around the polyion, and σ is Debye-Bueche's "shielding radio." Various limiting forms as well as an asymptotic expression of the u_p equation useful for large enough values of β and σ were derived. No numerical discussion of the analytic results obtained was made, however.

In a recent article dealing with the same problem in a somewhat different manner, Overbeek and Stigter[5] have pointed out that the u_p equation of Hermans and Fujita yields a u_p value smaller than the segment's electric mobility for some intermediate values of σ and β. They state that this is clearly impossible to obtain, and therefore comparison of their approximate solution with Hermans-Fujita's rigorous treatment must await a correction of the latter.

Careful re-examination of the mathematical analysis described in reference (1) was made,[6] and it was confirmed that the results of Hermans and Fujita involve no error at all, at least so far as the mathematical aspects are concerned. This would imply that Overbeek and Stigter must have made some error in their numerical examination of Hermans-Fujita's u_p equation. This is largely probable because the physical models used in both calculations were essentially the same. To check this point critically detailed numerical calculation of the u_p equation in question was carried out, and the results obtained are presented below. It is shown that, in contrast with the criticism offered by Overbeek and Stigter, no particular paired values σ and β are likely to exist for which the electrophoretic mobility of a polyelectrolyte calculated from Hermann-Fujita's equation assumes a value smaller than the electric mobility of its segment (or monomer) unit.

§ 2. The Equation for the Electrophoretic Mobility u_p

The exact equation for the electrophoretic mobility of a polyelectrolyte derived by Hermans and Fujita[1] reads

$$u_p = \frac{\rho}{\nu f}\left[1+\frac{\Phi(\sigma,\beta)}{1-\tanh\sigma/\sigma}\right], \tag{1}$$

where

$$\Phi(\sigma,\beta)=\frac{2}{3}\left(\frac{1+\beta}{\beta^2-\sigma^2}\right)e^{-\beta}[F(\sigma,\beta)+G(\sigma,\beta)]$$
$$+\frac{2}{3}(e^{-\beta}/\beta^2)(\cosh\beta-\sinh\beta/\beta)H(\sigma,\beta)\,, \tag{2}$$

$$F(\sigma,\beta)=\left(1+\frac{2}{3}\sigma^2\right)(1-\sigma^2/\beta^2)\cosh\beta$$
$$+\left(\sigma^2/\beta^2+\frac{2}{3}\sigma^4/\beta^2-1+\frac{1}{3}\sigma^2\right)\sinh\beta/\beta\,, \tag{3}$$

$$G(\sigma,\beta)=[(\sigma^2/\beta^2-1-\sigma^2)\cosh\beta$$
$$+(1-\sigma^2/\beta^2)\sinh\beta/\beta]\tanh\sigma/\sigma\,, \tag{4}$$

$$H(\sigma,\beta)=\frac{1}{3}\sigma^2(1+\beta)$$
$$-(\sigma^2\beta+1+\beta)(1-\tanh\sigma/\sigma)\,. \tag{5}$$

The symbols in Eq. (1) have the following significance:

u_p = electrophoretic mobility of a polyion (at infinite dilution),
ρ = density of fixed charges inside the polyion,
ν = density of polymer segments,
f = frictional factor per polymer segment,
σ = Debye-Bueche's shielding ratio,
$\beta=\kappa R$, where κ is the reciprocal characteristic length of the theory of Debye and Hückel and R is the mean radius of the coiled polyion sphere.

It is noted that $\rho/\nu f$ represents the electric mobility of an individual polymer segment (or monomer). The shielding ratio is expressed in terms of ν, f, R and solvent viscosity η by

$$\sigma^2=\nu f R^2/\eta\,. \tag{6}$$

When Eqs. (3), (4) and (5) are substituted in Eq. (2) and the resulting equation is arranged properly, we find

$$\Phi(\sigma,\beta)=\frac{2}{3}(\sigma^2/\beta^2)\,e^{-\beta}\cosh\beta\{(1-\tanh\beta/\beta)$$
$$\times(1+\beta\tanh\sigma/\sigma)+[\beta^2(1+\beta)/(\beta^2-\sigma^2)]$$
$$\times(\tanh\beta/\beta-\tanh\sigma/\sigma)\}\,. \tag{7}$$

This form of $\Phi(\sigma,\beta)$ is much more tractable for numerical calculation than its original appeared in reference (1). For numerical work the ratio of u_p to $(\rho/\nu f)$ is computed as functions of σ and β. This ratio represents how the electrophoretic mobility of a coiled polyelectrolyte molecule differs from that of its constituent segment, in accordance with the degree of free-drainage, σ, and the ionic strength of the surrounding medium, β.

§ 3. Limiting Forms

Hermans and Fujita[1] derived from Eq. (1) its various limiting forms for large or small values of σ and β. Those are summarized below, together with some approximate expressions of Eq. (1) derived newly in the present study.

(a) When $\sigma\to 0$, Eq. (1) yields for any positive β

$$u_p=\rho/\nu f\,. \tag{8}$$

(b) When $\beta\to 0$, Eq. (1) reduces to

$$u_p=\frac{2}{9}\,\frac{\rho}{\nu f}\,\frac{\sigma^2}{\psi(\sigma)}\,, \tag{9}$$

where $\psi(\sigma)$ is the characteristic function of σ in the theory of Debye and Bueche[3] for the sedimentation of uncharged polymer molecules, i.e,

$$\psi(\sigma)=\frac{1-\tanh\sigma/\sigma}{1+(3/2\sigma^2)(1-\tanh\sigma/\sigma)}\,. \tag{10}$$

(c) When β becomes infinite but σ remains finite, Eq. (1) reduces to the same form as Eq. (8), i.e.,

$$u_p=\rho/\nu f\,. \tag{11}$$

(d) When σ becomes infinite, the limiting form is

$$u_p = \frac{\rho R^2}{\eta} \frac{2}{3} (e^{-\beta}/\beta^2) \cosh \beta (1 - \tanh \beta/\beta). \tag{12}$$

This is in complete agreement with Henry's formula[7] for a compact sphere whose electric conductivity is the same as that of the medium. This is expected because in this limit the polymer molecule behaves like a compact sphere.

(e) For σ and β large enough compared with unity, Eq. (1) gives asymptotically

$$u_p = \frac{\rho}{\nu f} \left[1 + \frac{\sigma^2}{3\beta^2} \left(\frac{2\beta+\sigma}{\beta+\sigma} \right) \right]. \tag{13}$$

In deriving this, both $\tanh \sigma$ and $\tanh \beta$ have been set equal to unity, and moreover both $1/\sigma$ and $1/\beta$ have been neglected compared with unity. This latter neglect is much more crude than the former approximation; the approximation that $\tanh x=1$ is quite accurate for x larger than about 4. If use is made of this approximation only, Eq. (1) becomes

$$u_p = \frac{\rho}{\nu f} \left\{ 1 + \frac{\sigma^3}{3\beta^2(\sigma-1)} \left[\frac{2\beta+\sigma}{\beta+\sigma} - \frac{(\beta+\sigma)^2+\beta^2}{\beta\sigma(\beta+\sigma)} \right] \right\}. \tag{14}$$

(f) For σ and β sufficiently small compared with unity, Eq. (1) is expanded in a double series in σ and β to give

$$u_p = \frac{\rho}{\nu f} \left[1 + \frac{4}{15} \sigma^2 - \frac{2}{9} \sigma^2 \beta + \left(\frac{4}{35} \sigma^2 \beta^2 - \frac{2}{1575} \sigma^4 \right) + \cdots \right]. \tag{15}$$

Eqs. (14) and (15) have newly been derived in this study.

§ 4. Numerical Results and Discussion

Numerical values of u_p were computed from Eq. (1) with $\Phi(\sigma, \beta)$ given by Eq. (7) over ranges of σ and β that are of practical importance (see Table I). For paired values of σ and β sufficiently small compared with unity, Eq. (15) was also used to check the results from the exact equation (1). For paired values of σ and β larger than 5, Eq. (14) was found to yield values identical with those from Eq. (1) within a practical accuracy.*

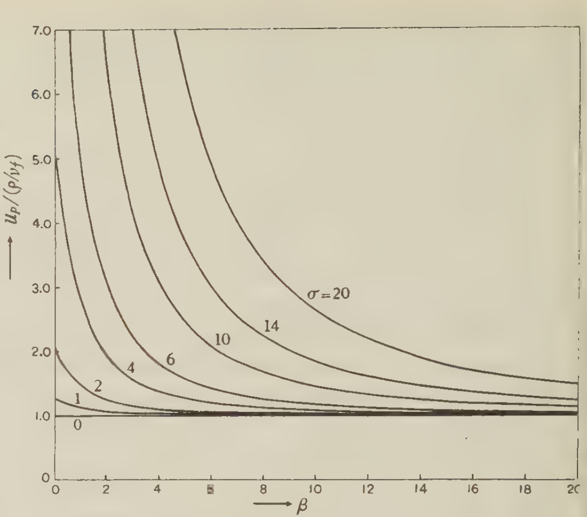

Fig. 1. Electrophoretic mobility u_p of a polyelectrolyte molecule relative to the mobility of its segment $\rho/\nu f$ as a function of β for different fixed values of σ.

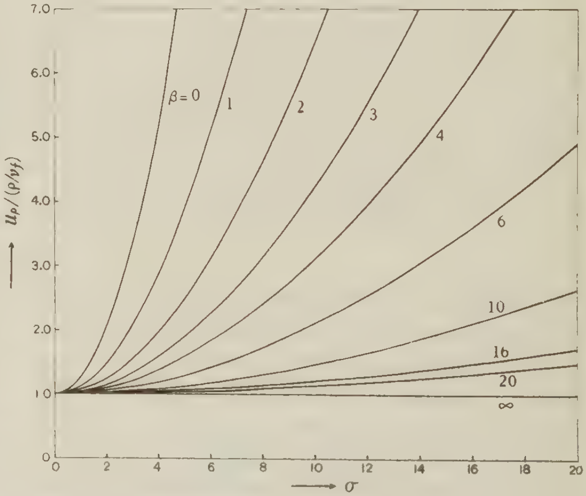

Fig. 2. Electrophoretic mobility u_p of a polyelectrolyte molecule relative to the mobility of its segment $\rho/\nu f$ as a function of σ for different fixed values of β.

The results obtained are shown graphically in Fig. 1 and 2. Fig. 1 gives the calculated u_p *vs.* β curves for several fixed values of σ. Fig. 2 shows the u_p *vs.* σ curves for different fixed values of β. To avoid confusion of the graph, only the curves for typical values of σ and β are presented here. Complete numerical values obtained are recorded in Table I. It is seen that for all pairs of the parameters treated in this calculation the u_p values are larger than or equal to $\rho/\nu f$. It is quite unlikely that there exist paired

---

* For the range σ and β both larger than 20, Eq. (13) can be satisfactorily used to predict values of u_p. Obviously, Eq. (13) yields u_p larger than $\rho/\nu f$ for any paired σ and β in this region.

values of σ and β for which u_p becomes smaller than $\rho/\nu f$. We may thus conclude almost definitely that the criticism offered by Overbeek and Stigter for the electrophoretic mobility equation of Hermans and Fujita is errorneous.

Besides this principal conclusion, some interesting property of the u_p curves shown in Fig. 1 may be pointed out. This is found by plotting the ratio of $u_p(\rho/\nu f)-1$ to $(u_p)_0/(\rho/\nu f)-1$ against β for various fixed values of σ. Here $(u_p)_0$ stands for the value of u_p at the limit of $\beta=0$, and is given by Eq. (9). Fig. 3 shows such plots.* It is rather surprising that the values of this ratio for considerably different σ fall approximately on a single curve over the entire range of β herein shown. This suggests that, to a first approximation, u_p may be written in the form

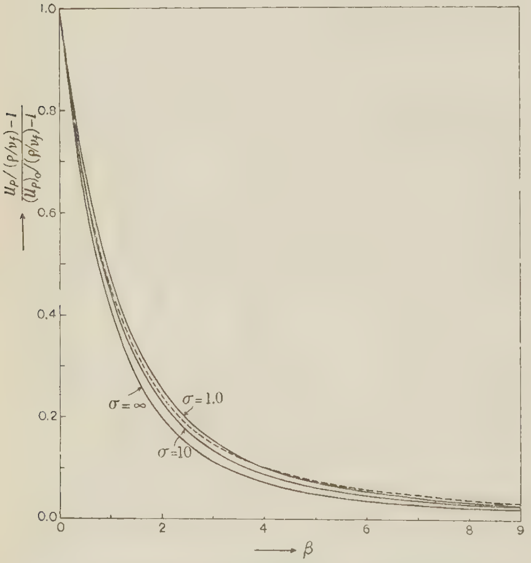

Fig. 3. Reduced electrophoretic mobility curves for different fixed values of σ; $(u_p)_0$ represents the values of u_p in the limit of zero ionic strength ($\beta=0$). The dashed line indicates the approximate reduced curve calculated from Eq. (19).

$$u_p=\frac{\rho}{\nu f}\left\{1+\left[\frac{(u_p)_0}{\rho/\nu f}-1\right]B(\beta)\right\}. \tag{16}$$

Here $B(\beta)$ is a function of β only. Actually, it may be taken as a mean curve running through the bundle of curves shown in Fig. 3.

The approximate equation for u_p obtained by Overbeek and Stigter[5)] may be written, in the notations of this article,

$$u_p=\frac{\rho}{\nu f}\left\{1+\left[\frac{(u_p)_0}{\rho/\nu f}-1\right]\right.$$
$$\left.\times\left[1-\frac{(2/9)\sigma^2}{(u_p)_0(\nu f/\rho)-1}\left(\frac{\beta}{1+\beta}\right)\right]C(\beta)\right\}, \tag{17}$$

where $C(\beta)$ stands for

$$C(\beta)=\frac{3}{2\beta^3}[(1+\beta)^2e^{-2\beta}-1+\beta^2]. \tag{18}$$

Numerical examination shows that the function $(2/9)\sigma^2/[(u_p)_0(\nu f/\rho)-1]$ varies very slowly with σ; it starts with 0.83333 (actually, 5/6) at $\sigma=0$, increases monotonically, and tends to unity for infinitely large σ. Accordingly, to a first approximation, we may replace it by some mean value between these two limits. Here, tentatively, a value of 0.90 is assigned to it. Then Eq. (17) reduces to

$$\frac{u_p/(\rho/\nu f)-1}{(u_p)_0/(\rho/\nu f)-1}$$
$$=\frac{3}{2\beta^3}[(1+\beta)e^{-2\beta}-1+\beta](1+0.1\beta). \tag{19}$$

Thus we find that a family of u_p *vs.* β curves for a series of fixed σ obtained from the equation of Overbeek and Stigter can also be reduced to a single curve if we replot those curves in the form of Fig. 3. The function of β in the right-hand side of Eq. (19) is indicated by a dashed line in Fig. 3. It is observed that this dashed line runs through or near-by the bundle of the solid curves calculated from the exact equation. This implies that the approximations used by Overbeek and Stigter permit remarkably accurate evalution of u_p as functions of σ and β.

Recently, Nagasawa[8)] reported interesting electrophoresis data on samples of sodium salt of sulphonated polyvinyl alcohol in aqueous sodium chloride solutions. When the ionic strength of the added electrolyte in

---

* From Eqs. (12) and (9) the limiting form of this ratio for $\sigma=\infty$ is obtained to give

$$\text{the ration}=3(e^{-\beta}/\beta^2)(\cosh\beta-\sinh\beta/\beta).$$

Similarly, by expanding the equations for u_p and $(u_p)_0$ in powers of σ, the limiting form of the ratio for $\sigma=0$ is obtained as

$$\text{the ratio}=15/2(e^{-\beta}/\beta^2)\cosh\beta\{(1+\beta)/3$$
$$-(1-\tanh\beta/\beta)[(\beta/3)+(1+\beta)/\beta^2]\}.$$

The curves for $\sigma=0$ and ∞ in Fig. 3 have been computed using these equations.

solution is decreased, his u_p data first go up following a curve quite similiar to the type shown in Fig. 1, but reaches a maxium at a certain finite ionic strength, then come down rapidly, and approach at the limit of zero ionic strength a value corresponding to the mobility of the monomer ion. At the limit of high enough ionic strength the curve again tends to the value equal to the mobility of the monomer ion. When comparing this behavior with the theory of Hermans and Fujita outlined above, it should be borne out in mind that the curves in Fig. 1 refer to fixed values of σ. As well known, the effective radius of the flexible polyelectrolyte molecule depends on the ionic strength κ^2, hence β, of the surrounding medium. This means that degree of free-drainage, σ, of the polyion changes with changing ionic strength of the external solution. At very low ionic strength the polymer coil becomes more expanded; therefore it becomes more free-drained so that σ becomes smaller. This explains that the electrophoretic mobility comes down again after passing through a maximum, when the electrolyte content of the solution is decreased down to zero.

Grateful acknowledgment is made for the assistance of Mr. K. Ninomiya and Miss A. Segawa of this Laboratory in the numerical calculation. This work was supported in part by a grant from the cooperative research project on the chemistry of polyelectrolytes under the supervision of Professor I. Kagawa, Department of Applied Chemistry, Nagoya University, and in part by a National Science Foundation Grant-G3599. Mention should be made that a brief description of the results obtained above has been presented elsewhere.⁹⁾

On the Variational Problem connected with the Thomas Fermi Method

By Yukito TANABE

Department of Applied Physics, Faculty of Engineering, Tokyo University, Tokyo

(Received June 13, 1957)

The Thomas-Fermi method has been applied not only to the problems of free atoms and ions but also to those of molecules and solids. To solve the appropriate three dimensional Thomas-Fermi (T.F.) equation in the latter problems is, however, extremely difficult because of the lack of the sperical symmetry[1]. In order to avoid this difficulty the problem is usually reduced to that of spherical symmetry under a suitable approximation. However, whether this approximation is good or not is not clear, and to improve the result by including the angle-dependent terms in the T.F. function is still more difficult. Therefore it seems desirable to apply the variational technique to these problems.

The attempt to connect the T.F. equation and the variational principle has been done by Umeda[2] and more recently by Ikebe and Kato[3] for neutral atom, but it seems to the wrinter that the relation between the variational principle for the T.F. equation and the principle of energy minimum is not fully realized by these authors. The purpose of this note is to derive the variational principle for the T.F. equation of the many centre system from the principle of energy minimum and to show how the result could be used to find the degree of approximation.

Consider the molecular system consisting of several atomic nuclei and N electrons. Using the conventional notations, the total energy E in the statistical treatment is written in the following way:

$$E\left[\frac{1}{4\pi}\nabla V_e, e\rho, T\right]=\int d\tau\left\{\frac{1}{8\pi}(\nabla V_e)^2+\frac{1}{4\pi}\nabla V_e\cdot\nabla V_N\right\}+\int_T d\tau\kappa\rho^{5/3}, \qquad (1)$$

where T is the total volume occupied by each electron. The first term on the right hand side is the potential energy and the second is the kinetic energy of the electron system. The well-known relation between the charge density and the potential is obtained[4] by minimizing the above expression with respect to $\frac{1}{4\pi}\nabla V_e, e\rho$ and T under the subsidary conditions

$$\nabla\cdot\frac{1}{4\pi}\nabla V_e=\begin{cases}e\rho & \text{in } T\\ 0 & \text{otherwise,}\end{cases}$$

and

$$\int_T e\rho d\tau=N_e\,.$$

By introducing Lagrange's multipliers, the problem is converted to the minimum problem without the subsidary conditions and, imposing the natural condition on this problem, our problem is reduced to the maximization of the following functional (involutory transformation):

$$I[U,T]=N_eU(\infty)-\int d\tau\frac{1}{8\pi}(\nabla U-\nabla V_N)^2-\frac{1}{4\pi}\int_T d\tau\frac{2}{5}\mu U^{5/2*}, \qquad (2)$$

which is just the functional used by the above mentioned authors. From this maximum problem we can derive the usual T.F. equation together with the boundary conditions.

If we denote the correct T.F. energy by E_0, the above derivation ensures, for approximate U and ∇V_e, the inequality[5]

$$I[U,T']\leq E_0\leq E\left[\frac{1}{4\pi}\nabla V_e, T\right] \qquad (3)$$

This is equivalent to the inequality used by Ikebe and Kato to estimate the upper and lower bound of B_0. Furthermore, $8\pi\left\{E\left[\frac{1}{4\pi}\nabla V_e\right]-I[U]\right\}$ gives the upper bound of the mean square error of the approximate U or ∇V_e, as is easily shown[6].

The practical application of the variational priciple (2) is now being carried out for the problem of octahedral complex ion[7] and the details will be given in a later communication.

Magnetic Anisotropy in Connection with Rolling in the Course of Producing Single Crystals of Silicon Steel

By Tadayoshi YAMASHITA* and Eiji TATSUMOTO**

**Department of Physics, National Defense Academy*

***Department of Physics, Faculty of Science, Hirohima University*

(Received June 5, 1957)

In the single crystal strips (⊥) (001)-[100](1) produced by the special strain anneal method* from the commercial silicon steel sheets it has been discovered by one of the authors(2) that the energy is lower by 4×10^2 erg/cc, which corresponds to about 100 gr/mm^2 of the internal stress when the magnetization is in the perpendicular direction than in the parallel direction of the strips. In the present experiment, the cause of this anisotropy was investigated by means of the optical and electron microscopies.

Fig. 1. Optical microphotograph of electropolished surface. ×560.

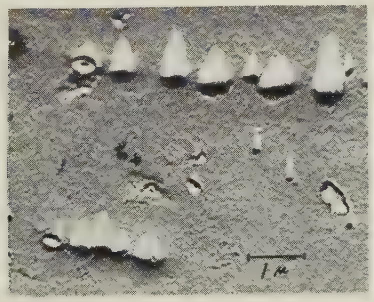

Fig. 2. Electronmicrograph of pits.

On the electropolished surfaces of the single crystals as well as the annealed polycrystals many arrays of the small pits are observed by the optical microscope as shown in Fig. 1. These pits are the nearly spherical holes as shown in Fig. 2 which is observed by the electron microscope by means of the carbon replica method shadowed by chromium. The arrays of the holes are always parallel to the rolling direction of the sheets. They are not influenced by the heatings before and after the preparation of the single crystals and are independent upon the crystal orientation and the processes of electropolishing. It is, thus, unquestionable that these holes are not produced by electropolishing, but the ones originally existed.

Magnetostatic energy due to the free poles appearing on the surfaces of the holes depends upon the direction of magnetization with respect to the arrays of the holes(3). The energy is the greatest and the smallest in the cases that the angles are 90° and 0° respectively. The energy difference between both extreme cases can be regarded as the anisotropy energy obtained already by one of us(2). It can be estimated easily with the average size, separation and density of the holes indicated in Fig. 3, and it is about 5×10^2 erg/cc. This value agrees satisfactorily with the observed 4×10^2 erg/cc.

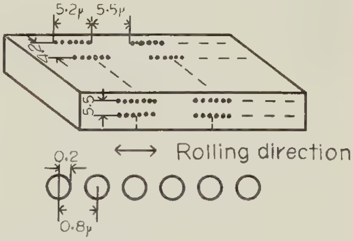

Fig. 3. Schematic diagram of average dimension and arrangement of holes.

In conclusion, the magnetic anisotropy associated with rolling may be attributed to the small pin holes linning up in groups parallel to the rolling direction of the sheets.

Etch Pits in Silicon Single Crystals

By Yasuo MATUKURA and Takeaki SUZUKI
Electrotechnical Laboratory, Tokyo, Japan

(Received May 21, 1957)

Since it is known that dislocations affect certain properties of semiconductors, a visual method for determining the number and distribution of such imperfections would have useful application both for practical tecknique and fundamental research. F. L. Vogel and L. C. Lovell[1] reported that the etching solution containing a small amount of mercuric nitrate was suitable to form clear etch pits in silicon. Presented here are some results of an investigation of methods for producing clearly defined dislocation etch pits in silicon with the etching solution containing potassium nitrate.

The composition of the etching solution is as follows:

4 parts HF (48%)
5 parts HNO$_3$ (75%)
2 parts glacial acetic acid
1/3 parts 1 mol % aqueous KNO$_3$.

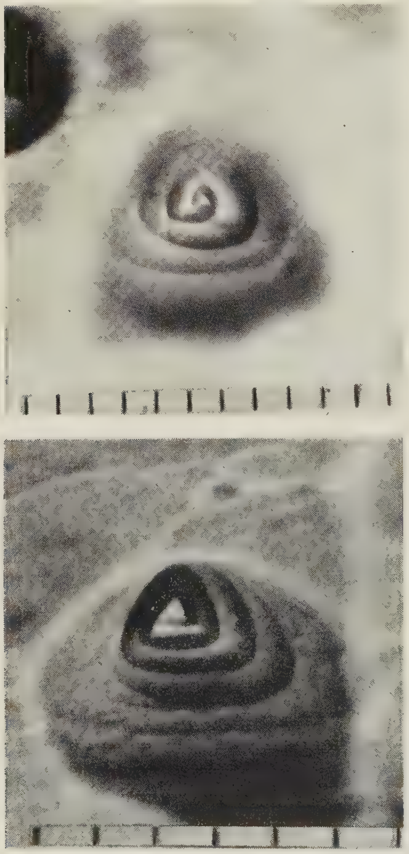

Fig. 1. Upper- and lower-handed screw etch pits on (111) surface of silicon crystal. One division of the scale is $10\,\mu$.

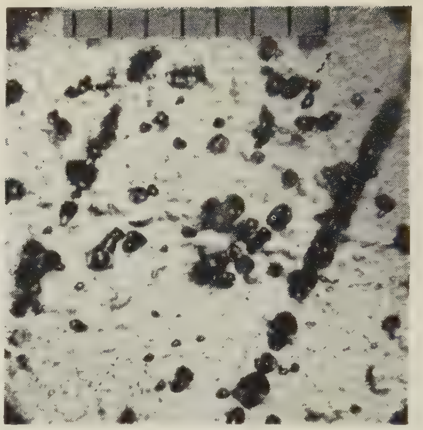

Fig. 2. Dislocation etch pits in slip lines. One division of the scale is $100\,\mu$.

Deionized water is used to make the potassium nitrate solution, and it has been found that excess water roughen the final surface.

The etching technique used is as follows. First, crystals are oriented and cut to expose the (111) surface. The surface is then lapped with 800 mesh carborundum on a glass plate. A light preliminary etching in CP-4 proved to be helpful in many cases in providing a smoother surface. Immersion in the etching solution for 20 minutes usually yields a well-defined, reproducible pits. In many cases, satisfactory results are obtained by etching for few seconds in CP-4 after the main etching.

The features of pits obtained are that its depth is reached to several ten microns and while the outline of shallow etch pits is trigonal, the upper outline of the deep ones is nearly circular, and that large pits with terraces or spiral terreces develop accasionally. Fig. 1 shows typical spiral etch pits which seem to indicate a screw dislocation[1], [2] or a lameller growth[3]. It is noticed that both upper- and lower-handed screw terraces are observed and the step heights are roughly reached to $10\,\mu$. Fig. 2 shows the array of dislocation etch pits, which may correspond to one of the slip lines.

The authors wish to express their gratitude to Mr. M. Kikuchi for various inspiring discussions.

A Characteristic of Tomotika-Tamada's Gas as Affecting the Velocity Distribution Around a Profile

By Hideo Takami
Department of Physics, Faculty of Science, University of Tokyo
and Humio Naruse
Department of Physics, Faculty of Science, Tokyo Metropolitan University

(Received June 8, 1957)

In previous papers [2] [3], present authors studied the compressible flow past a Tomotika-Tamada profile [4] by the use of various approximate methods. But certain discrepancy was seen to exist between their results and that of Tomotika and Tamada in the velocity distributions.

Here it will be shown that this discrepancy is attributed to the difference between the characteristics of Tomotika-Tamada's and the adiabatic gases.

(A) In our previous papers, the values of q/c_* were obtained from q/q_∞ by multiplying q_∞/c_* ($=0.748$ for $M_\infty=0.717$) corresponding to the adiabatic gas with $\gamma=1.4$. For comparison, however, we ought to have calculated $q/c_{*T}=(q/q_\infty)(q_\infty/c_{*T})$, where c_{*T} denotes the critical sound velocity for Tomotika-Tamada's gas. The factor q_∞/c_{*T} is calculated to be 0.769 from the pressure-density relation of this hypothetical gas.

(B) It has been shown by Imai [1] that, in applying the M^2-expansion or thin-wing-expansion method, a gas for which $p=p(\rho)$ (p: pressure, ρ: density) can be regarded, with high accuracy, as a gas with the adiabatic exponent $\gamma=1+[(\rho/c^2)\times d^2p/d\rho^2]_\infty$, where c is the sound velocity and the suffix ∞ denotes the value in the uniform flow. Using the (p, ρ)-relation for Tomotika-Tamada's gas we calculated $1+(\rho/c^2)\,d^2p/d\rho^2$ for various values of q/c_{*T} (Fig. 1). The value of $1+[(\rho/c^2)\,d^2p/d\rho^2]_\infty$ for our case is found to be 1.822 from Fig. 1, so that our previous values of q/q_∞ must be modified in the second approximation, because γ appears for the first time in this approximation.

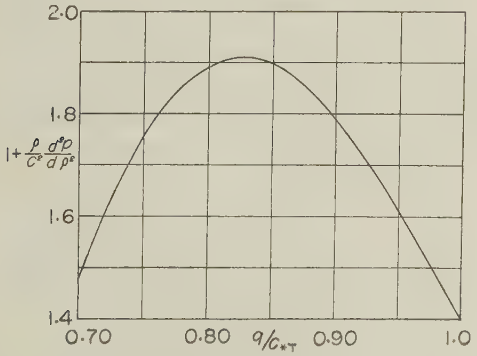

Fig. 1. $1+(\rho/c^2)d^2p/d\rho^2$ for various values of q/c_{*T}, calculated by using the (p, ρ)-relation for Tomotika-Tamada's gas.

The final results are shown in Fig. 2. (For comparison, one of the previous results for the adiabatic gas is also shown.) Modification due to (A) results in an increase of the velocity about 3%, while the increment due to (B) is less than 0.4%, so that we can say that the discrepancy was mainly due to the difference between the critical sound velocities of the two kinds of gases.

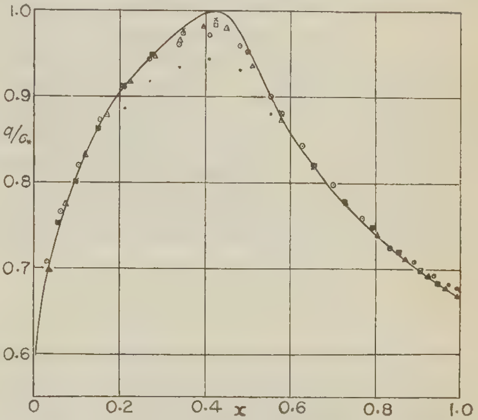

Fig. 2. The velocity distributions over the surface of Tomotika-Tamada's profile ($M_\infty=0.717$), modified due to (A).

Notes on the Ground State of Antiferromagnetism

By Ôjirô NAGAI

Department of Physics, Faculty of Science,
Kyusyu University

(Received June 11, 1957)

Recently, Marshall[1] and Taketa and Nakamura[2] generalized Hulthen's[3] and Kasteleijn's[4] methods of obtaining the ground state of antiferromagnetism to the cases of two and three dimensional lattices.

In particular, Kasteleijn and Taketa and Nakamura studied the anisotropic exchange Hamiltonian

$$\mathscr{H}=(1-a)J\sum_{<j,k>}(S_j{}^+S_k{}^-+S_j{}^-S_k{}^+)+2J\sum_{<j,k>}S_j{}^zS_k{}^z$$

where all the notations in this note are the same as those of Taketa and Nakamura. They obtained the critical values of the anisotropic parameter a at which the system becomes antiferromagnetic. In Taketa and Nakamura's calculation, it was found that with increasing coordination number the critical value decreases rapidly.

On the other hand, Marshall calculated the ground energy by a method different from Taketa and Nakamura's. He took into account partly the correlation among the spins neighbouring to a spin pair, which was neglected in Taketa and Nakamura's procedure. If the correlation among the spins could stabilize the antiferromagnetic ordering, the critical values from Marshall's treatment should be smaller than those from Taketa and Nakamura's.

Hence the writer calculated the critical values in Marshall's treatment. They are pretty higher than those from Taketa and Nakamura's as can be seen in Table I. In actual matters, spins are ordering without or with very small anisotropic effective fields.

In Table II, we should note that the numbers of antiparallel pairs from Marshall's and Taketa and Nakamura's treatments are decreasing with increasing coordination number. These results are contrary to our anticipation that with increasing number of neighbouring magnetic atoms the antiparallel orientations of spin pairs should be bound more tightly[5]. The results from the spin wave theory[6] prove our correct anticipation.

Table I. The critical values of a. z is the coordination number.

Method	$z=2$	$z=4$	$z=6$	$z=8$
Taketa and Nakamura	0.517	0.108	0.046	0.024
Marshall	0.517	0.193	0.080	—

Table II. The numbers of antiparallel pairs, $q/\frac{1}{2}Nz$, where q denotes the number of antiparallel pairs and N is the total number of spins.

Method	$z=2$	$z=4$	$z=6$	$z=8$
Taketa and Nakamura	0.774	0.637	0.589	0.566
Marshall	0.774	0.681	0.624	0.609
Spin Wave Theory	—	0.607	0.844	0.882

From the above facts, we may conclude that both Marshall's and Taketa and Nakamura's treatments overestimate the quantum effect arising from the non-diagonal elements of Hamiltonian and especially Marshall's method is not always better than Taketa and Nakamura's method.

The writer wishes to express his sincere thanks to Dr. T. Nakamura for his continual interest and and encouragement.

Also, the writer is much indebted to Professor T. Tanaka for his kind inspection of the manuscript and to Mr. S. Tosima for his helpful discussions.

Acoustoelectric Effect in n-type Germanium

Wataru SASAKI and Eiichi YOSHIDA
Electrotechnical Laboratory, Nagatacho, Tokyo

(Received June 8, 1957)

Parmenter[1] suggested that electrons in a conductive crystal could be dragged by progressive acoustic waves in the crystal. We have observed this effect in an n-type germanium crystal.

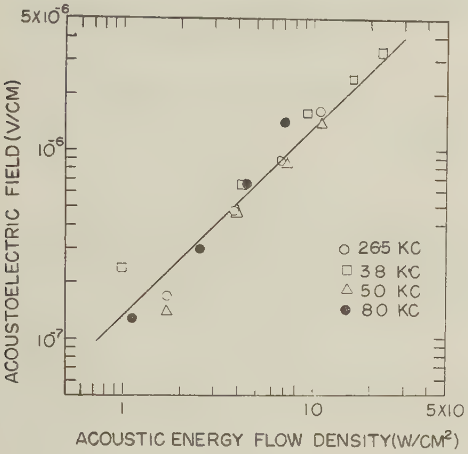

Fig. 1.

Longitudinal acoustic wave was excited by a magnetostrictive oscillator attatched on one end of the acoustic system, and the acoustic energy passed through the specimen was dissipated in copper wire on the other end. The copper wire was put in a water bath and the acoustic energy flow was estimated by the temperature rise of this bath.

The specimen used was a single crystal of n-type germanium of about 5.5 ohm-cm, and was 1.5 cm in length with cross sectional dimensions of 0.2 cm.

The open circuit voltage induced in the specimen by chopped acoustic wave was measured by a tuned phase sensitive amplifier. The frequency of the acoustic wave was varied from 26.5 kc to 80 kc/sec, thus the wave length of these waves was far beyond the dimensions of the specimen. The result of the experiment at room temperature is shown in Fig. 1.

Following features are noticeable.

a) The sign of the induced electric field is such that the short circuitted current is carried in the crystal by majority carriers moving in the same direction with acoustic wave.

b) The induce electric field is proportional to the acoustic energy flow density.

c) The induced electric field per unit acoustic energy flow density varies little with acoustic frequency.

In regard to (a), our observation agree with the prediction by Parmenter[1], but not with the revision of his theory by Weinreich[2]. As for the magnitude of the effect, our observation is extremely smaller than Parmenter's estimation, and Weinreich's comment on Parmenter's treatment of the problem should be justified.

The authors wish to represent their thanks to G. M. Hatoyama and M. Shibuya for their interest and discussions to this work.

Elastic Scattering of 5.7 MeV Protons

By Minoru TAKEDA, Michiya KONDO, Ryuzo NAKASIMA, Chuin HU, Atsutomo TOI*, Takashi YAMAZAKI and Shotaro YAMABE
Department of Physics, Osaka University, Osaka
**Kobe University of Mercantile Marine, Kobe*

(Received May 17, 1957)

It has been pointed out experimentally[1),2)] that the angular dependences of the deviations from the Rutherford scattering for Cu and Ni have characteristic features. In particular, the behaviors at large angles are very different for both elements. Bromley and Wall[1)] suggested that these pronounced differences may be due to the spin dependent nuclear interaction.

We have extended these investigations for other adjacent elements in order to check the suggestion of Bromley and Wall by means of nuclear emulsion technique. The experimental arrangement and procedure were same as our previous work[2)]. Fe($Z=26$), Cr($Z=24$) and Ti($Z=22$) were chosen as the targets, and also the elastic scattering of 5.7 MeV protons on gold was examined. The Fe target was a self-supporting foil of 3.8 mg/cm^2 thick and the thickness of Au target was 1.9 mg/cm^2.

The results obtained are shown in Fig. 1. In the case of gold, the differential cross section agrees with that of the Rutherford scattering as is expected. For iron, however, the differential cross section, in the ratio to the Rutherford cross section, increases linearly at large angles. The shape of this rise at large angles is quite similar to that of previous results on Ni. Preliminary results on Cr and Ti show also the same situations.

Although our present experiments are restricted in the target nuclei with zero spin (even-even nuclei), the data of the elastic scattering of protons from neighbouring odd-A nuclei (with non-zero spin) should be accumulated in order to emphasize the presence of these characteristics in even-even nuclei of medium weight region.

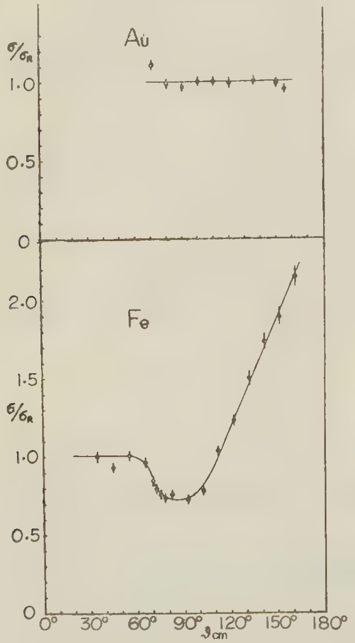

Fig. 1. Angular dependences of the deviations from the Rutherford scatterings for Au and Fe.

We are now scanning the plates for Cr and Ti to establish more complete data, and the report of these results will be published in near future.

Series Expansion of the Fermi Part η_0 of the TF Function[*]

By Shigehiro Kobayashi

Department of Physics, Kagawa University, Takamatsu

(Received June 25, 1957)

The Fermi part $\eta_0(x)$ in the Thomas-Fermi (TF) function $\phi(x)$ for free positive ion expressed approximately with the ordinary TF function $\phi_0(x)$ as

$$\phi(x)=\phi_0(x)+k\eta_0(x)\,,$$

where k is a constant depending on the ionization degree q roughly as $k=-0.0542\cdot q^{2.86}$[**], is given numerically in a table refined recently by the present author1).

In the course of evaluation of some physical quantities, for example atomic scattering factor etc., using its tabulated values, the series expansion of it near the origin is often needed. Thus, it has been calculated here up to the term $x^{19/2}$ as follows.

$$\begin{aligned}\eta_0(x)=&\,x+\frac{2}{5}x^{5/2}+\frac{3}{35}B_0x^{7/2}+\frac{2}{15}x^4-\frac{1}{84}B_0^2x^{9/2}+\frac{2}{175}B_0x^5+\frac{1}{33}\left(\frac{31}{45}+\frac{1}{8}B_0^3\right)x^{11/2}+\frac{4}{525}B_0^2x^6\\&+\frac{1}{286}B_0\left(\frac{557}{175}-\frac{15}{32}B_0^3\right)x^{13/2}+\frac{4}{693}\left(1-\frac{29}{35}B_0^3\right)x^7+\frac{7}{520}B_0^2\left(-\frac{89}{225}+\frac{1}{16}B_0^3\right)x^{15/2}\\&+\frac{4}{3003}B_0\left(-\frac{23}{15}+\frac{17}{7}B_0^3\right)x^8+\frac{1}{20}\left(-\frac{113}{58905}+\frac{153173}{1455300}B_0^3-\frac{21}{2176}B_0^6\right)x^{17/2}\\&+\frac{2}{3465}B_0^3\left(\frac{523}{65}+4B_0^3\right)x^9+\frac{1}{76}B_0\left(\frac{101523673}{58351293}-\frac{38221171}{104264160}B_0^3+\frac{99}{4352}B_0^6\right)x^{19/2}\\&+\cdots\cdots\cdots,\end{aligned}$$

where $B_0=1.5880710$ is the initial slope of $\phi_0(x)$, as given previously by the present author and others2).

The author wishes to express his sincere thanks to Professor K. Umeda of Okayama University for his kind guidance.

Supplementary Note to "On the Transonic Flow past a Nearly Axisymmetric Slender Body"

By Ken-ichi KUSUKAWA

Department of Physics, Faculty of Science
Tokyo Metropolitan University

(Received July 5, 1957)

In a recent paper[1], the perturbation velocity potential φ of the transonic flow of a compressible fluid past a nearly axisymmetric slender body was expanded into Fourier series as

$$\varphi=u_0(x,r)+\sum_{n=1}^{\infty}u_n(x,r)\cos(n\theta+\beta_n)\ , \qquad (1)$$

and the surface of the body was represented by

$$R=F(x,\theta)=F_0(x)+\sum_{n=1}^{\infty}F_n(x)\cos(n\theta+\alpha_n)\ , \qquad (2)$$

where x, r, θ denote the cylindrical coordinates.

Considering the singularity along the axis, the order estimation of the usual slender body theory[2],[3] may be available near the surface. Since the body is nearly axisymmetric, we can assume $O(F_n)=O(t)O(F_0)$ and $O(u_n)=O(t)O(u_0)$, where t is the thickness ratio. Thus the pressure coefficient C_p on the surface of the body is given by

$$C_p=-2(\partial\varphi/\partial x)-(\partial\varphi/\partial r)^2+O(t^4\log^2 t)\ , \qquad (3)$$

and the use of the linearized equation (4.12) of Reference [1] does not give the correct value of the pressure. The boundary condition on the surface of the body is expressed by

$$(\partial\varphi/\partial r)_{r=F}=dF/dx\ . \qquad (4)$$

In the previous paper[1], the left hand side of Eq. (4) was approximately replaced by the value on the surface of a body of revolution represented by $r=F_0(x)$. However, for the purpose of evaluating the correct pressure by Eq. (3), we have to refine the treatment as follows:

$$\left(\frac{\partial\varphi}{\partial r}\right)_{r=F}=\left(\frac{\partial\varphi}{\partial r}\right)_{r=F_0}-\frac{1}{F_0}\frac{dF_0}{dx}(F-F_0)\ , \qquad (5)$$

$$\left(\frac{\partial\varphi}{\partial x}\right)_{r=F}=\left(\frac{\partial\varphi}{\partial x}\right)_{r=F_0}+\frac{1}{F_0}\frac{d}{dx}\left(F_0\frac{dF_0}{dx}\right)(F-F_0)\ . \qquad (6)$$

Consequently the pressure on the surface is given by

$$C_p=C_{p0}+2\sum_{n=1}^{\infty}\left[\frac{1}{nF_0{}^n}\frac{d}{dx}\left\{F_0{}^n\frac{d}{dx}(F_0F_n)\right\}-\frac{dF_0}{dx}\frac{dF_n}{dx}-\frac{F_n}{F_0}\frac{d}{dx}\left(F_0\frac{dF_0}{dx}\right)\right]\cos(n\theta+\alpha_n)\ , \qquad (7)$$

where C_{p0} denotes pressure coefficient on the surface of the body of revolution. The distributions of C_{p0} were obtained by Yoshihara[4] for a cone-cylinder (relaxation method), and by the present author[5],[6] for several bodies of revolution with a curved surface (approximate treatment).

Finally we shall study the transonic flow past a body of revolution with a flat base at a small incidence α. Assuming $O(\alpha/t)=O(t)$, Eq. (7) becomes

$$C_p=C_{p0}-4\alpha F_0'(x)\cos\theta\ . \qquad (8)$$

Integrating Eq. (8), and taking account of the base pressure, the drag and the lift coefficients C_d, C_L are obtained as follows:

$$C_d=C_{d0}+O(t^4\log^2 t)\ , \qquad (9)$$

$$C_L=2\alpha+O(t^3\log^2 t)\ , \qquad (10)$$

where C_{d0} denotes the value at zero incidence, and is of the order of $O(t^2\log t)$ for a pointed body. (cf. Eq. (6.47) of Reference [5].) These results are consistent with those for the supersonic flow obtained by the slender body theory[3]. On the other hand, the head drag coefficient of a paraboloid of revolution of finite length at sonic and high subsonic speeds is of the order of $O(t^2)$[1],[5],[6].

Theory of the Wiedemann Effect

By Mikio YAMAMOTO

The Research Institute for Iron,
Steel and Other Metals,
Tôhoku University

(Received May 27, 1957)

As regards the classical problem of the Wiedemann effect in ferromagnetic polycrystalline substance, any satisfactory theory has not yet been proposed, except Fromy's[1] theory for the case of a thin-walled tube specimen which has been almost entirely neglected in the literature. I give here a theory of the effect for the case of a cylindrical rod specimen, which involves Fromy's theory as a limiting case.

Let us consider a ferromagnetic cylindrical-rod specimen with the diameter a which is fixed at its one end. When this rod is magnetized under longitudinal magnetic field, $\vec{H}_l$, parallel to, and circular field, $\vec{H}_c$, centered at, the rod axis, the resultant magnetic field, H_r, at a point P in the specimen apart from the rod axis by the distance r, is given by $(H_l{}^2+H_{cr}{}^2)^{1/2}$ (H_{cr} is H_c at P), pointing to a direction which makes an angle $\varphi_r=\tan^{-1}(H_{cr}/H_l)$ against the direction of $\vec{H}_l$. The magnetization, $\vec{I}_r$, at P takes a direction for which the sum of the magnetic field and elastic energies is minimum and thus the direction of $\vec{I}_r$ generally does not coincides with that of $\vec{H}_r$ but makes a small angle ε_r with the direction of $\vec{H}_r$ in the $(\vec{H}_l, \vec{H}_{cr})$ plane. Of the components of magnetostrictive strain tensor associated with $\vec{I}_r$, referred to the cylindrical coodinate system (r, z, θ), of which the z axis is the rod axis and the r axis is the direction of radius passing through P, e_{rr}, $e_{\theta\theta}$, e_{zz}, and

$$e_{\theta z}=2\{\lambda_l(I_r)-\lambda_t(I_r)\}\cdot I_{rl}I_{rc}/I_r{}^2 \qquad (1)$$

are not zero, where $\lambda_l(I_r)$ and $\lambda_t(I_r)$ are, respectively, the longitudinal and transverse magnetostrictions associated with $\vec{I}_r$, $I_{rl}=I_r\cos(\varphi_r+\varepsilon_r)$, and $I_{rc}=I_r\sin(\varphi_r+\varepsilon_r)$. $e_{\theta z}$ expresses the shear of unit volume at P along the direction of the rod axis and that along the direction normal to it and the unit volume may be regarded as fixed at its one face, so that $e_{\theta z}$ results the torsion

$$\theta_r=e_{\theta z}/r=(2/r)\{\lambda_l(I_r)-\lambda_t(I_r)\}\cdot I_{rl}I_{rc}/I_r{}^2\,, \qquad (2)$$

this torsion being the Wiedemann effect.

Now, for normal ferromagnetic substances, in which the elastic energy is far smaller than the magnetic field energy and hence the direction of $\vec{I}_r$ coincides with that of $\vec{H}_r$, Eq. (2) may be written as

$$\theta_r=(2/r)\{\lambda_l(H_r)-\lambda_t(H_r)\}\cdot H_lH_{cr}/H_r{}^2\,, \qquad (3)$$

which becomes, for the surface of the rod,

$$\theta_a=(2/a)\{\lambda_l(H_a)-\lambda_t(H_a)\}\cdot H_lH_c{}^a/H_a{}^2\,. \qquad (4)$$

Eq. (4), which holds also for a thin-walled tube, is the expression derived already by Fromy[1] through an elementally and hence lengthy consideration.

Further, if the volume magnetostriction may be neglected as in normal ferromagnetics, Eq. (4) reduces simply to

$$\theta_a=(3/a)\lambda_l(H_a)\cdot H_lH_{ca}/H_a{}^2\,. \qquad (5)$$

It can be shown that Eq. (5) explains quantitatively well all of available experimental facts regarding the Wiedemann effect of cylindrical rod specimens.

Multichannel Angular Correlation Measurement of Gamma Rays from the Disintegration of Ag^{110m} and Spin Assignment of Excited Levels of Cd^{110}

By Mitsuo SAKAI*, Haruko OHMURA and Teruo MOMOTA

Department of Physics, Faculty of Science, University of Tokyo

(Received May 9, 1957)

The angular correlation of gamma rays from the disintegration of Ag^{110} has been studied with scintillation spectrometers. Ten correlation functions were measured by taking advantage of multichannel characteristic of a twenty-channel pulse height analyzer. The spin values of Cd^{110} in 2.93, 2.48, and 1.54-MeV excited states were found to be 3−, 2+ and 2± respectively and the radiation characteristic of three gamma rays of energies 0.885, 0.935 and 1.390-MeV were also determined.

§1. Introduction

The energy levels of Cd^{110} have been studied on the basis of the decay schemes of Ag^{110}, Ag^{110m} In^{110}, and In^{110m} by a number of investigators. Especially, the complex radiations from the disintegration of Ag^{110m} were studied very carefully by K. Siegbahn, measuring conversion electrons and photoelectrons with beta-ray spectrometer and a decay scheme was proposed by help of Ritz's law in nuclear spectroscopy and of the intensity ratio of gamma rays[1),2)]. The proposed decay scheme is presented in Fig. 1. Since then scintillation counter techniques being developed remarkably, it seems worth while to reexamine the level scheme of the daughter nuclide Cd^{110} by using these techniques. Moreover the advanced angular correlation technique makes one possible for assigning spin values to this complex level system.

In the pursuit of the present work, use of a multi-channel pulse height analyzer is believed to have been essential for the reduction of errors which is due to long-term variation of experimental conditions. In the present work, a twenty-channel pulse height analyzer was used, and the angular correlation functions of several energy intervals in the pulse height spectrum taken by this spectrometer were analyzed on the basis of the decay scheme newly confirmed by the present gamma-gamma scintillation coincidence measurements.

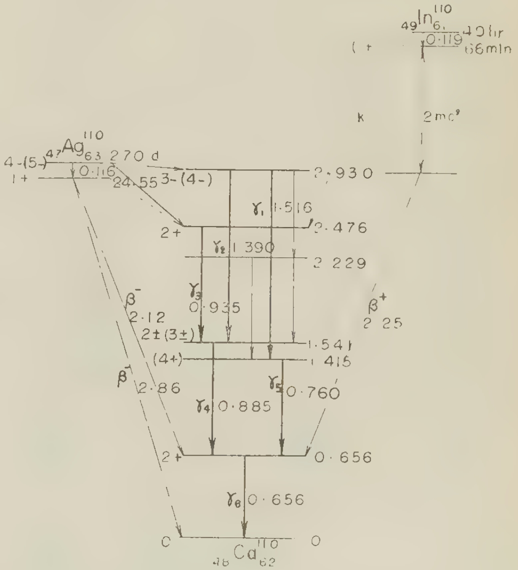

Fig. 1. Level Scheme of Cd^{110}. The studies of In^{110} have not been performed precisely.

§2. Genetic Relation of Gamma Rays

The apparatus consisted of a single channel pulse height analyzer (reference analyzer) and an Atomic twenty-channel pulse height analyzer (main analyzer). The former selected pulses of a certain pulse height from the reference counter and sent to the coincidence unit in the main analyzer. The latter sorted those pulses from the main counter which coincided with the reference channel pulses. The gamma-ray detector attached to the main analyzer was a DuMont 6292 photo-multiplier tube coupled with a mounted 1½″×1″ NaI (Tl) crystal and that of the reference analyzer was a RCA 5819 photo-multiplier tube coupl-

ed with a $1\frac{1}{2}'' \times 1\frac{1}{2}''$NaI(Tl) crystal. Fig. 2 shows the total pulse height spectrum taken by the main analyzer. Arrows show the pulse-height positions of the full-energy peaks of gamma rays which are indicated as γ_1 through γ_6 (see Fig. 1.)

The genetic relations of γ_1 and γ_2 to the other gamma rays were first investigated. A, B and C in Fig. 3 are the coincidence pulse height spectra taken with the gate of the reference analyzer set at a(1.65-MeV), b(1.55-MeV) and c(1.40-MeV) respectively. The ordinate shows counting rate of the main analyzer relative to the normalized counting rate of the reference analyzer. From these spectra following facts are revealed.

1) The genetic relation between γ_1 and γ_6 is the same as that between γ_2 and γ_6 because the height of each spectrum at 0.65-MeV are almost equal.
2) The coincidence rate at 0.76-MeV decreases in order of A, B and C. This fact can be explained by the genetic relation between γ_1 and γ_5.
3) The coincidence counting rate at 0.885-MeV region increases rapidly in order of A, B and C. The presence of the genetic relation between γ_2 and γ_4 is evident. The partial scheme in the inset of Fig. 3 is thus confirmed.

Next the genetic relation of γ_3 and γ_4 was investigated. In this case the gate of the reference analyzer was set at d(0.96-MeV), e(0.89-MeV) and f(0.82-MeV). (See Fig. 4 inset). The coincidence spectra taken with the main analyzer are presented in Fig. 4 as D, E and F respectively. From these curves one is led to the following conclusions.

4) The coincidence peak at 0.65-MeV shows the presence of the genetic relation of γ_3 and γ_4 to γ_6 and the fact that this peak diminished in order of D, E and F indicates that γ_4 coincides with γ_6, and partly with γ_3. This means that the emission of γ_3 is earlier than that of γ_4.
5) The width of the 0.65-MeV peak of the D-curve is narrower than those of the others. This seems to indicate the coincidence of γ_4 with weak gamma rays of 0.706-MeV and 0.671-Mev reported by K. Siegbahn[1].
6) The peak at about 0.9-MeV moves to the high energy side in order of D, E and F,

This fact indicates the cascade relation of γ_3 and γ_4. The partial decay scheme inserted in Fig. 4 is thus confirmed.

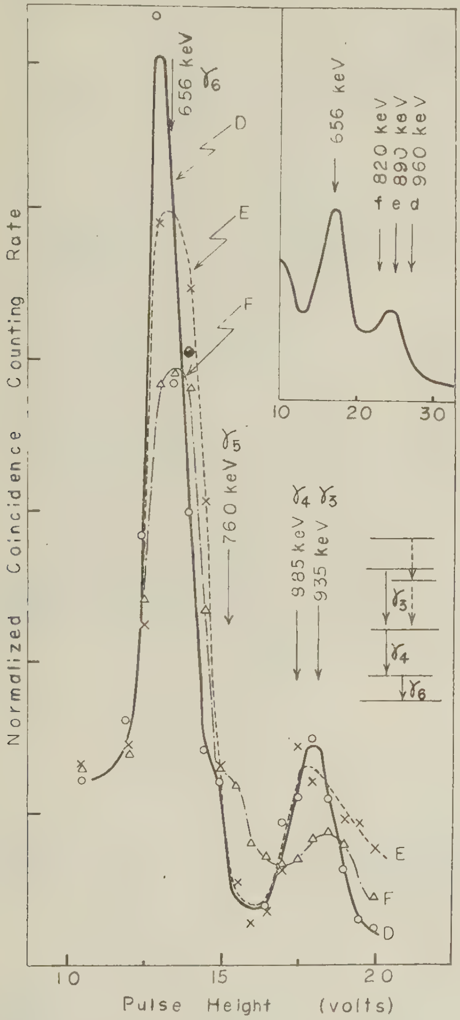

Fig. 4. Coincidence spectra. D, E and F are the coincidence spectra taken by setting the reference gate at d, e and f. The normalization of the curves is same as that in Fig. 3.

By combining above two measurements the main scheme of gamma ray transitions as proposed by K. Siegbahn[1] is established.

§ 3. Angular Correlation Experiment

The angular correlation function is usually written in the form:

$$W(\theta)=1+G_2A_2P_2(\cos\theta)+G_4A_4P_4(\cos\theta), \quad (1)$$

where A_2 and A_4 are the correlation coefficients and G_2* and G_4* are the geometrical attenuation coefficients. The same apparatus was used as in the preceding section. The coefficients G_2, G_4 were deduced from the resolution curve of the annihilation radiation of Co^{56} by Church and Kraushaar's method[3], and their magnitudes were found to be 0.930 and 0.782 respectively. The characteristic of the apparatus was checked by measuring the well-known angular correlation function of gamma rays from Co^{60}. The result is presented in Fig. 5. The agreement with theory is satisfactory.

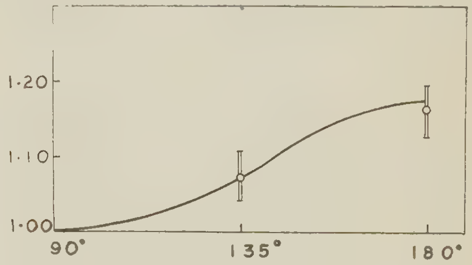

Fig. 5. Angular correlation of Co^{60}. The curve presents the theoretical correlation function. The probable errors at 135° and 180° are taken account of the propagation of error at 90°.

For the Ag^{110m} experiment, the gate of the reference analyzer was set at three positions P_A', P_3' and P_4' shown in Fig. 6b. When the gate was set at P_4', the pulses resistered by the main pulse sorter were composed in the coincidence pulses with those pulses which corresponded to the full energy peak of γ_4 and a certain portions of continuous pluse height spectra of γ_3, γ_2 and γ_1. Similarly, when the gate was set at P_3', pulses corresponding to full energy peak of γ_3 and a portion of Compton plateaus of γ_2 and γ_1 were permitted to pass to the main pulse sorter; while at P_A', Compton pulses of γ_2 and γ_1 only.

For each gate setting of the reference analyzer, coincidence rates in four regions of the pulse height spectrum were taken with the main counter at angles of 90°, 135°, and 180° with respect to the reference one. The four regions mentioned above consisted of R_I'', R_{II}'', R_{III}'' and R_{IV}'', as shown in Fig. 6a, the first of which comprised Compton plateaus of six gamma rays; the second the full energy peak of γ_6 and Compton plateaus

---

* The attenuation due to the extra-nuclear field was not considered in the present paper, because the source was used in the form of an aqueous silver nitrate solution.

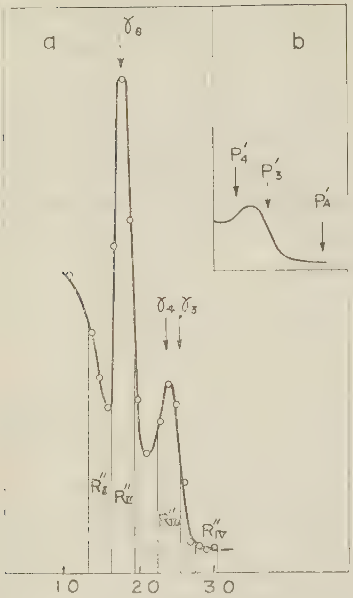

Fig. 6. Pulse-height intervals concidered in the angular correlation masurement of gamma rays from the disintegration of Ag^{110m}. The figure b shows the gate settings in the reference channel.

of γ_5 through γ_1; the third full energy peaks of γ_4 and γ_3 and Compton plateaus of γ_2 and γ_1; while the fourth Compton plateaus of γ_2 and γ_1 only. By this procedure ten possible correlation data were obtained.
They are presented in Table I.

Table I. Coincidence Counting Rate per 10 min.

	90°	135°	180°
$\langle P_A', R_{III}''\rangle$	5.98±0.16	5.24±0.15	4.61±0.14
$\langle P_A', R_{II}''\rangle$	20.18±0.42	17.79±0.40	14.64±0.37
$\langle P_A', R_I''\rangle$	11.14±0.36	9.16±0.30	8.73±0.29
$\langle P_3', R_{III}''\rangle$	29.52±0.62	28.82±0.60	29.91±0.62
$\langle P_3', R_{II}''\rangle$	81.30±0.98	82.44±1.03	78.60±0.97
$\langle P_3', R_I''\rangle$	38.52±0.68	37.87±0.70	37.49±0.72
$\langle P_4', R_{IV}''\rangle$	7.64±0.34	6.83±0.32	5.89±0.30
$\langle P_4', R_{III}''\rangle$	44.38±0.82	43.79±0.81	45.06±0.83
$\langle P_4', R_{II}''\rangle$	156.88±1.54	161.58±1.56	166.39±1.59
$\langle P_4', R_I''\rangle$	67.45±1.01	65.53±1.00	68.06±1.01

The mentioned coincidence counting rates can be written down as the sum of partial ones according to the decay scheme confirmed in the preceding section.

$$\langle P_A', R_{III}''\rangle=\langle n_2(P_A'), n_4(R_{III}'')\rangle \tag{2}$$

$$\begin{aligned}\langle P_A', R_{II}''\rangle=&\langle n_2(P_A'), n_4(R_{II}'')\rangle+\langle n_2(P_A'), n_6(R_{II}'')\rangle\\&+\langle n_1(P_A'), n_5(R_{II}'')\rangle+\langle n_1(P_A'), n_6(R_{II}'')\rangle\end{aligned} \tag{3}$$

$$\begin{aligned}\langle P_A', R_I''\rangle=&\langle n_2(P_A'), n_4(R_I'')\rangle+\langle n_2(P_A'), n_6(R_I'')\rangle\\&+\langle n_1(P_A'), n_5((R_I'')\rangle+\langle n_1(P_A'), n_6(R_I'')\rangle\end{aligned} \tag{4}$$

$$\langle P_3', R_{III}''\rangle=\langle n_3(P_3'), n_4(R_{III}'')\rangle+\langle P_A', R_{III}''\rangle \tag{5}$$

$$\langle P_3', R_{II}''\rangle=\langle n_3(P_3'), n_6(R_{II}'')\rangle+\langle n_3(P_3'), n_4(R_{II}'')\rangle+\langle P_A', R_{II}''\rangle \tag{6}$$

$$\langle P_3', R_I''\rangle=\langle n_3(P_3'), n_6(R_I'')\rangle+\langle n_3(P_3'), n_4(R_I'')\rangle+\langle P_A', R_I''\rangle \tag{7}$$

$$\langle P_4', R_{IV}''\rangle=\langle n_4(P_4'), n_2(R_{IV}'')\rangle \tag{8}$$

$$\langle P_4', R_{III}''\rangle=\langle n_3(P_4'), n_4(R_{III}'')\rangle+\langle n_4(P_4'), n_3(R_{III}'')\rangle+\langle P_4', R_{IV}''\rangle+\langle P_A', R_{III}''\rangle \tag{9}$$

$$\begin{aligned}\langle P_4', R_{II}''\rangle=&\langle n_4(P_4'), n_6(R_{II}'')\rangle+\langle n_3(P_4'), n_6(R_{II}'')\rangle\\&+\langle n_3(P_4'), n_4(R_{II}'')\rangle+\langle n_4(P_4'), n_3(R_{II}'')\rangle+\langle P_4', R_{IV}''\rangle+\langle P_A', R_{II}''\rangle\end{aligned} \tag{10}$$

$$\begin{aligned}\langle P_4', R_I''\rangle=&\langle n_4(P_4'), n_6(R_I'')\rangle+\langle n_3(P_4'), n_6(R_I'')\rangle\\&+\langle n_3(P_4'), n_4(R_I'')\rangle+\langle n_4(P_4'), n_3(R_I'')\rangle+\langle P_4', R_{IV}''\rangle+\langle P_A', R_I''\rangle,\end{aligned} \tag{11}$$

where $\langle X, Y\rangle$ represents the coincidence rate between pulses with height specified by notation X and those specified by Y; $n_i(X)$ or $n_i(Y)$ are their partial counting rate, that is, counting rate due to the ith γ ray; and $\langle n_i(X), n_j(Y)\rangle$ stands for the coincidence rate between $n_i(X)$ and $n_j(Y)$. The following approximations were used for deriving the above formulas;

$$n_1(P_A')\approx n_1(P_3')\approx n_1(P_4'),$$

$$n_2(P_4')\approx n_2(P_3')\approx n_2(P_4')$$

and

$$n_2(R_{\rm I}'')\approx n_2(R_{\rm II}'')\approx n_2(R_{\rm III}'')\approx n_2({\rm R}_{\rm IV}'').$$

The correlation function for a cascade $\gamma_i-\gamma_j$ which is represented by $\langle n_i, n_j\rangle$ can be deduced from the above ten equations. $\langle n_2, n_4\rangle$ is given directly by Eqs. (2) or (8). The agreement between both results is perfect. $\langle n_3, n_4\rangle$ is obtained from Eqs. (5) or (9), by introducing Eqs. (2) or (8) to them. $\langle n_3, n_6\rangle$ can be derived by subtracting Eqs. (6) from (7), namely:

$$\begin{aligned}&\langle n_3(P_3'),\ n_6(R_{\rm II}''-R_{\rm I}''))\rangle\\&\quad=\langle P_3',\ R_{\rm II}''\rangle-\langle P_3',\ R_{\rm I}''\rangle+\langle P_4',\ R_{\rm I}''\rangle\\&\qquad-\langle P_4',\ R_{\rm II}''\rangle\end{aligned}\tag{12}$$

where an approximation $n_4(R_{\rm I}'')\approx n_4(R_{\rm II}'')$ is made. In the same procedure the following equation is obtained from Eqs. (10) and (11),

$$\begin{aligned}&\langle n_4(P_4'),\ n_6(R_{\rm II}''-R_{\rm I}''))\rangle+\langle n_3(P_4'),\\&\quad n_6(R_{\rm II}''-R_{\rm I}'))\rangle=\langle P_4',\ R_{\rm II}''\rangle-\langle P_4',\ R_{\rm I}''\rangle\\&+\langle P_4',\ R_{\rm I}''\rangle-\langle P_4',\ R_{\rm II}''\rangle\cdots\end{aligned}\tag{13}$$

Then the correlation function $\langle n_4, n_6\rangle$ is given by the following formula:

$$\begin{aligned}&\langle n_4(P_4'),\ n_6(R_{\rm II}''-R_{\rm I}''))\rangle\\&\qquad=\langle\beta\rangle-\frac{n_3(P_4')}{n_3(P_3')}\langle\alpha\rangle\ ,\end{aligned}$$

where $\langle\alpha\rangle$ and $\langle\beta\rangle$ denote the quantities expressed by (12) and (13) respectively. The ratio $n_3(P_4')/n_3(P_3')$ can not be estimated exactly. But this ambiguity scarcely influences on the anisotropy of $\langle n_4, n_6\rangle$. For instance, its variation from 0.4 to 0.7 produces a difference of only few per cent in the anisotropy. The experimental correlation functions are plotted in Fig. 7, and the numerical data are presented in Table II.

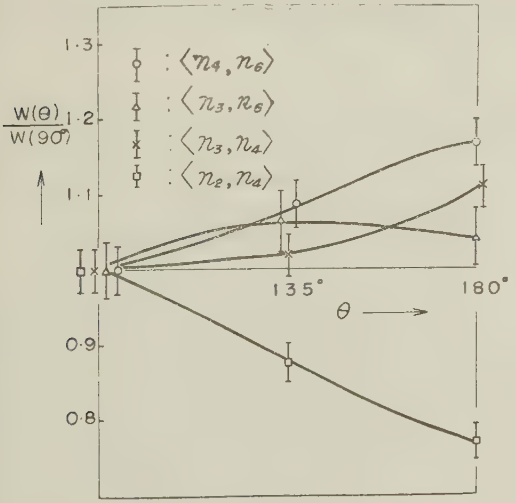

Fig. 7. Angular correlation functions.

Table II.

	90°	135°	180°
$\langle n_2, n_4\rangle$	1.000±0.027	0.876±0.025	0.770±0.023

$\langle n_4, n_6\rangle$	1.000±0.032	1.087±0.032	1.168±0.032

§ 4. Analysis of the Results

For analyzing the results of the preceding section, G_2A_2 and G_4A_4 were first calculated by making use of Eq. (1) and Table II. G_2 and G_4 being the known quantities, the values of A_2 and A_4 were obtained. The Table III is the list of A_2 and A_4.

Table III.

	A_2	A_4
$\langle n_4, n_6\rangle$	0.1151±0.0316	−0.0032±0.0339
$\langle n_3, n_4\rangle$	0.0577±0.0286	0.0366±0.0308
$\langle n_3, n_6\rangle$	0.0460±0.0381	−0.0486±0.0413
$\langle n_2, n_4\rangle$	−0.1835±0.0282	0.0114±0.0304

The characteristics of gamma rays γ_1 to γ_6 were analyzed according to Biedenharn and Rose's paper[4),5)] and Krohn and Roboy's paper[6)]. The former treated the mixed gamma-mixed gamma angular correlation and the latter treated the mixed gamma correlation with the intermediate radiation unobserved. The essential points of this analysis are as follows.

1) The first excited level was assumed to be 2+ because all first excited levels of even-even nuclei have spin 2+ with very few exceptions[7)].

2) The spin value of the third 1.54-MeV excited level was investigated for the possible cases of 2, 3 and 4.

The last possibility was, however, eliminated in this stage. The experimental A_2 and A_4 values of $\langle n_4, n_6\rangle$ agreed with the theoretical values for this case which were 0.102 and 0.0091 respectively. But if this spin sequence of 0–2–4 is the case, $\langle n_3, n_6\rangle$ should always be equal to $\langle n_3, n_4\rangle$. This fact can be easily verified by a simple calculation and the experimental values are in contradiction to this theorem[8]. Therefore we were led to the conclusion that this level did not have the spin value of 4.

So we have to seek the possibility for the case of spin 2 or 3, by searching the possible domain of the mixing ratio δ_4 of γ_4 which gives the correlation function consistent with the experimental data, where δ_4 is defined as the ratio of transition matrix element of $E2$ to that of $M1$[4]. The possible domains of δ_4 were found to be $0.12 < \delta_4(-) < 0.20$ and $0.22 < \delta_4(-) < 0.34$ for the cases of spin 2 and 3 respectively. (See Fig. 8).

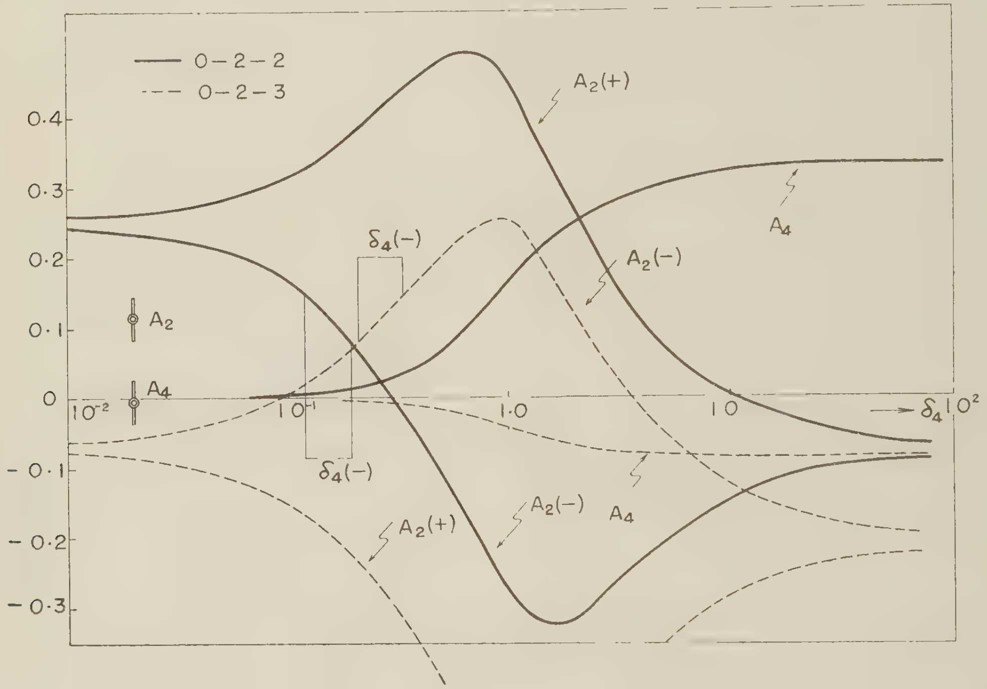

Fig. 8. Theoretical curves of A_2 and A_4 for the decay sequences of $2(\delta_4)2(Q)0$ and $3(\delta_4)2(Q)0$. The experimental values of A_2 and A_4 and the regions of probable mixing ratio are also indicated in the same figure.

3) The results of $\langle n_3, n_6\rangle$ and $\langle n_3, n_4\rangle$ enable use to make the cross check on the assignment for the fourth 2.48-MeV excited level. This means that for the fixed δ_4 obtained from the analysis of 2), we have to have the δ_3 value of γ_3 which can explain both of the correlation behavior of $\langle n_3, n_6\rangle$ and $\langle n_3, n_4\rangle$ at the same time. The analysis were made for the cases of the spin value 2, 3, 4 and 5. By this procedure many combinations of δ_4 and δ_3 were excluded.*

4) Using δ_4 consistent with the analysis of 2) and 3) the analysis was extended to the determination of spin value of the fifth 2.93-MeV excited level by using the data of $\langle n_2, n_4\rangle$ and the consistent domain of δ_2 was determined. The results of 3) and 4) are summarized in Table IV, a and b.

The possible spin sequence obtained from these analyses were listed in Table V.

Up to present, the spin sequence was discussed purely by the information from the gamma-gamma angular correlation experiments. For the further analysis, it is helpful to make use of the knowledges from the beta disintegration. As is well known, the spin of the ground state of Ag^{110} is 1+ because of the allowed characteristic of the two beta decays involved in this state to the ground and to the first excited state of the daughter nucleus of Cd^{110}. The K/L ratio of 116-KeV gamma ray from the isomeric state

---

* For this case the sign of δ_4 deduced from 2) should be changed in the deduction of the theoretical correlation function, according to its definition in Biedenharn and Rose's paper[4].

Table IV. a.

0-2-2 Sequence $0.12 < \delta_4(-) < 0.20$

Spin Sequence		$A_2(34)$	$A_4(34)$	$A_2(36)$	$A_4(36)$	$A_2(24)$	$A_4(24)$
	Experimental value	0.0577 ± 0.0286	0.0366 ± 0.0308	0.0460 ± 0.0381	-0.0486 ± 0.0413	-0.1835 ± 0.0283	0.0114 ± 0.0304
0- 2-2-2	Theoretical value	$\left\{\begin{matrix}-0.5532\\-0.6321\end{matrix}\right\}\alpha_{22}(\delta_3)$	$\left\{\begin{matrix}0.0013\\0.0036\end{matrix}\right\}\beta_{22}(\delta_3)$	$\left\{\begin{matrix}-0.2926\\-0.2826\end{matrix}\right\}\alpha_{22}(\delta_3)$	$\left\{\begin{matrix}-0.2125\\-0.2056\end{matrix}\right\}\beta_{22}(\delta_3)$	$\left\{\begin{matrix}-0.5532\\-0.6321\end{matrix}\right\}\alpha_{22}(\delta_2)$	$\left\{\begin{matrix}0.0013\\0.0036\end{matrix}\right\}\beta_{22}(\delta_2)$
	Remark	The possible region for δ_3 around -0.27 is found. The theoretical values for this case are as follows, $0.040 < A_2(34) < 0.046$, $0.0001 < A_4(34) < 0.0003$, $0.0206 < A_2(36) < 0.0213$ and $-0.0144 < A_4(36) < -0.0139$				The possible domains for δ_2 are $0.56 < \delta_2(-) < 0.72$ and $4.3 < \delta_2(-) < 10.0$	
0-2-2-3	Theoretical value	$\left\{\begin{matrix}-0.5532\\-0.6321\end{matrix}\right\}\alpha_{23}(\delta_3)$	$\left\{\begin{matrix}-0.0003\\-0.0009\end{matrix}\right\}\beta_{23}(\delta_3)$	$\left\{\begin{matrix}-0.2926\\-0.2826\end{matrix}\right\}\alpha_{23}(\delta_3)$	$\left\{\begin{matrix}0.0531\\0.0514\end{matrix}\right\}\beta_{23}(\delta_3)$	$\left\{\begin{matrix}-0.5532\\-0.6321\end{matrix}\right\}\alpha_{23}(\delta_2)$	$\left\{\begin{matrix}-0.0003\\-0.0009\end{matrix}\right\}\beta_{23}(\delta_2)$
	Remark	The remarkable contradiction of the theoretical $A_4(36)$ against the experimental one and a small discrepancy of $A_4(34)$ between the theoretical and the experimental one exclude the possibility of this spin sequence.				The δ_2 value in the domains of $0.10 < \delta_2(+) < 0.18$, $50 < \delta_2(+)$ and $13 < \delta_2(-)$ makes the experimental value consistent with the theoretical one.	
0-2-2 4	Theoretical value	$\left\{\begin{matrix}0.0946\\0.1081\end{matrix}\right\}$	$\left\{\begin{matrix}0.00004\\0.0001\end{matrix}\right\}$	$\left\{\begin{matrix}0.0500\\0.0483\end{matrix}\right\}$	$\left\{\begin{matrix}-0.0059\\-0.0057\end{matrix}\right\}$	$\left\{\begin{matrix}0.0946\\0.1081\end{matrix}\right\}$	$\left\{\begin{matrix}0.00004\\0.0001\end{matrix}\right\}$
	Remark	The theoretical values of $A_2(34)$, $A_4(34)$ and $A_4(36)$ are just outside of the experimental ones. Therefore this spin sequence must be eliminated.				The positive theoretical correlation function excludes this spin sequence.	

$\alpha_{ij}(\delta_k)$ and $\beta_{ij}(\delta_k)$ are defined as follows.

$$\alpha_{22}(\delta_k)=\frac{-0.4183-1.226\delta_k+0.1281\delta_k^2}{1+\delta_k^2}, \qquad \alpha_{23}(\delta_k)=\frac{0.1195+1.310\delta_k+0.3415\delta_k^2}{1+\delta_k^2}$$

$$\beta_{22}(\delta_k)=\beta_{23}(\delta_k)=\frac{\delta_k^2}{1+\delta_k^2}$$

Table IV. b.

0-2-3 Sequence $0.22 < \delta_4(-) < 0.34$

Spin sequence		$A_2(34)$	$A_4(34)$	$A_2(36)$	$A_4(36)$	$A_2(24)$	$A_4(24)$
	Experimental value	0.0577 ± 0.0286	0.0366 ± 0.0308	0.0460 ± 0.0381	-0.0486 ± 0.0413	-0.1835 ± 0.0282	0.0114 ± 0.0304
0 2-3-2	Theoretical value	$\left\{\begin{matrix}-0.074\\-0.281\end{matrix}\right\}\alpha_{32}(\delta_3)$	$\left\{\begin{matrix}0.0207\\0.0466\end{matrix}\right\}\beta_{32}(\delta_3)$	$\left\{\begin{matrix}-0.480\\-0.458\end{matrix}\right\}\alpha_{32}(\delta_3)$	$\left\{\begin{matrix}-0.2653\\-0.2220\end{matrix}\right\}\beta_{32}(\delta_3)$	$\left\{\begin{matrix}-0.074\\-0.281\end{matrix}\right\}\alpha_{32}(\delta_2)$	$\left\{\begin{matrix}0.0207\\0.0466\end{matrix}\right\}\beta_{32}(\delta_2)$
	Remark	The possible region of δ_3 is found around $+0.26$. For this case the theoretical A_2 and A_4 are as follows: $0.0107 < A_2(34) < 0.0406$, $0.0013 < A_4(34) < 0.0030$; $0.0663 < A_2(36) < 0.0694$, $-0.0168 < A_4(36) < -0.0141$				The region of $0.11 < \delta_2(-) < 2.5$ gives the theoretical correlation function consistent with the experimental one.	
0-2-3 3	Theoretical value	$\left\{\begin{matrix}-0.074\\-0.281\end{matrix}\right\}\alpha_{33}(\delta_3)$	$\left\{\begin{matrix}-0.0139\\-0.0312\end{matrix}\right\}\beta_{33}(\delta_3)$	$\left\{\begin{matrix}-0.480\\-0.458\end{matrix}\right\}\alpha_{33}(\delta_3)$	$\left\{\begin{matrix}0.177\\0.148\end{matrix}\right\}\beta_{33}(\delta_3)$	$\left\{\begin{matrix}-0.074\\-0.281\end{matrix}\right\}\alpha_{33}(\delta_2)$	$\left\{\begin{matrix}-0.0139\\-0.0312\end{matrix}\right\}\beta_{33}(\delta_2)$
	Remark	The signs of the theoretical $A_4(34)$ and $A_4(36)$ are in contradiction to the experimental values. Therefore the possibility of this sequence can be excluded.				The theoretical $A_2(24)$ is not compatible with the experimental one.	
0-2-3-4	Theoretical value	$\left\{\begin{matrix}-0.074\\-0.281\end{matrix}\right\}\alpha_{34}(\delta_3)$	$\left\{\begin{matrix}0.0046\\0.0104\end{matrix}\right\}\beta_{34}(\delta_3)$	$\left\{\begin{matrix}-0.480\\-0.458\end{matrix}\right\}\alpha_{34}(\delta_3)$	$\left\{\begin{matrix}-0.0589\\-0.0492\end{matrix}\right\}\beta_{34}(\delta_3)$	$\left\{\begin{matrix}-0.074\\-0.281\end{matrix}\right\}\alpha_{34}(\delta_2)$	$\left\{\begin{matrix}0.0046\\0.0104\end{matrix}\right\}\beta_{34}(\delta_2)$
	Remark	The common domain of δ_3 is found for this case to be $2.9 < \delta_3(-) < 3.3$. For the value of $\delta_3(-) = 3.1$, we find the following values: $0.0095 < A_2(34) < 0.0359$, $0.0042 < A_4(34) < 0.0094$; $0.0586 < A_2(36) < 0.0614$, $-0.0533 < A_4(36) < -0.0446$				We find a possible correlation function for the domain of $0.28 < \delta_2(+) < 6.0$	
0 2-3-5	Theoretical value	$\left\{\begin{matrix}0.0152\\0.0585\end{matrix}\right\}$	$\left\{\begin{matrix}-0.001\\-0.002\end{matrix}\right\}$	$\left\{\begin{matrix}0.0990\\0.0944\end{matrix}\right\}$	$\left\{\begin{matrix}0.0120\\0.0101\end{matrix}\right\}$	$\left\{\begin{matrix}0.0152\\0.0585\end{matrix}\right\}$	$\left\{\begin{matrix}-0.001\\-0.002\end{matrix}\right\}$
	Remark	The theoretical values of $A_4(34)$, $A_2(36)$ and $A_4(36)$ are outside of the probable error of the experimental values. So this possibility is eliminated.				The theoretical positive tendency is in contradiction to the experimental value.	

$\alpha_{ij}(\delta_k)$ and $\beta_{ij}(\delta_k)$ are defined as follows.

$$\alpha_{32}(\delta_k) = \frac{0.3464 - 1.897\delta_k - 0.1237\delta_k^2}{1+\delta_k^2}, \qquad \alpha_{33}(\delta_k) = \frac{-0.4330 - 0.868\delta_k + 0.2268\delta_k^2}{1+\delta_k^2}, \qquad \alpha_{34}(\delta_k) = \frac{0.1443 + 1.445\delta_k + 0.3093\delta_k^2}{1+\delta_k^2}$$

and

$$\beta_{32}(\delta_k) = \beta_{33}(\delta_k) = \beta_{34}(\delta_k) = \frac{\delta_k^2}{1+\delta_k^2}$$

was deduced by the careful interpolation of the Rose's Table[9]. The values obtained for the cases of $E3$, $M3$, $E4$, $M4$, $E5$ and $M5$ are presented in Table VI with the experimental value. From this table the $E3$ transition seems to be more probable than other possibilities. But, of course $M4$ transition could not entirely be excluded. Then the spin of the isomeric state of Ag^{110m} may be 4− or 5−. Since the 87-KeV beta transition involved in this level is allowed type it seems reasonable to assign 3−, 4− or 5− to the 2.93-MeV level. Therefore the spin sequences of D, E and F in Table V are eliminated. The 530-KeV beta transition has a $f-t$ value of 10^8, indicating even parity and possible spin value 2+, 3+, 6+ and 7+ for the 2.48-MeV level. On the other hand, there is an indication[10] which shows the ground state of Ag^{110} decays partially to this level. This fact may exclude the spin sequence C of the Table V.

Table V. The most probable spin and parity assignments in order of decreasing probability.

Energy (MeV) / Scheme	2.93	2.48	1.541	0.656	0
A	3−	2+	2±	2+	0
B	4−	2+	3±	2+	0
C	4−	4+	3±	2+	0
D	2−	2+	2±	2+	0
E	2−	2+	3±	2+	0
F	2−	4+	3±	2+	0

Table VI. K/L ratio for 116-KeV gamma ray.

Theoretical value						Experimental value
$E3$	$M3$	$E4$	$M4$	$E5$	$M5$	
1.63	3.61	0.46	1.73	0.185	1.04	1.3

Therefore we have two probable spin assignment, A and B for the excited levels of Cd^{110}. As one can see from the Table IV, a and b, the theoretical $A_4(34)$ of A and B is out side of the experimental value. But in reality, the determination of A_4 from the angular correlation work is very delicate and we can not say that this discrepancy is very serious. In the present experimental stage we can not choose the one of these alternatives. However it seems that we have a reason to prefer A over B. In progress of experimental technique, the decay scheme becomes clearer, and the spin doublet of 2+ and 4+ due to the core excitation[11] can be found in many nuclei, for instance, Fe^{56}, Co^{60}, Kr^{84}, Cd^{114} and Hg^{198}. And the application of this spin doublet idea[12] for this case is very attractive. Especially it is interesting to compare the decay scheme of Cd^{114} recently explored by Motz[13]. By this comparison the second 1.415-MeV excited state of Cd^{110} may have the spin 4+. Then the reason why the gamma transition from the third level to the ground level did not exist or it was scarcely detected could be explained by the difficulty of two phonon transition. But of course the possibility of the sequence B is not excluded. This ambiguity will be reduced if the exact knowledge on the beta disintegration of Ag^{110} and In^{110,110m} could be obtained. A more elaborate measurements are desired in future.

The authors would like to express their sincere thanks to Dr. M. Morita for the valuable theoretical discussions.

Temperature Variation of Mayer's Cluster Integrals

By Taro KIHARA and Shobu KANEKO

Department of Physics, Faculty of Science, University of Tokyo

(Received June 8, 1957)

By use of the square-well model of intermolecular potential, temperature variation of Mayer's cluster integrals, b_l for $l=2, 3, \cdots$, has been investigated (except the region of very high temperature where soft repulsive potential must be taken into account). The b_2 is monotone; b_3 has a minimum near the Boyle temperature T_B; b_4 has a minimum below T_B and a maximum above T_B; b_5 has a sharp minimum below T_B, a maximum near T_B, and a minimum above T_B; and so forth. Curves are shown up to b_6.

By use of Mayer's cluster integrals, b_l for $l=1, 2, \cdots$, the equation of state of gases is expressed in the form of parameter representation ($b_1=1$)

$$P=kT(z+b_2z^2+b_3z^3+\cdots)\ ,$$

$$N=V(z+2b_2z^2+3b_3z^3+\cdots)\ .$$

Here P is the pressure, T the temperature, k Boltzmann's constant, N the number of molecules in the volume V. The parameter z is a kind of fugacity or activity. Eliminating z from these two series we obtain an expansion in $v^{-1}\equiv N/V$

$$P=kT\left(v^{-1}-\frac{1}{2}\,\beta_1 v^{-2}-\frac{2}{3}\,\beta_2 v^{-3}-\cdots\right),$$

β_l being called lth irreducible integral. Relations between the cluster integrals and the irreducible integrals are the following[1]:

$$b_2=\frac{1}{2}\beta_1\ ,$$

$$b_3=\frac{1}{2}\beta_1^2+\frac{1}{3}\beta_2\ ,$$

$$b_4=\frac{2}{3}\beta_1^3+\beta_1\beta_2+\frac{1}{4}\beta_3\ ,$$

$$b_5=\frac{25}{24}\beta_1^4+\frac{5}{2}\beta_1^2\beta_2+\beta_1\beta_3+\frac{1}{2}\beta_2^2+\frac{1}{5}\beta_4\ ,$$

$$b_6=\frac{9}{5}\beta_1^5+6\beta_1^3\beta_2+3\beta_1^2\beta_3+\beta_1\beta_4+3\beta_1\beta_2^2$$
$$+\beta_2\beta_3+\frac{1}{6}\beta_5\ .$$

The second and third cluster integrals have been calculated in detail for adequate intermolecular potentials; the results explain temperature variations of the corresponding observed values. As regards fourth and higher cluster integrals detailed calculation is still lacking. In fact minute evaluation may not be needed, because their observed values are not accurate at all. It is desirable, however, to know characteristic feature of the temperature variation of cluster integrals, partly because the cluster integrals play an essential role in theories of condensation.

The characteristic feature of the cluster integrals for simple gases can be obtained by calculating them for the square-well potential[2]

$$U(r)=\begin{cases}\infty & \text{for}\quad r<r_0\\ -U_0 & \text{for}\quad r_0<r<gr_0\\ 0 & \text{for}\quad gr_0<r\end{cases}\qquad(1)$$

between two molecules, which potential is assumed to be additive in a system of three and more molecules. Here r is the intermolecular distance, r_0 is the diameter of the hard core of a molecule, U_0 denotes the depth of the potential well, and g is a parameter indicating the width of the well, appropriate value of g being probablly between 1.5 and 2. The second cluster integral for this model is simply given by

$$b_2=4v_0[(g^3-1)x-1]\ ,$$

where

$$x\equiv\exp(U_0/kT)-1\ ,$$

and

$$v_0\equiv(\pi/6)r_0^3$$

is the volume of the hard core of a molecule. The third cluster integral is a polynomial of third order in x:

$$b_3=v_0^2[27+(g^6-18\,g^4-32\,g^3+49)x$$
$$+(34\,g^6-36\,g^4-32\,g^3+18\,g^2+16)x^2$$
$$+(6\,g^6-18\,g^4+18\,g^2-6)x^3]\quad\text{for}\ g\leqq 2\ ,$$

$$b_3=v_0^2[27-(64\,g^3-81)x$$
$$+(32\,g^6-96\,g^3+18\,g^2+80)x^2$$

$$+(5g^6-32g^3+18g^2+26)x^3] \quad \text{for } g \leq 2.$$

There is a temperature, T_B, called Boyle temperature, below which b_2 is positive and above which it is negative. In connection to the Boyle temperature, let us define a volume v_B by the negative derivative of b_2 with respect to T/T_B:

$$v_B = -\left(T\frac{db_2}{dT}\right)_{T=T_B}.$$

For our square-well potential, these quantities are related to the model constants by the relations

$$\frac{U_0}{kT_B} = \ln\frac{g^3}{g^3-1}, \quad \frac{v_B}{4v_0} = g^3 \ln\frac{g^3}{g^3-1}.$$

Taking the characteristic values T_B and v_B as units, let us consider dimensionless "normalized cluster integral"

$$b_l^* = b_l/v_B^{l-1}$$

as functions of T/T_B. Owing to this procedure we can eliminate model constants, r_0 and U_0. The normalized second and third cluster integrals are shown in Fig. 1. Curves for $g=\infty$ indicate the limits for $g\to\infty$ and $U_0\to 0$, g^3U_0 being kept constant, at which

$$kT_B = g^3U_0, \quad v_B = 4v_0.$$

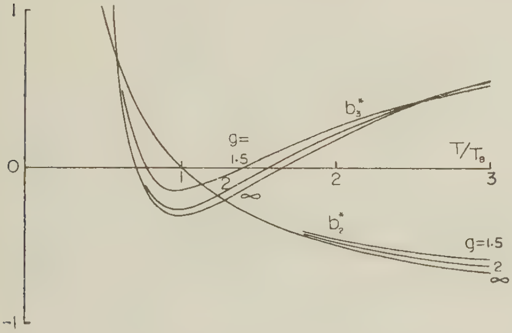

Fig. 1. Normalized second and third cluster integrals for the square-well potential.

They are given by

$$b_2^* = \frac{T_B}{T} - 1,$$

$$b_3^* = 2\left(\frac{T_B}{T} - 1\right)^2 - \frac{5}{16}.$$

It is important to notice that normalized cluster integrals are not very sensitive to the parameter g so far as $g \geq 2$. Hence general characteristics of the fourth and higher cluster integrals can be obtained by calculating them in the limiting case of $g=\infty$. Fortunately, the cluster integrals in this limiting case can be obtained by virtue of the following theorem.

The third and higher irreducible integrals, β_l for $l \geq 3$, for the square-well potential (1) with $g\to\infty$ and $U_0 \to g^{-3}kT_B$ are equal to the corresponding quantities for rigid spheres of the diameter r_0:

$$U(r)\begin{cases}\infty & \text{for } r<r_0 \\ 0 & \text{for } r>r_0.\end{cases}$$

In other words, attractive part of the intermolecular potential in this limiting case does not influence the third and higher irreducible integrals. A proof can easily be made when we use Mayer's expression for the irreducible integrals.

Thus in our limiting case, higher irreducible integrals are independent of the temperature:

$$\beta_2 = -\frac{15}{16}v_B^2, \quad \beta_3 = -\gamma_4 v_B^3, \quad \beta_4 = -\gamma_5 v_B^4, \cdots.$$

Here numerical values of γ_4 and γ_5 are[3,4]

$$\gamma_4 = 0.383, \quad \gamma_5 = 0.14.$$

By use of relations between cluster integrals and irreducible integrals we finally obtain

$$b_4^* = \frac{16}{3}\left(\frac{T_B}{T}-1\right)^3 - \frac{15}{8}\left(\frac{T_B}{T}-1\right) - \frac{1}{4}\gamma_4,$$

$$b_5^* = \frac{50}{3}\left(\frac{T_B}{T}-1\right)^4 - \frac{75}{8}\left(\frac{T_B}{T}-1\right)^2 - 2\gamma_4\left(\frac{T_B}{T}-1\right) + \frac{1}{2}\left(\frac{15}{16}\right)^2 - \frac{1}{5}\gamma_5.$$

These are continuations of the expressions for

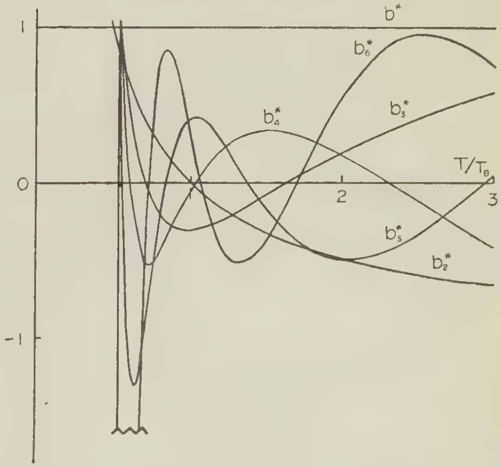

Fig. 2. Normalized cluster integrals for the square-well potential with $g=\infty$.

b_2^* and b_3^* given before. Curves representing these functions are shown in Fig. 2.

The numerical value of γ_5 is not accurate, but it does not influence the curve of b_5^*. Moreover we can draw the curve of

$$b_6^* = \frac{288}{5}\left(\frac{T_B}{T}-1\right)^5 - 45\left(\frac{T_B}{T}-1\right)^3 - 12\gamma_4\left(\frac{T_B}{T}-1\right)^2 + 2\left\{3\left(\frac{15}{16}\right)^2 - \gamma_5\right\}\left(\frac{T_B}{T}-1\right) + \frac{15}{16}\gamma_4 - \frac{1}{6}\gamma_6 \,.$$

without knowing the numerical value of γ_6, which curve is also included in Fig. 2.

Stress-Strain Relations for Viscoelastic Large Deformation

By Wataru SEGAWA

Training Institute for Education, Mishima, Shizuoka-ken

(Received March 18, 1957)

Stress-strain relation for non-homogeneous, three-dimensional and infinitesimal deformation were given by T. Alfrey[1] as follows:

$$d\gamma_i/dt = \frac{1}{G}\sum_j a_{ij}dS_j/dt + \frac{1}{\eta}\sum_j a_{ij}S_j \qquad \text{for Maxwellian material}$$

$$\sum_j a_{ij}S_j = G\gamma_i + \eta d\gamma_i/dt \qquad \text{for Voigtian material}$$

In this paper, the relations corresponding to above two equations are extended so as to be valid for large deformation. For example, the equations for incompressible Maxwellian material having a single relaxation time are as follows:

$$\partial(2\varepsilon_{xx})/\partial t = 1/\mu\cdot\partial/\partial t\cdot(P_{xx}+\mu\varphi) + 1/\eta(P_{xx}+\mu\varphi)$$

$$\partial(\varepsilon_{yz})/\partial t = 1/\mu\cdot\partial/\partial t\cdot(P_{yz}) + 1/\eta\cdot(P_{yz})$$

and corresponding equations for the other stress components.

These equations are then applied to three cases (constant stress, constant strain, and constant strain rate), results of which can be reduced to those of the ordinary case, if higher terms of strain can be neglected.

§ 1. Introduction

Stress-strain relations for Maxwellian and Voigtian material were given by T. Alfrey[1] as follows:

$$\frac{d\gamma_i}{dt} = \frac{1}{G}\sum_j a_{ij}\frac{dS_j}{dt} + \frac{1}{\eta}\sum_j a_{ij}S_j$$

for Maxwellian material (1)

$$\sum_j a_{ij}S_j = G\gamma_i + \eta\frac{d\gamma_i}{dt}$$

for Voigtian material (2)

These equations can be derived by combining the equation of elasticity,

$$\gamma_i = \frac{1}{G}\sum_j a_{ij}S_j \qquad (3)$$

which holds for purely elastic material, with the viscosity relationship.

Equations (1) and (2) are valid for infinitesimal deformation of incompressible isotropic material as well as equation (3) is.

Thus, if we want to extend the equation (1) or (2) to the case of large deformation, we must replace equation (3) by another equation which is valid for large deformation.

In this paper, we shall use the stress-strain relation of rubber[2),3)] in the Neo-Hookian theory, instead of equation (3). First we shall construct the stress-strain relations of incompressible isotropic materials for large deformation and then some simple applications of them will be done.

§ 2. Fundamental Equations

According to the Neo-Hookian theory, the stress-strain relation of rubber[2),3)] is given by the following equations:

$$\left.\begin{aligned} P_{xx}&=\mu\left(\frac{1+2\varepsilon_{xx}}{\det T}-\varphi\right) \\ P_{yz}&=\mu\cdot\varepsilon_{yz}/\det T \end{aligned}\right\} \qquad (4)$$

and corresponding equations for the other stress conponents, where T is given by

$$T=\begin{pmatrix} \frac{\partial X}{\partial x} & \frac{\partial X}{\partial y} & \frac{\partial X}{\partial z} \\ \frac{\partial Y}{\partial x} & \frac{\partial Y}{\partial y} & \frac{\partial Y}{\partial z} \\ \frac{\partial Z}{\partial x} & \frac{\partial Z}{\partial y} & \frac{\partial Z}{\partial z} \end{pmatrix} \qquad (5)$$

and $\det T$ represents the volume dilation, and φ is the undetermined isotropic component of stress.

In this paper, we treat only the incompressible case, so we can use the condition $\det T=1$, and the equation (4) results in the next equation.

$$\left.\begin{aligned} 1+2\varepsilon_{xx}&=\frac{1}{\mu}(P_{xx}+\mu\varphi) \\ \varepsilon_{yz}&=\frac{1}{\mu}P_{yz} \end{aligned}\right\} \qquad (4')$$

and corresponding equations for the other strain components.

Thus, by the same procedure as we convert equations (3) to (1), we can derive the following equations from equations (4′):

$$\left.\begin{aligned} \frac{\partial(2\varepsilon_{xx})}{\partial t}&=\frac{1}{\mu}\frac{\partial}{\partial t}(P_{xx}+\mu\varphi)+\frac{1}{\eta}(P_{xx}+\mu\varphi) \\ \frac{\partial\varepsilon_{yz}}{\partial t}&=\frac{1}{\mu}\frac{\partial P_{yz}}{\partial t}+\frac{1}{\eta}P_{yz} \end{aligned}\right\} \qquad (6)$$

and corresponding equations for the other strain components. Here we presumed that the volume viscosity can be neglected.

Similarly as above, we can gain the equations corresponding to equation (2) as follows:

$$\left.\begin{aligned} P_{xx}+\mu\varphi&=\mu(1+2\varepsilon_{xx})+\eta\frac{\partial(2\varepsilon_{xx})}{\partial t} \\ P_{yz}&=\mu\varepsilon_{yz}+\eta\frac{\partial\varepsilon_{yz}}{\partial t} \end{aligned}\right\} \qquad (7)$$

The equations for the shearing components in equation (6) and (7) are the same as the ordinary equation, except here strains are not infinitesimal but finite. If we use either of them, together with the equation of motion, the definition of finite strains and the boundary conditions as well as in the ordinary elasticity theory and $\det T=1$, we can solve the problems in incompressible large deformation, in principle.

§ 3. Simple Applications

Consider the incompressible deformation of rod- like material in the direction of its length, which we can select as the direction of x-axis. Then, x, y, and z axis becoming the principal axis, we need not the equation for shearing components and it can be assumed the following relations hold.

$$P_{yy}=P_{zz}=0 \qquad (a)$$

$$\varepsilon_{yy}=\varepsilon_{zz} \qquad (b)$$

$$\det T=1 \qquad (c)$$

Put

$$1+2\varepsilon_{xx}=\lambda^2 \qquad (d)$$

then, λ represents elongation ratio. From (b) and (c), we have

$$1+2\varepsilon_{yy}=1+2\varepsilon_{zz}=1/\lambda \qquad (e)$$

Under the above assumptions and relations, let us apply the above-obtained equations ((6) and (7)) to well-known three cases:

(1) $dP_{xx}/dt=0$,

(2) $d\varepsilon_{xx}/dt=0$,

(3) $2d\varepsilon_{xx}/dt=d(\lambda^2)/dt=\text{const.}$

The calculations are comparatively easy, so we will not describe their precise process. The results of calculations are listed belows. (It was proved that the behaviours for $d\varepsilon_{xx}/dt=0$ were the same as those in the ordinary case, so they are neglected belows.)

(1) When $dP_{xx}/dt=0$

From (6) $$\lambda^2-\frac{1}{\lambda}=\frac{P_{xx}}{\eta}t+\text{const.} \qquad (8)$$

From (7) $$\lambda_2-\frac{1}{\lambda}=\frac{P_{xx}}{\mu}(1-e^{-t/\tau}) \qquad (9)$$

(2) When $2d\varepsilon_{xx}/dt=d(\lambda^2)/dt=\text{const.}=a$

From (6)
$$P_{xx}=\mu\exp(-\lambda^2/\tau a)\int_0^\lambda d\left(\lambda^2-\frac{1}{\lambda}\right)\Big/d\lambda\cdot\exp(\lambda^2/\tau a)d\lambda \tag{10}$$

From (7)
$$P_{xx}=\mu\left(\lambda^2-\frac{1}{\lambda}\right)+\eta a\,d\left(\lambda^2-\frac{1}{\lambda}\right)\Big/d\lambda\cdot\frac{1}{2\lambda} \tag{11}$$

Where $\tau=\eta/\mu$

We can easily prove that if strains are small and higher terms of them can be neglected, these results can be reduced to those in the ordinary theory. Let us show this for equation (8) and (10). For example, next relations can hold.

$$\lambda=(1+2\varepsilon_{xx})^{1/2}=1+\varepsilon_{xx}$$
$$\lambda^2-1/\lambda=1+2\varepsilon_{xx}-(1+2\varepsilon_{xx})^{-1/2}=3\varepsilon_{xx}$$

Thus, from equation (8), we have

$$3\varepsilon_{xx}=\frac{P_{xx}}{\eta}t+\text{const.}$$
$$\therefore\quad \varepsilon_{xx}=\frac{P_{xx}}{3\eta}t+\text{const.} \tag{12}$$

and from equation (10) we have

$$P_{xx}=\mu\exp\left(-\frac{1+2\varepsilon_{xx}}{2\tau\dot{\varepsilon}_{xx}}\right)$$
$$\cdot\left[\int\frac{d(3\varepsilon_{xx})}{d\varepsilon_{xx}}\exp\left(\frac{1+2\varepsilon_{xx}}{2\tau\dot{\varepsilon}_{xx}}\right)d\varepsilon_{xx}+\text{const.}\right]$$
$$\therefore\quad P_{xx}=3\mu\tau\dot{\varepsilon}_{xx}\left[1-\exp\left(-\frac{\varepsilon_{xx}}{\tau\dot{\varepsilon}_{xx}}\right)\right] \tag{13}$$

On the Twin Structure of Nickel Films Electrodeposited on Single Crystals of Copper

By Shiro OGAWA, Joji MIZUNO, Denjiro WATANABE and F. Eiichi FUJITA*

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai, Japan

(Received April 1, 1957)

Single-crystal-like nickel films electrodeposited on copper single crystals were examined by electron diffraction and electron microscopy after films were detached from the substrates. The twin structure in the films which has so far been observed only through diffraction patterns revealed themselves in electron micrographs. In films deposited on electropolished surfaces well marked {111} twin lamellae were observed and their directions satisfied the crystallographical relation. They were scatteringly located and their width ranged from less than 100 Å to several thousand Å. They grew up sometimes to be more than 10 μ in length. In films deposited on etched surfaces, on the other hand, such a coarse twin structure was hardly found and the finer one took place. The finer twins were in general 100 Å or less in width and were finely spaced at intervals somewhat larger than the width. The above results were obtained in films deposited on (110) and (001) faces of copper. Films deposited on surfaces with higher indices, (310) and (531), also showed high epitaxy and marked twin structures.

§ 1. Introduction

As Cochrane observed[1], face-centred cubic metals such as nickel, copper and silver electrodeposited on a single crystal of face-centred cubic metal, say copper, are oriented following the substrate, that is, epitaxy occurs. On that occasion, {111} twins are found in deposited layers. These circumstances are quite similar to those in thin films of face-centred cubic metals evaporated on rocksalt[2]. Reflection patterns of electron diffraction so far observed with electroplated surfaces gave indeed a positive evidence for the twin formation, but could inform us little of the width of twin lamellae and the frequency of their formation. These quantities will be known from electron micrographs of electroplated surfaces. Ueda, Kawai and Watanabe[3] carried out electron microscopic observations of nickel-plated surfaces of copper single crystal using replicas, but reported little about the twin structure. If electrodeposited films are thin enough to transmit electrons and are detached from substrates, their transmission electron micrographs will give more information about the twin formation than replicas. Weil and Read[4] and recently Reimer[5] detached nickel films from nickel-plated copper by a suitable reagent and examined them by electron microscope. They electroplated, however, polycrystalline copper and they did not examine the twin structure.

In order to examine the twin formation in nickel films electrodeposited on single crystals of copper, we detached the films from the nickel-plated crystals in a similar way to Weil and Read and observed them by electron diffraction and electron microscopy. The results obtained were almost satisfactory in giving detailed information about the twin formation.

§ 2. Experimental Method

Single crystal discs of copper 2 mm. in thickness and 10 to 20 mm². in area were cut, parallel to (110) or (001), out of rectangular rods 3 mm. in diameter. These rods of single crystal were kindly dispensed by Dr. H. Suzuki who prepared them by melting in a graphite mold. Their orientations were roughly determined by the light figure method. The discs were carefully cut out by a fret saw, polished by emery paper till 05, electropolished and, if necessary, etched. Then, the orientations were determined by the X-ray Laue method. Misorientations were found to be about 2° in (110) and (001) discs. Specimens were electropolished in aqueous solution of 600 cc/l H_3PO_4 and immediately, or after being etched in 5% KCN solution, plated with nickel in aqueous solution of 300 gr. $NiSO_4 6H_2O$, 3.1 gr. NaCl and 6.2 gr. H_3BO_3 in 1l. Plating current density ranged from 22 to 31 $\mu A/cm^2$. Current density less than these values caused no appreciable plating. Nickel films deposited were left after the copper was dissolved in aqueous solution of 500 gr. CrO_3 and 50 gr. H_2SO_4 in 1l. They were washed and scooped on meshes. It was difficult to obtain films of large area, and the largest film was only about 1 mm^2. in area.

* Now at the Japan Atomic Energy Research Institute, Tokyo, Japan.

Electron microscopy and electron diffraction were carried out by the apparatuses previously used[2)], except cases where defocused diffraction patterns of selected area were needed. In these cases an electron microscope, JEM-5C type of the Japan Electron Optics Laboratory Co., was used. The accelerating voltage of 80 KV was applied to this microscope.

§ 3. Experimental Results and Their Interpretation

(*a*) *Nickel films deposited on (110) face of copper*

At an early stage of the present work, copper surfaces were plated after etching in 5% KCN solution for about 5 min., because there was an anxiety that a good orientation of nickel layer could not probably be obtained on an electropolished surface owing to an oxide layer present there. A nickel-plated (110) face gave a single-crystalline reflection pattern shown in Fig. 1*a* which proved the epitaxial growth. Twin spots and junction spots[6)] are clearly visible in this pattern. The nickel film was then detached from the substrate. It gave a transmission pattern shown in Fig. 1*b*, where, though fairly strong Debye rings appeared, two kinds of extra spots, *e.g.*, such as weak E_1 lying in the oblique direction from a main spot M and strong E_2 lying in the vertical direction from the relevant spot M, were visible.

The relation between the twin spots in the reflection pattern and those in the transmission pattern is seen from Figs. 2*a* and *b*. In Fig. 2*a*, ABCD is parallel to the specimen surface and OBF, OCF, OBC and FBC are {111} planes on which twinning can occur. Fig. 2*b* represents a reciprocal lattice corresponding to the lattice containing four kinds of twins. The twin spots lie on the body-diagonals of the reciprocal lattice. When the incident beam is parallel to BC in the reflection case, the pattern obtained will almost be in agreement with the intensity distribution in OC′G′H′. On the other hand, when the incident beam is perpendicular to the film surface, *i.e.*, parallel to FO in the transmission case, the pattern obtained will almost be in agreement with the intensity distribution in A′B′C′O. The twin spots in Fig. 1*a* must have, therefore, arisen from twin lattices different from those causing twin spots in Fig. 1*b*. In the latter case, only the extra spots of the weak kind represented by E_1, lying on the body-diagonals in A′B′C′O, can be expected as the twin or junction spots, but those of the strong kind represented by E_2 cannot. If considerable rotations of crystallites took place, however, the latter spots can also be identified as the twin or junction spots. That is, the twin or junction spots lying on the reciprocal planes parallel to OC′G′H′ come to reflecting positions due to the rotations. In this case, these spots are doubled in intensity, owing to the two symmetrical positions referring to A′B′C′O.

In Fig. 1*b*, the spot E_2 lies on a direction parallel to A′B′ through the relevant main spot $(1\bar{1}1)$ in Fig. 2*b* and, after detailed observation, it was found that the spot E_2 was often separated into two parts. This fact means that there are two rotation axes in the film plane. Thus, four kinds of {111} twin lamellae were proved to exist in nickel films formed on (110) face of copper single crystal. The twin spots due to twins on OBF and OCF, *i.e.*, the kind represented by E_1 in the transmission pattern, are far weaker in intensity than those due to twins on OBC and FBC which appeared in the reflection pattern as well as in the transmission pattern. This means that twin lamellae oblique to the film plane are more frequently formed than those perpendicular to this plane, even if the doubled intensity of E_2 is considered.

Next, the detached films were examined by transmission electron microscopy. Micrographs obtained showed, however, very much complex structures, so that twin lamellae could scarcely be identified, against our expectation. Since this condition was considered to originate from etching before plating, immediate nickel-plating after electropolishing was tried. The detached nickel film exhibited an excellent single-crystalline diffraction pattern showing the epitaxial growth, in spite of our initial anxiety. The intensity of twin spots was, however, much weaker than in the case of etching. One of the electron micrographs of this film is shown in Fig. 3. Such a structure as observed in Fig. 3 was rarely observed through the whole film. In Fig. 3, a wide bright stripe runs, making an angle of about 54° with several narrow stripes about 300Å in width. This angular relation can clearly be understood, if the former stripe is parallel to BC in Fig. 2*a*, which is the intersection of OBC with the film

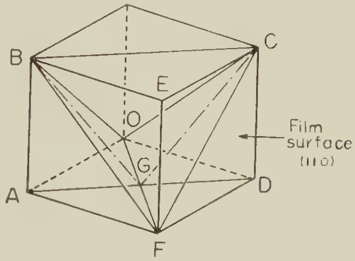

Fig. 2. *a*: Geometrical relation between (110) film surface and four {111} planes.

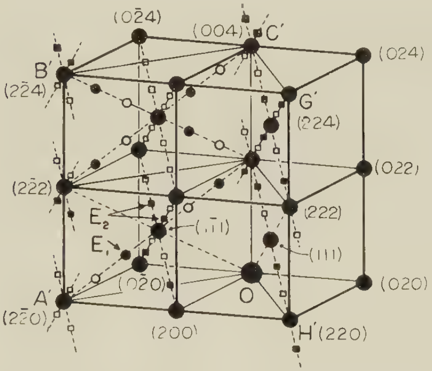

Fig. 2. *b*: Reciprocal lattice corresponding to the lattice containing four kinds of twins. Large full circles are main lattice points, small full circles and squares are twin spots, and small open circles and squares are junction spots. Small circles are caused by twins on OBF and OCF in *a*, and small squares by twins on OBC and FBC.

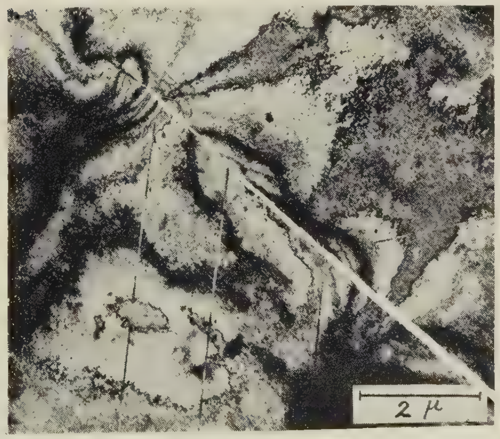

Fig. 3. Electron micrograph of a nickel film on electropolished (110) face of copper. Electrodeposited with current density 30μA/cm² for period 7 hr.

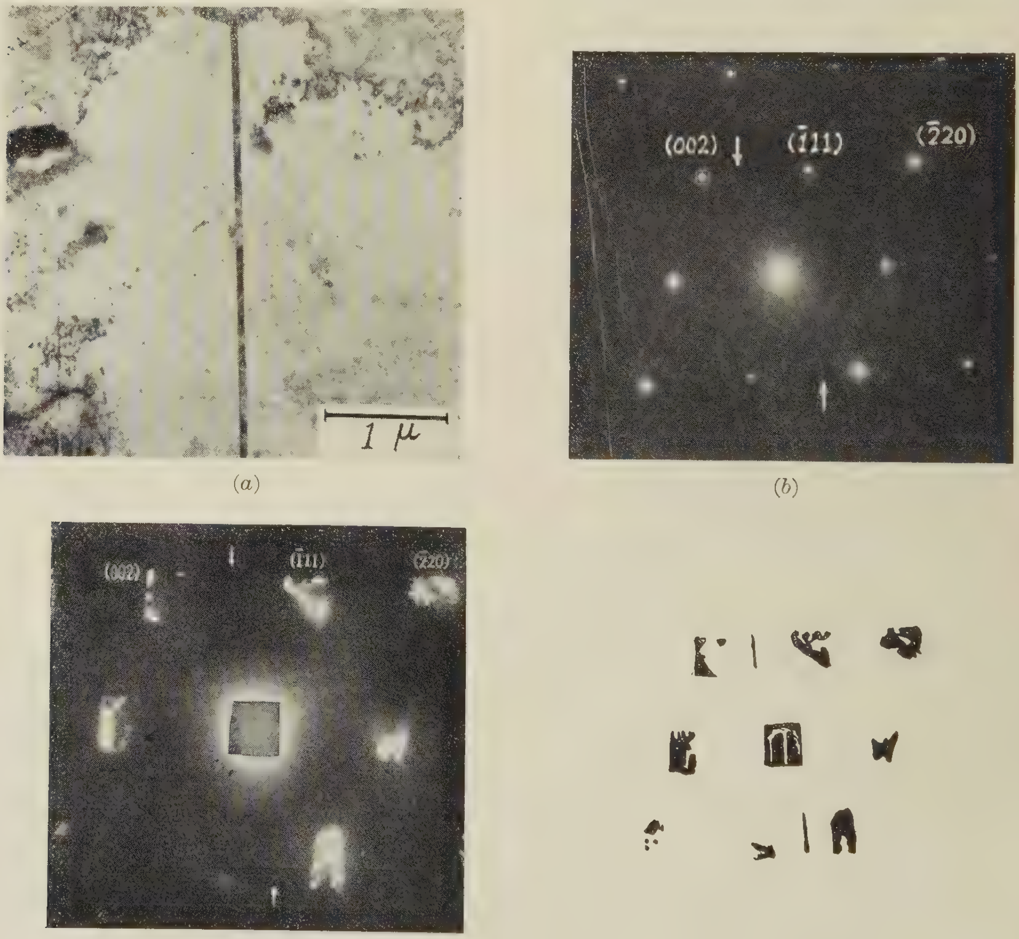
plane, and if the latter stripes are parallel to BG (or CG), which is the intersection of OBF (or OCF) with the film plane. BC makes an angle of 54°44′ with BG or CG. Thus, the wide stripe can be thought to represent a twin lamellae oblique to the film plane and hence to appear wider than its true thickness (this stripe seems, however, to change into a rip in its middle), and the narrow stripes can be thought to represent twin lamellae perpendicular to the film plane and hence to show their true width. The contrast changes along the narrow stripes, owing to the change of condition of Bragg reflections due to bending. Thus, it is sure that the stripes in Fig. 3 reveal the twin lamellae growing in the nickel film, and the fact that similar stripes were rarely observed explains the weak intensity of the twin spots in the diffraction pattern.

The facts stated above connot be, however, a conclusive evidence of the stripes representing the twin lamellae. The proof should be given by defocused diffraction patterns, just as given by Fischer and Richter⁷⁾. They observed the stripes similar to those in Fig. 3 in evaporated germanium films irradiated with electron beam and proved by the said method that they arose from the twin lamel-



(*a*) (*b*)

(*c*) (*c*′)

Fig. 4. Electron micrograph and diffraction patterns of a (110) nickel film prepared under the same condition as in Fig. 3. In *a*, *b* and *c*, the specimen was placed at the usual position, *i.e.*, before the objective lens. *b* and *c* were taken without an objective aperture. Defocusing was carried out by adjusting the current of the intermediate lens. In *a*, faint stripes are also visible, running parallel to the intense stripe. In *c*, dark field images appear at positions corresponding to the diffraction spots in *b*. The arrows in *b* and *c* indicate the twin spots and the stripes due to twins, respectively.

lae. Fig. 4a* is an electron micrograph of a nickel film deposited on (110) copper face, Fig. 4b a selected area diffraction pattern of Fig. 4a, Fig. 4c the defocused pattern of Fig. 4b and Fig. 4c′ an illustration of Fig. 4c. The central small region of Fig. 4c is a reduced image of Fig. 4a. A dark stripe is seen through its middle. This stripe reveals itself, however, as a bright one in the defocused diffraction pattern, and its position corresponds just to that to be expected for the twin spot. Thus, the stripes in the micrographs were proved to arise from the twin lamellae.

(b) *Nickel films deposited on (001) face of copper*

Nickel films were very difficult to be detached from etched (001) faces, so that most works were carried out by plating without etching. The diffraction patterns exhibited the epitaxial growth also in this case. The twin spots were in general faint in reflection as well as in transmission, especially, scarcely visible in the latter case. There appeared, however, many dark and bright stripes in the transmission electron micrograph taken from a selected region (Fig. 5). The stripes are several hundred to several thousand Å in width and were classified into two groups perpendicular to each other. These stripes are similar to those obtained previously from thin films of face-centred cubic metals evaporated on cleavage surface of rocksalt[2]), though the former stripes are more coarsely spaced than the latter. Thus, it can be concluded that the stripes in Fig. 5 are caused by the twin lamellae and their directions are [110] and [$\bar{1}$10] respectively which represent the directions of intersection of {111} planes with (001) film plane. Fig. 6 shows another example of (001) nickel films. Here we see, besides such stripes as in Fig. 5, several square frameworks of different sizes which are connected with the stripes. The following suggestion may be permitted concerning the origin of these frameworks, remembering the directions of the stripes to be face-diagonal: Twin lamellae of nickel grew up on four faces of octahedral pits existing originally on the copper surface. At places where lamellae growing on neighbouring faces collided, the lattice epitaxial to the substrate was formed due to the symmetry relation. This suggestion seems to be supported by the fact that broad, curved dark lines due to Bragg reflections are seen inside the frameworks and straight dark lines are marked at the corners of the frameworks as if these places had the lattice continued from the outside region of the frameworks.

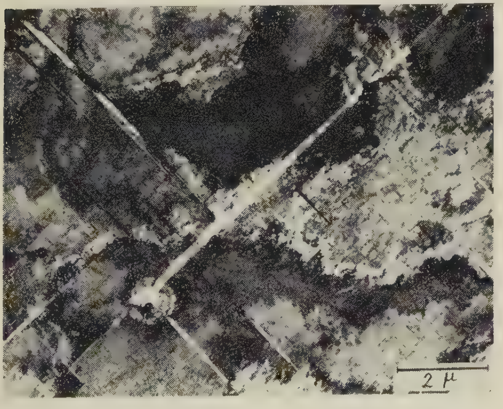


Fig. 5. Electron micrograph of a nickel film on electropolished (001) face of copper. Electrodeposited with current density 24 μA/cm² for period 14 hr.

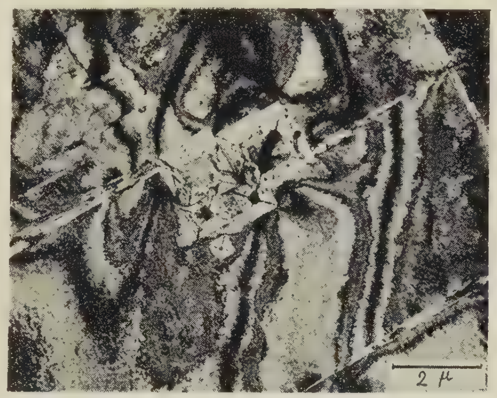

Fig. 6. Electron micrograph of a nickel film deposited on electropolished (001) face of copper which was slightly etched before plating. Plated with current density 23 μA/cm² for 31 hr.

It was proved also in the (001) case by the same method as used in the (110) case that the stripes arose from the twin lamellae.

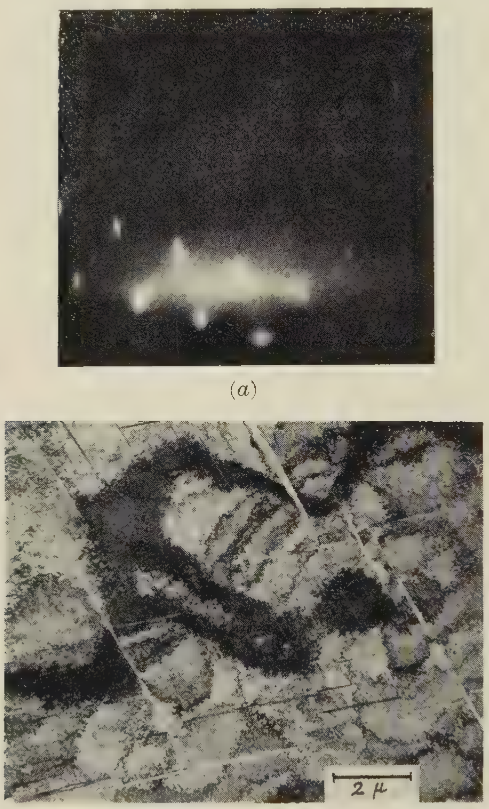
(c) *Nickel films deposited on other faces of copper*

In order to examine whether the epitaxial growth occurred or not on crystal faces of higher indices and to see the aspect of the twin formation if this occurred, (310) and (531) discs were cut out. Misorientations were 5~6° in both cases.

---

* For photographing of Fig. 4a, b and c, we are much indebted to Dr. M. Watanabe.

Diffraction patterns obtained from nickel films formed on electropolished surfaces of these discs inform us that the orientations of the substrates were well followed by the deposited films. In these patterns and also in the transmission patterns obtained from the detached films the twin spots appear faint, but when the films were tilted in the latter case, they became strong. Fig. 7*a* shows a reflection pattern of the (310) case. Transmission electron micrographs obtained from the detached films showed the twin lamellae in both (310) and (531) cases. Fig. 7*b* was obtained from the (310) film. Most of lamellae appear bright, being in agreement with the fact that the twin spots in the diffraction patterns were faint in the normal incidence. The angles between the stripes satisfy the crystallographical relation.



(*a*)

(*b*)

Fig. 7. Electron diffraction pattern and electron micrograph of a nickel film deposited on electropolished (310) face of copper. In a electron beam is nearly parallel to [1$\bar{3}$3]. The micrograph in *b* was obtained from the detached film. Plated with current density 30μA/cm^2 for 6.5hr.

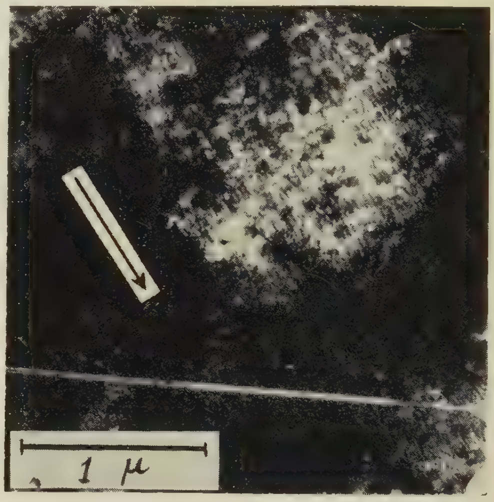


Fig. 8. Electron micrograph of a nickel film on etched (110) face of copper. Etching was carried out in 5% KCN solution for 1 min. Electrodeposited with current density 26μA/cm^2 for period 20hr.

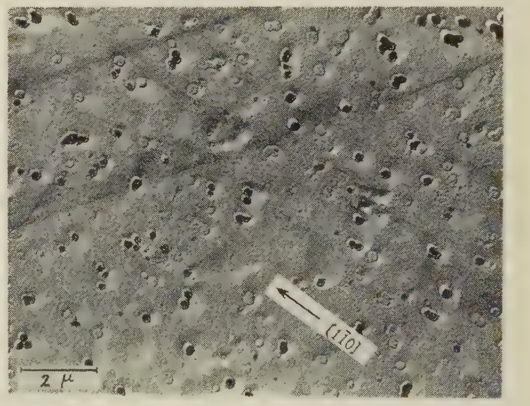

Fig. 9. Electron micrograph of a replica of nickel-plated (110) face of copper. Two-stage replica of methylmethacrylate and chromium was used. Chromium metal was evaporated along the direction making an angle of 30° with the surface and whose projection on the surface made an angle of 27° with [1$\bar{1}$0] lying on the surface.

Among the twin lamellae mentioned in subsections (a), (b) and (c), those with comparatively short length (~0.5μ) had, in general, a tendency to decrease in number with the increase of the depositing current density, while this increase was not the case with longer lamellae.

(*d*) *Nickel films deposited on etched faces of copper*

As already described in (a), every nickel film deposited on copper faces etched for about 5 min. in KCN of 5% gave comparatively strong diffraction spots due to twins, but its electron microscopic structure was so complex that the twin lamellae could not be identified. In order to obtain a simpler electron microscopic structure, (110) face was nickel-plated, etching duration being shortened and varied from 15 to 60 sec. Even when the etching was done for the shortest duration, the stripes as seen in Fig. 3 almost vanished. (But such twin lamellae were rarely observed even on the substrate etched for 3 min., if the depositing current density was high, *i.e.*, about 30 $\mu A/\text{cm}^2$.) Detailed observation enabled us, however, to find stripes caused by twin lamellae, even when the familiar stripes vanished. In Fig. 8, many dark fine stripes are observed along the direction of the arrow. They are in general 100Å or less in width and are spaced at intervals somewhat larger than the width. A bright stripe of the familiar type remains in the middle of the dark region of the figure. The angle between the direction of this stripe and that of the above-mentioned fine stripes is about 54°, which convinces us that the latter stripes represent nothing but the fine twin lamellae very frequently formed, if the angular relation in Fig. 3 is remembered. Such fine stripes were found, after detailed observation, in most places of the micrographs, and therefore, they could yield strong diffraction spots due to twins in spite of their indistinct microscopic pattern, while the distinct twin lamellae as seen in Fig. 3 yielded only faint twin spots, due to their small total volume. The fine twin lamellae have never been found in films formed without etching of the substrate.

§ 4. Discussion

Twins occurring in crystals are classified into two kinds[7]. One is named "growth twin", which occurs as a result of stacking disorder of (111) plane in the course of crystal growth, and the other "deformation twin", which is formed under stress as a mode of deformation. The coarse twin lamellae of the films formed on electropolished surfaces were occasionally more than 10μ in length. Such lamellae seemed at first sight to be deformation twins which occurred at the time of detachment of the films. A micrograph shown in Fig. 9, however, denies this conjecture. This micrograph was taken from a replica of nickel-plated (110) copper face and shows several diffuse stripes. These are classified into two groups of parallel stripes which intersect each other with an angle somewhat larger than 50°. Moreover, it is seen from the shadowing direction that the one group runs parallel to $[1\bar{1}0]$ lying on the surface. As the contrast in a replica micrograph mean some unevenness formed on the original surface, the said stripes may be considered as marks due to the twin lamellae, if these lamellae cause the surface to be uneven. Thus, the coarse twin structure seems to exist originally in the deposit*.

From the above consideration it is concluded that the twin structure of films electrodeposited on electropolished faces of copper are considerably different from and far coarser than that of the evaporated films. The twin structure of films electrodeposited on etched faces are, on the other hand, extremely fine and similar to that of the evaporated films in width as well as in spacing. The reason why the aspect of the twin formation depends on the surface condition of the substrate is not clear, but the following supposition may be allowed: According to Setty and Wilman[8], who examined the epitaxial growth of silver electrodeposited on electropolished (110), (001) and (111) faces of a silver single crystal, the twinned structure developed more frequently when the current density was increased. Now that etched surfaces are submicroscopically rough, on the top of projections it is likely that the current density is higher than the average. Then, chance for the twin formation will increase at such places, according to the results of Setty and Wilman. Moreover, the twins will be cut in pieces by surface irregularity. Thus, minute twinned lattices can frequently grow up on etched surfaces. On the other hand, electropolished surfaces have atomic smoothness, and hence only coarse twins grow up scatteringly.

---

* In single crystal discs of copper employed in the present work, twin layers were not found by X-ray and electron diffraction.

The above consideration seems to suggest that we deal with growth twins in the cases of electropolished as well as etched faces, as it is difficult to consider in the course of growth the occurrence of any stress other than that which is induced by unfitness between the lattices of the deposit and the substrate. The latter stress cannot be a cause of the twin formation, because twins are formed even when the same substance as substrate is deposited as in the case of Setty and Wilman.

We wish to express our sincere thanks to Dr. H. Suzuki for his kind dispensation of copper single crystals. We are much indebted also to the Japan Electron Optics Laboratory Co. and its member, Dr. M. Watanabe, for their kindness which they did us in photographing some electron micrographs.

The present work has been supported partly by the fund of the Ministry of Education in Aid of Scientific Researches.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 9, SEPTEMBER, 1957

Characteristics of the Beam Type Maser I

By Koichi SHIMODA

Department of Physics, Faculty of Science, University of Tokyo

(Received May 29, 1957)

Velocity distribution of molecules in the beam type maser is considered fairly completely, though the mathematical approach is rather approximate. Because slower molecules spend longer time in the cavity, the effective average velocity of molecules is considerably smaller than the most probable velocity, when the rf power level and the focuser voltage are low. Amplitude vs. focuser voltage and vs. frequency characteristics are obtained, which seem to be in good agreements with experiments. Finally frequency shift due to the unresolved hyperfine structure is discussed and shown to be appreciable (a few parts in 10^8).

§ 1. Introduction

A type of devices which utilize atomic processes of induced emission as oscillators, frequency converters, and amplifiers has been called a MASER. It has become feasible at first by a molecular beam type maser[1] and secondly by a solid state maser[2][3]. This paper is concerned with the characteristics of the beam type maser, particularly of ammonia maser. Molecules other than ammonia have not yet been used successfully for the maser.

Theories of the beam type maser have already been given[4][5][6]. However experimental results show that these theories are not satisfactory in describing the characteristics of ammonia masers. Particularly, Helmer has recently reported considerable frequency variations of an ammonia maser oscillator with source pressure and with focuser voltage[7]. It is shown in the following discussion that, if the presence of unresolved hyperfine components and velocity distribution of molecules are taken into account, this type of frequency shift can be predicted and other characteristics are also obtained in better agreement with experimental results. A preliminary discussion of this consideration was briefly reported[8] concerning the frequency difference between an absorption type frequency standard by the present author and a maser oscillator by Bonanomi[9]. Theoretical discussions of the beam type maser are described in this paper, while the experimental results will appear in part II.

§ 2. Velocity Distribution

Velocity distribution of molecules in the beam was first taken into account in the theory of the maser by Helmer[4]. However, his treatment was incomplete, because only the distribution of speeds was taken into consideration and the distribution of directions of velocities was neglected. Here a more complete treatment is described.

Velocity distribution of molecules which are effused from a molecular beam source may be assumed as that of Maxwell-Boltzmann type, since highly directional source has been found very difficult to realize. The number of molecules in a unit volume with velocity components, v_x, v_y, and v_z, is

$$N(v_x, v_y, v_z)dv_xdv_ydv_z=\frac{2N}{\alpha^3\pi^{3/2}}e^{-v^2/\alpha^2}dv_xdv_ydv_z, \tag{2.1}$$

where N is the number density of molecules in a particular energy level of interest independent of their velocities, α the most probable velocity given by

$$1/2\cdot m\alpha^2=kT \quad \text{or} \quad \alpha=(2kT/m)^{1/2}$$

and

$$v^2=v_x^2+v_y^2+v_z^2 \, .$$

If z-axis is chosen along the direction of the beam, v_x and v_y may take any values but v_z must be positive. Using a cylindrical coordinate, radial component is given by $v_r^2=v_x^2+v_y^2$, and the velocity distribution is

$$N(v_r, v_z)dv_rdv_z=\frac{4Nv_r}{\alpha^3\sqrt{\pi}}e^{-v^2/\alpha^2}dv_rdv_z \, . \tag{2.2}$$

The focuser exerts radial force outwards for ammonia molecules in the lower inversion state, while inwards for those in the upper state. Electro-static potential in a $2n$-pole focuser can be approximately expressed by

$$\phi=\frac{V}{2R^n}\mathrm{Re}(x+iy)^n \, , \tag{2.3}$$

where R is the radius of the focusing field and $\pm V/2$ the voltages of the alternate electrodes. That is, when the every other electrodes are grounded, the applied focuser voltage is V. Then the electro-static field in the focuser is

$$E_s=\frac{nr^{n-1}}{2R^n}V \, , \tag{2.4}$$

and the maximum field intensity is

$$E_m=\frac{n}{2R}V \, . \tag{2.5}$$

Fig. 1 shows the distribution of E^2, which is roughly proportional to the potential energy of molecules.

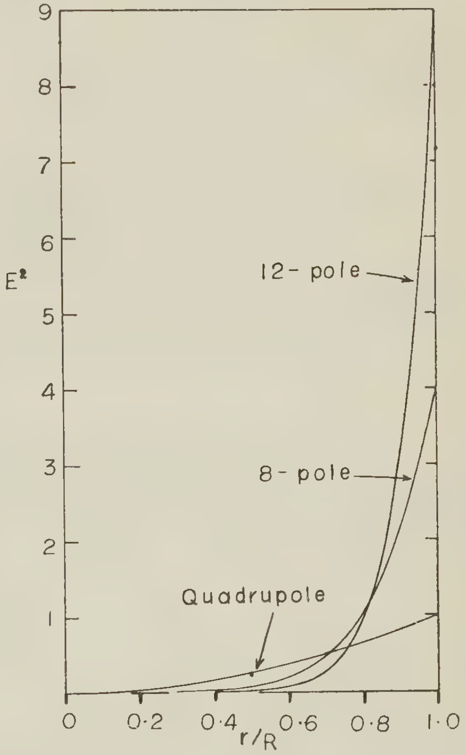

Fig. 1. Distribution of E^2 in a $2n$-pole focuser.

The molecules in the upper inversion state are focused, when the radial kinetic energy is smaller than the maximum Stark energy, which is

$$\varDelta W_E=\left[\left(\frac{h\nu_0}{2}\right)^2+\left(\frac{\mu MK}{J(J+1)}E_m\right)^2\right]^{1/2}-\frac{h\nu_0}{2} \, . \tag{2.6}$$

Then the focusing criterion is given by

$$\frac{1}{2}mv_r^2<\varDelta W_E\equiv\frac{1}{2}mv_c^2 \, . \tag{2.7}$$

If $\varDelta W_E \ll h\nu_0$, the critical radial velocity, v_c, is proportional to the focuser voltage, since

$$v_c \simeq \frac{\mu MK}{J(J+1)} E_m \left(\frac{2}{mh\nu_0} \right)^{1/2} \tag{2.8}$$

However, when the z-component of the velocity is large, the molecule cannot spend enough time to be focused within the focuser and also the molecules in the lower state cannot be sufficiently removed from the beam. Since $\frac{\pi}{2} \frac{R}{v_c} v_z$ is just half the focal length in a quadrupole focuser, the condition determined by the length of the focuser, l, may be written approximately as

$$\frac{l}{v_z} > \frac{\pi}{2} \frac{R}{v_c} \tag{2.9}$$

Thus the velocity of molecules to be focused should satisfy the conditions,

$$v_r < v_c \quad \text{and} \quad v_z < \frac{2}{\pi} \frac{l}{R} v_c$$

though the second condition is rather approximate. More accurate evaluation should of course be carried out by computing trajectories of molecules.

The number of focused molecules entering the cavity resonator in a unit time with velocity components, v_r and v_z, is

$$n(v_r, v_z) = A_i v_z N(v_r, v_z) , \tag{2.10}$$

where A_i is the area of the inlet hole through which the uniform density of molecules is assumed to pass. Then the rf power emitted from the beam of molecules is given by

$$\Delta P = \int_0^{v_c} \int_0^{(2/\pi)(l/R)v_c} n(v_r, v_z) |a_1(\tau)|^2 dv_z dv_r \tag{2.11}$$

where $|a_1(\tau)|^2$ is the transition probability[5)]. This equation should be modified when a long cavity is used as in the ordinary maser. In such a case, Eq. (2.1) may be divided into two parts, ΔP_1 and ΔP_2: One is the contribution of molecules which pass through the whole length of the cavity, and the other is that of molecules which collide with the cavity wall before it can pass through the cavity. Duration of interaction with the rf field in the cavity is $\tau = L/v_z$ in the former case, while it is approximately $\tau = R/v_r$ in the latter case, where L and R are the length and radius of the cavity.

In order that the molecules can pass through the cavity before they collide with the cavity wall, an approximate condition

$$\frac{v_z}{L} > \frac{v_r}{R}$$

must be satisfied. This condition is accurate for the molecules just focused at the center of inlet hole of the cavity, while for other molecules it may be considered as an average condition. For finite sizes of source and of inlet hole of the cavity each focused molecule generally takes different values of v_r before and after it passes the focuser, but as a statistical average, v_r can be considered as almost unchanged. Thus we may use the velocity distribution of Eq. (2.2) for the molecules flowing into the cavity with $v_r < v_c$.

From equation (4) in reference 5, hereafter referred as SWT, when the oscillation frequency is equal to that of molecular resonance, we obtain

$$|a_1(\tau)|^2 = \sin^2 \frac{x\tau}{2} , \tag{2.12}$$

where $x = E\bar{\mu}/\hbar$ and E is the intensity of rf field in the cavity.

Emitted Power

Assuming $x\tau/2 \ll 1$ so that $\sin \frac{1}{2}x\tau = \frac{1}{2}x\tau$, the power emitted from the molecules which pass through the cavity is obtained from Eqs. (2.2), (2.10), (2.11), and (2.12).

$$\begin{aligned} \Delta P_1 &= \frac{x^2}{4} h\nu_0 \frac{4NL^2A_i}{\sqrt{\pi}\,\alpha^3} \int_0^{v_c} \int_{(L/R)v_r}^{(2/\pi)(l/R)v_c} \frac{v_r}{v_z} e^{-v^2/\alpha^2} dv_z dv_r \\ &\cong x^2 h\nu_0 \frac{NR^2A_i}{\sqrt{\pi}\,\alpha} \int_0^a \int_\eta^b \frac{\eta}{\xi} e^{-\xi^2} d\xi d\eta , \end{aligned} \tag{2.13}$$

where

$$\xi = \frac{v_z}{\alpha} \cong \frac{v}{\alpha} , \qquad \eta = \frac{L}{R} \frac{v_r}{\alpha} ,$$

$$a = \frac{L}{R} \frac{v_c}{\alpha} , \quad \text{and} \quad b = \frac{2}{\pi} \frac{l}{R} \frac{v_c}{\alpha} .$$

As the length of the focuser, l, is considerably longer than that of the cavity, L, in masers so far constructed, we may assume $a<b$. The integration in (2.13) can be expressed in terms of exponential integrals, so that

$$\varDelta P_1=\frac{x^2}{4}h\nu_0\frac{NR^2A_i}{\sqrt{\pi}\,\alpha}[1-e^{-a^2}-a^2Ei(-a^2)+a^2Ei(-b^2)]\,. \tag{2.14}$$

Secondly, the emitted power from the molecules which collide with the cavity wall is calculated. The result is

$$\varDelta P_2=x^2h\nu_0\frac{NR^2A_i}{\sqrt{\pi}\,\alpha^3}\int_0^{v_c}\int_0^{(L/R)v_r}\frac{v_z}{v_r}e^{-v^2/\alpha^2}\,dv_zdv_r$$

$$=\frac{x^2}{4}h\nu_0\frac{NR^2A_i}{\sqrt{\pi}\,\alpha}[2\ln a-Ei(-a^2)+C]\,. \tag{2.15a}$$

Here $C=0.577216$ is the Euler's constant. Eq. (2.15a) may be expressed in a power series of a^2 as

$$\varDelta P_2=\frac{x^2}{4}h\nu_0\frac{NR^2A_i}{\sqrt{\pi}\,\alpha}\sum_{n=1}^{\infty}\frac{(-1)^{n-1}a^{2n}}{n\cdot n!}\,. \tag{2.15b}$$

The cavity loss including power flow from the output waveguide is

$$\varDelta P'=\frac{\omega W}{Q}=\frac{x^2h^2\nu_0LA}{16\,\pi^2\mu^2Q}\,, \tag{2.16}$$

where W is the stored energy, Q the loaded-Q and A the effective cross-section of the cavity. Then the threshold or the starting condition of maser oscillation is obtained from $\varDelta P'\leq\varDelta P=\varDelta P_1+\varDelta P_2$.

$$\frac{hLA}{4\pi^2\bar{\mu}^2Q}=\frac{NR^2A_i}{\sqrt{\pi}\,\alpha}\left[\sum_{n=1}^{\infty}(-1)^{n-1}\frac{n+1}{n\cdot n!}\,a^{2n}-a^2Ei(-a^2)+a^2Ei(-b^2)\right]. \tag{2.17}$$

In ammonia masers, the starting focuser voltage is not so large that $v_c\ll\alpha$ and $a^2\ll1$ may be a good approximation. In such a case higher order terms of a^2 can be neglected and Eq. (2.17) is expressed in the form,

$$\frac{hLA}{4\pi^2\bar{\mu}^2Q}=\frac{NR^2A_i}{\sqrt{\pi}\,\alpha}\,2a^2\left(1+\ln\frac{b}{a}\right)$$

$$=\frac{2\pi L^2}{\sqrt{\pi}\,\alpha^3}v_c^2\left(1+\ln\frac{2l}{\pi L}\right). \tag{2.18}$$

The critical radial velocity v_c is approximately proportional to the focuser voltage according to Eq. (2.8). It is noted that the starting condition, Eq. (2.17), includes the length of the focuser in a rather simple form.

The effective Average Velocity

The effective average velocity of molecules in the beam contributing to the oscillation is calculated. The weighted average velocity, $\langle v\rangle=\alpha\langle\xi\rangle$, is given by

$$\langle\xi\rangle=\frac{\displaystyle\int_0^a\int_\eta^b\xi\cdot\frac{\eta}{\xi}\,e^{-\xi^2}d\xi d\eta+\int_0^a\int_0^\eta\xi\cdot\frac{\xi}{\eta}\,e^{-\xi^2}d\xi d\eta}{\displaystyle\int_0^a\int_\eta^b\frac{\eta}{\xi}\,e^{-\xi^2}d\xi d\eta+\int_0^a\int_0^\eta\frac{\xi}{\eta}\,e^{-\xi^2}d\xi d\eta}\,. \tag{2.19}$$

The integrals in the denominator have already been given in Eqs. (2.14) and (2.15). The integrals in the numerator denoted by I_1 and I_2 are expressed in power series of a^2 as

$$I_1=\frac{\sqrt{\pi}}{4}a^2\Phi(b)-a^3\sum_{n=0}^{\infty}\frac{(-1)^n a^{2n}}{(2n+1)(2n+3)n!}, \tag{2.20}$$

and

$$I_2=a^3\sum_{n=0}^{\infty}\frac{(-1)_u a^{2n}}{(2n+3)^2 n!}, \tag{2.21}$$

where $\Phi(b)$ is the error integral. Then the numerator of (2.19) is

$$I_1+I_2=\frac{\sqrt{\pi}}{4}a^2\Phi(b)-2a^3\sum_{n=0}^{\infty}\frac{(-1)^n a^{2n}}{(2n+1)(2n+3)^2 n!}. \tag{2.22}$$

Now $\langle v\rangle=\alpha\langle\xi\rangle$ can be computed from (2.19) with (2.14), (2.15), and (2.22).

The ammonia masers hitherto constructed have the focuser about 2 to 3 times longer than the cavity. Therefore, almost all the reasonable designs of masers seem to fall in the range from $b=a$ to $b=5a$. Numerical computations of $\langle\xi\rangle$ for $a\leq b\leq 5a$ show that Eq. (2.19) may be approximated by a simple expression,

$$\langle\xi\rangle=(a+b)/4 \tag{2.23}$$

within the accuracy of about ±10%, when $b<1.4$. Using this approximation, the effective average velocity of molecules is expressed by

$$\langle v\rangle=\frac{\pi L+2l}{4\pi R}v_c. \tag{2.24}$$

This approximation is useful because of its simplicity.

Because slower molecules spend longer time in the cavity and have larger transition probabilities, the weighted average velocities of molecules contributing to induced emission is considerably smaller than the most probable velocity. However, this is not contradictory to the observed line width which corresponds to the molecular velocity approximately equal to the most probable velocity. In this section the effective average velocity has been calculated for $\omega=\omega_0$. On the other hand, when the emission line shape is observed by sweeping the frequency of incident microwaves, the contribution of slow molecules is rather small at the wing of the line $(\omega\not\doteqdot\omega_0)$, because the transition probability is

$$|a_1(\tau)|^2\cong\frac{x^2}{(\omega-\omega_0)^2}\sin^2(\omega-\omega_0)\frac{L}{2v}$$

in this case, and the contribution of slower molecules does not predominate when $(\omega-\omega_0)\times L/2v\gtrsim 1$.

§ 3. Saturation Characteristics

Oscillation amplitude of the ammonia maser is derived in this section as a function of focuser voltage, density of molecules, and dimensions of the cavity and the focuser. It is assumed here that the hyperfine structures do not exist, and the effects of unresolved hyperfine components will be discussed in the next section.

If the hyperfine effects are negligible, the Stark energy of ammonia in the upper inversion state is given by (2.6). The projection of J along the direction of electro-static field, M, takes $2J+1$ different values, from $-J$ to $+J$. The numbers of focused molecules are proportional to M^2, and the maximum radial velocities of focused molecules are different for those in different M states. Instead of calculating the sum of contributions from different M states, the weighted average of M^2 may be used to simplify the calculation.

$$\langle M^2\rangle=\frac{\Sigma M^2\cdot M^2}{\Sigma M^2}=\frac{6J^3+9J^2+J-1}{5(2J+1)}. \tag{3.1}$$

For the strongest line of ammonia $J=3$ gives $\langle M^2\rangle=7$. In equation (3.1) the deviation of the relative number of focused molecules from M^2 was neglected which would give only higher order small corrections in the further calculation.

The calculated maximum radial velocity, v_c, for the 3,3 line of ammonia is shown in Fig. 2, where the abscissa is the quadrupole focuser voltage, V_4, for $R=0.5$ cm. For the $2n$-pole focuser the voltage, V_{2n}, that produces the same maximum field as V_4 is from Eq. (2.5)

$$V_{2n}=\frac{2}{n}V_4. \tag{3.2}$$

In order to obtain approximate value of v_c for each value of M from Fig. 2, the scale in the ordinate should be multiplied by $M/7^{1/2}$.

The induced emission of molecules with velocity distribution may be considered as equivalent to that of uniform average velocity, $\langle v\rangle$, which was obtained in § 2. In the following discussion a variable θ defined by

$$\theta=[(\omega-\omega_0)^2+x^2]^{1/2}\,L/2\,\langle v\rangle \tag{3.3}$$

will be used. Although $\langle v\rangle$ has been obtained for small values of θ, the change of $\langle v\rangle$ by considering the effect of saturation can be regarded as the second order correction.

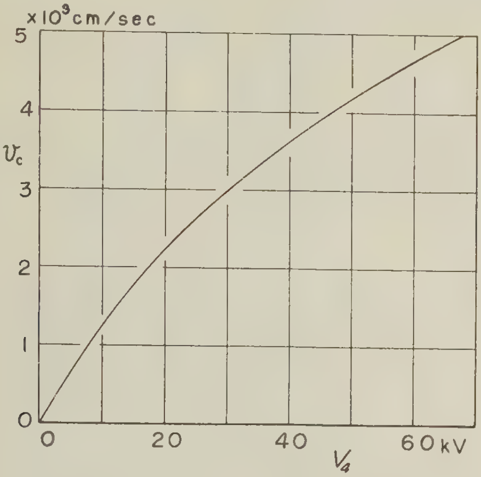

Fig. 2. Critical radial velocity of ammonia for $J=K=3$, $\langle M^2\rangle=7$, and $R=0.5$ cm.

The saturation characteristics was given by Eq. (31) in SWT as $n/n_{th}=\theta^2/\sin^2\theta$. However, in order to allow for the velocity distribution and the change of effective average velocity with operating conditions, this equation should be somewhat modified.

The transition probability of a molecule with the velocity equal to $\langle v\rangle$ is expressed as

$$|a_1(\tau)|^2=\frac{L^2x^2}{4\langle v\rangle^2\theta^2}\sin^2\theta \tag{3.4}$$

from Eq. (4) in SWT. Thus the emitted power from a beam of n molecules in a unit time is given by

$$\Delta P=\frac{x^2}{4}h\nu_0\frac{nL^2}{\langle v\rangle^2}\frac{\sin^2\theta}{\theta^2}\,. \tag{3.5}$$

The emitted power must be equal to the loss of the cavity given by (2.16), so that

$$\frac{Ah}{4\pi^2\overline{\mu}^2QL}=\frac{n}{\langle v\rangle^2}\frac{\sin^2\theta}{\theta^2}\,. \tag{3.6}$$

The threshold intensity of moleculer beam, n_0, is obtained from Eq. (3.6) by putting $\sin\theta=\theta$.

$$n_0=\frac{h\langle v_0\rangle^2A}{4\pi^2\overline{\mu}^2QL}\,. \tag{3.7}$$

This is almost the same as (30) in SWT except that here $\langle v_0\rangle$ is the effective average velocity at the threshold which is much smaller than the most probable velocity.

Using (3.7), we can write for the finite values of θ

$$\frac{n_0}{n}\frac{\langle v\rangle^2}{\langle v_0\rangle^2}=\frac{\sin^2\theta}{\theta^2}\,, \tag{3.8}$$

which is not same as Eq. (31) in SWT. Since n is approximately proportional to v_c^4 as

$$n=\int_0^{v_c}\int_0^{(2/\pi)(l/R)v_c} n(v_r,\,v_z)dv_zdv_r$$
$$=\frac{NA_i}{\sqrt{\pi}\,\alpha}v_c^2(1-e^{-b^2})\simeq\frac{4NA_i}{\pi^{5/2}\alpha^3}\frac{l^2}{R^2}v_c^4\,, \tag{3.9}$$

the saturation characteristics is expressed in the form

$$\frac{v_{c0}}{v_c}=\frac{\sin\theta}{\theta}\,. \tag{3.10}$$

Now the amplitude of oscillation, x, can be calculated as a function of focuser voltage, using Eqs. (2.7), (3.3), and (3.10). A typical example for the focuser length $l=30$ cm, cavity length $L=11$ cm, focuser radius $R=0.5$ cm, and the starting voltage $V_{4,0}=5$ kV with a quadrupole focuser is shown in Fig. 3. Saturation characteristics given by the uni-velocity theory in SWT and velocity distribution theory by Helmer[4] are also shown for comparison.

In this example the present theory gives $\langle v\rangle=15.0\,v_c$ from Eq. (2.24). This approximation is applicable when $b=38.2\,v_c/\alpha$ is smaller than 1.4, or when $V_4<16$ kV. Beyond this voltage the magnitude of $\langle v\rangle$ computed from complicated integrations in (2.19) tends to be smaller than the simple approximation. However, if the starting voltage is fairly small, the finite rf amplitude must be taken into account when b becomes large. In such a case $|a_1(\tau)|^2$ can not be approximated by $(xL/2v)^2$ which increases infinitely with decreasing v, but it must be $\sin^2(xL/2v)$. This factor takes a maximum value when $v=xL/\pi$ and becomes zero when $v=xL/2\pi$, taking oscillating values between 0 and 1 for the smaller values of v. Therefore, when $xL/2v\gtrsim 1$, the saturation effect will result in the increase of the effective average velocity.

Since the two sources of deviations from (2.24) requires corrections of different sign at nearly the same region, they more or less compensate each other, and the approximation, (2.24), may be used up to higher focuser voltage and larger amplitude of oscillation than $b=1.4$ or $xL/2v=1$. Of cource $\langle v\rangle$ would be nearly α for large values of V and x, and a plausible estimate is shown by a broken line in Fig. 3.

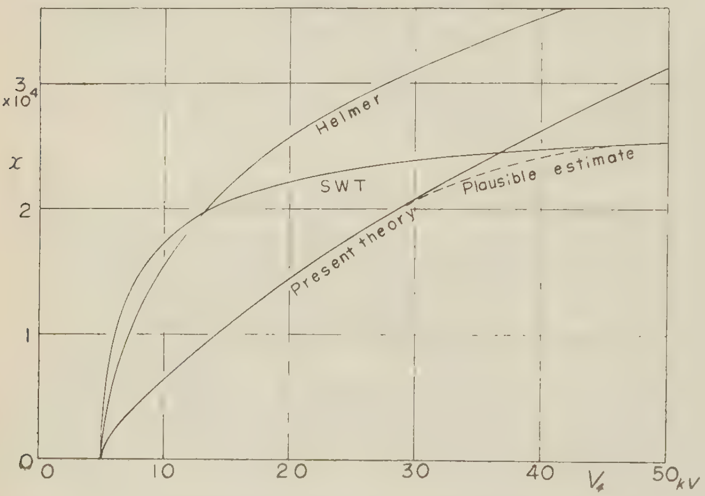

Fig. 3. Theoretical saturation characteristics of a maser oscillator.

The present theory has been found to agree with experimental results better than the former ones as will be described in part II.

It must be remembered that the relative numbers of molecules in each M state changes in a complex way with increasing focuser voltage. The number of focused molecules in a larger M state saturates faster than that in a smaller M state, and also their transition probability saturates faster with increasing x. Hence the contribution of smaller M states will increase in a large signal region discussed above.

§ 4. Effects of Unresolved Hyperfine Structure

Each inversion pair of energy levels of ammonia is split into hyperfine levels by the coupling with the quadrupole moment of nitrogen nucleus, N^{14}. Quadrupole hyperfine levels are designated by an angular momentum $F_1=J+I$. Inversion transitions corresponding to $\Delta F_1=\pm 1$ are the two pairs of satellites. The center line consists of three $\Delta F_1=0$ components which have not yet been resolved.

However, Gordon observed[10)] a significant asymmetry of the magnetic hyperfine structures about the center line, and it was ascribed to the change of quadrupole coupling constant eqQ in the upper and lower inversion states. He found the increase of $\Delta eqQ=4\pm1$ kc/sec in the lower state for the 3,3 line. The change of eqQ results in the separation of three components in the center inversion lines, with a sole exception for the 3,2 line in which the quadrupole hyperfine structure is absent.

When the molecules are in thermal equilibrium, the relative intensities of these three components are proportional to $2F_1+1$, and the weighted average frequency just coincides with that not displaced by hyperfine structure. The ratio of intensities of three components with $F_1=3, 4$, and 2 of the 3,3 line is 7:9:5 as shown in Fig. 4 (a).

The relative intensities of these three components in the maser are different from those in thermal equilibrium, since the number of molecules in respective F_1 states are determined by the focusing force which is approximately proportional to M^2 in the strong field region*. Assuming that the transition from the intermediate to strong field case is adiabatic, relative numbers of focused molecules in the weak field F_1 states are calculated as approximately $\sum M^2$, where the summation

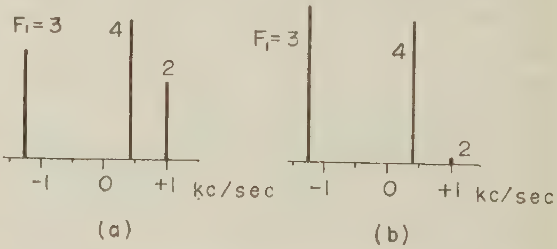

Fig. 4. Relative intensities of hyperfine components in the 3,3 center line of ammonia. (a): Thermal equilibrium, (b): In the maser.

---

* See Eq. (2.6). M_J is written simply M, but it is not M_F.

is for all levels which go to respective F_1 level in weak field. The approximate ratio of focused molecules for $F_1=3$, 4, and 2 in the 3,3 line is 45:37:2.

The probability of the transition $\Delta F_1=0$ has a factor,

$$f(F_1)=\frac{[F_1(F_1+1)+J(J+1)-I(I+1)]^2}{F_1(F_1+1)} \quad (4.1)$$

which is 121/3: 45: 128/3 for $F_1=3$, 4, and 2. Then the relative intensity is given by $c(F_1)=f(F_1)\cdot\sum M^2$, and the ratio for the 3,3 line is 1: 0.9174: 0.0470, as illustrated in Fig. 4 (b).

In observing the emission spectrum, these three components cannot be resolved, so far as the cavity is not extremely long, and the center line is observed at the frequency very close to the weighted average of the three components. Since the hyperfine shifts are -1.25, $+0.42$, and $+1.00$ kc/sec for $F_1=3$, 4, and 2, using the value $\Delta eqQ=4$ kc/sec*, the center frequency of the emission line is calculated to be -0.42 kc/sec.

The frequency of maser oscillator would be somewhat different, particularly near the threshold of oscillation where the oscillation amplitude is small and the focuser voltage is low. As discussed in § 2, the effective average velocity is so small in this case that the starting frequency might be near the strongest hyperfine component, $F_1=3$.

As a general extension of Eq. (44) in Appendix, the condition of oscillation with several hyperfine components can be expressed in the form

$$c_0\left(1+2iQ\frac{\omega-\omega_c}{\omega_c}\right) =\sum_j \frac{c_j}{\theta_j^2}\left[\sin^2\theta_j-i(\omega-\omega_j)\frac{L}{2\langle v\rangle} \times\left(1-\frac{\sin 2\theta_j}{2\theta_j}\right)\right], \quad (4.2)$$

where c_j is the relative intensity corresponding to $c(F_1)$ and also to $n/\langle v\rangle^2$, $\omega_j/2\pi$ the frequency of j-th hyperfine component, also

$$\theta_j=[(\omega-\omega_j)^2+x^2]^{1/2}\frac{L}{2\langle v\rangle}, \quad (4.3)$$

and c_0 is a constant corresponding to the relative intensity at the threshold of oscillation. Other notations are the same as in SWT and in § 2.

From the real part of Eq. (4.2) the amplitude of oscillation is obtained as

$$c_0=\sum_j c_j\frac{\sin^2\theta_j}{\theta_j^2}. \quad (4.4)$$

The imaginary part of Eq. (4.2) gives the frequency of oscillation by

$$2c_0Q\frac{\omega_c-\omega}{\omega_c} =\sum_j \frac{c_j}{\theta_j^2}(\omega-\omega_j)\frac{L}{2\langle v\rangle}\left(1-\frac{\sin 2\theta_j}{2\theta_j}\right). \quad (4.5)$$

It seems rather difficult to express amplitude and frequency of oscillation in explicit forms from (4.4) and (4.5). Then a typical case of the 3,3 line of ammonia will be numerically given. Because the relative intensity of the $F_1=2$ component is much smaller than the other two, as discussed above, calculation with only two components, $F_1=3$, and 4, would give fairly accurate results.

Amplitude vs. Frequency Characteristics

The amplitude of oscillation, x, due to the emission of two hyperfine components at ω_1 and ω_2 is determined from

$$\theta_1=[(\omega-\omega_1)^2+x^2]^{1/2}L/2\langle v\rangle,$$
$$\theta_2=[(\omega-\omega_2)^2+x^2]^{1/2}L/2\langle v\rangle, \quad (4.6)$$

and

$$c_0=c_1\frac{\sin^2\theta_1}{\theta_1^2}+c_2\frac{\sin^2\theta_2}{\theta_2^2}. \quad (4.7)$$

The ratio c_1: c_2 is known to be 1: 0.9174 in the case of the 3,3 line of ammonia, if the effect of saturation is neglected.

Since $\sin^2\theta_1/\theta_1^2=c_1/c_0=$const. is presented by a circle in the ω-x plane with its center at $\omega=\omega_1$, while $\sin^2\theta_2/\theta_2^2$ by another circle with its center at $\omega=\omega_2$, a set of θ_1 and θ_2 can be determined from Eq. (4.7) by a graphical method. Each set of θ_1 and θ_2 determine a set of ω and x from (4.6). Thus the amplitnde vs. frequency characteristics is obtained. An example for $V_4=14$ kV, $\langle v\rangle=15\,v_c=2.6\times10^4$ cm/sec is shown in Fig. 5, where the parameter is the beam intensity.

It is evident that by increasing the focuser voltage the characteristic curves in ω-x plane tend to be circular like those in the absence of hyperfine structure. The curves in Fig. 5 are very close to ellipses (note that the vertical scale is expanded) inconsistent with the observation by Helmer[7]. However, it must have come from the use of a single effective average velocity which is not a good approximation for large θ, as already discussed at the end of § 3.

---

* Bonanomi has recently obtained a somewhat smaller value as 3 kc/sec. Private communication.

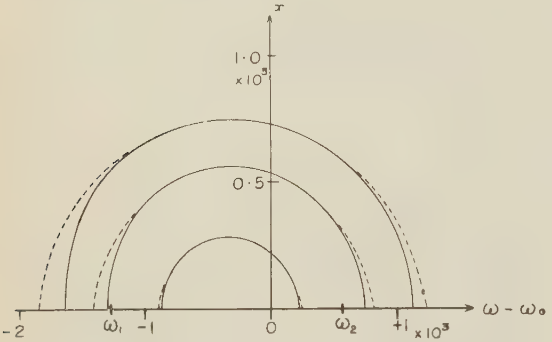

Fig. 5. Amplitude vs. frequency characteristics. Dotted curves show plausible modifications corresponding to those in Fig. 6.

The expression $\sin^2\theta/\theta^2$ must be somewhat modified when $\theta \gtrsim \pi/2$ as shown by a dotted curve in Fig. 6. This modification will spread the characteristic curve at the region where θ_1 or θ_2 is large, and then it will be consistent with experimental results. Because the higher frequency component ($F_1=4$) is weaker, there would occur more spread at the lower frequency wing of the characteristic curve where θ_2 is larger than θ_1 in the other wing.

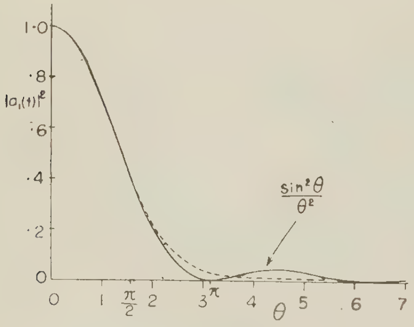

Fig. 6. Transition probability, $\sin^2\theta/\theta^2$ and its modification.

Frequency Shift

The frequency of oscillation, $\omega/2\pi$, due to the emission of two unresolved components is obtained from Eq. (4.5). It can be seen that the frequency pulling by the cavity occurs in a similar manner as described before[1)5)4)]. In this paper we are interested in the center frequency of oscillation which can be found or defined by putting $\omega_c=\omega$, although experimental determination of the corresponding line center needs a little troublesome procedure. Then Eq. (4.5) becomes

$$c_1\frac{\omega-\omega_1}{\theta_1^2}\left(1-\frac{\sin 2\theta_1}{2\theta_1}\right)+c_2\frac{\omega-\omega_2}{\theta_2^2}\left(1-\frac{\sin 2\theta_2}{2\theta_2}\right)=0. \tag{4.8}$$

Taking $x=0$ in order to find the starting frequency,

$$\theta_1=|\omega-\omega_1|L/2\langle v\rangle,\quad \theta_2=|\omega-\omega_2|L/2\langle v\rangle\ , \tag{4.9}$$

Eq. (4.8) is written as

$$\frac{c_1}{2\theta_1}\left(1-\frac{\sin 2\theta_1}{2\theta_1}\right)=\frac{c_2}{2\theta_2}\left(1-\frac{\sin 2\theta_2}{2\theta_2}\right), \tag{4.10}$$

since $\omega_1<\omega<\omega_2$, when $\omega_1<\omega_2$. The ratio c_1: c_2 is known and also

$$\theta_1+\theta_2=|\omega_2-\omega_1|L/2\langle v\rangle \tag{4.11}$$

is a known constant. Then the frequency of oscillation can be obtained from Eqs. (4.9), (4.10), and (4.11) as a function of $\langle v\rangle$.

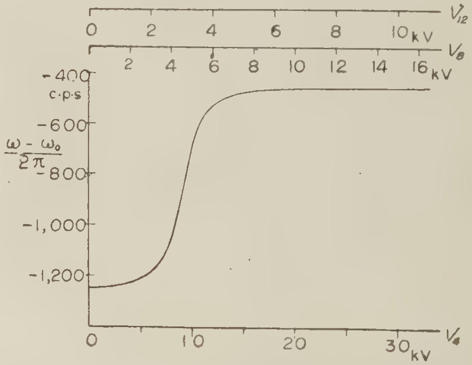

Fig. 7. Calculated frequency shift of the 3,3 line due to unresolved hyperfine structure. Changes of relative intensities by saturation effect are neglected.

An example for the 3,3 line of ammonia was calculated by plotting functions of the type, $(1-\sin 2\theta/2\theta)/2\theta$. The result is shown in Fig. 7, where the abscissa is the focuser voltage. Scales for the 8- and 12- pole focuser voltages, V_8, and V_{12}, as well as the quadrupole focuser voltage, V_4, are indicated for convenience. The conversion from $\langle v\rangle$ to V was done by Eqs. (2.24) and (2.7) or Fig. 2, using following values: $l=30$ cm, $L=11$ cm, $R=0.5$ cm, $\mu=1.44$ D, and $\langle M^2\rangle=7$. The frequency shift is shown in c.p.s. with respect to the center frequency not displaced by hyperfine structure.

The calculated frequency shown in Fig. 7 is the starting frequency as a function of the focuser voltage. Frequency shift for the finite amplitude of oscillation has to be computed from (4.8) instead of (4.10). The computation can be carried out by a graphical method, and it may be conjectured that the oscillation frequency in this case changes nearly the same way as Fig. 7 with increasing focuser voltage under a constant beam source hence with increasing amplitude of oscillation. Suppose, for example, a maser with threshold voltage of $V_{4,0}=10$ kV, it will start oscillation at the frequency 690 c.p.s. lower than the true center, and the frequency increases up to about -450 c. p. s.* at high voltages.

The frequency shift beyond the quadrupole focuser voltage of 15 kV is shown to be considerably small, of the order of 1 c. p. s./kV. On the other hand, it is appreciable below 15 kV, and its change is seen to amount to 2 to 3 parts in 10^8. Therefore, the frequency shift of this type would be studied better by a maser with lower starting voltage.

Of course the calculations used was not very accurate, but the conclusion such as that shown in Fig. 7 would be correct at least qualitatively. In particular, changes of the relative abundance of molecules in different F_1 states with increasing V and x, as described at the end of § 3, must cause considerable shift.

Since $F_1=3$ component has the lowest frequency and the largest value of $\sum M^2$, saturation effect tends to have less contribution of $F_1=3$ component and more of $F_1=2$ component, hence the oscillation frequency will be increased. Increasing the length of the cavity increases the saturation effect, because $\theta \propto L$, and will increase the oscillation frequency. Of course actual frequency shift of the maser oscillator includes other types of shifts such as those due to traveling wave component in the cavity, cavity pulling, and collision of molecules. Therefore, determination of the absolute shift seems to be very difficult, and the maser on the 3,3 line of ammonia may not be a good primary standard of frequency. However, excellent resettability of about 10^{-10} is practicable and it must be quite useful.

Appendix

It is shown that Eq. (46) in SWT can easily be obtained without any restriction of the frequencies. On page 1313 of SWT from line 28 should read as follows:
a slight deviation from Eq. (41). Therefore the following result is obtained.

$$\tfrac{1}{2}E=-i\frac{4\pi Q}{L}\left(1+2iQ\frac{\omega-\omega_c}{\omega_c}\right)^{-1}\int_0^L P^\dagger(z)dz\ . \tag{42}$$

By using Eq. (38), Eq. (42) may be written

$$\tfrac{1}{2}E=-i\frac{4\pi nQ}{vAL}\left(1+2iQ\,\frac{\omega-\omega_c}{\omega_c}\right)^{-1}\int_0^L p^\dagger(z)dz\ . \tag{43}$$

Since $p(z)$ has been given as a function of $x=E\bar{\mu}/\hbar$, the condition of stationary oscillation is obtained from Eqs. (43) and (37) as

$$\begin{aligned}\frac{x}{2}=&\frac{4\pi^2Qn\bar{\mu}^2}{vhAL}\left(1+2iQ\,\frac{\omega-\omega_c}{\omega_c}\right)^{-1}\frac{x}{[(\omega-\omega_0)^2+x^2]^{1/2}}\\ &\times\int_0^L\left\{\sin[(\omega-\omega_0)^2+x^2]^{1/2}\,\frac{z}{v}\right.\\ &-i\,\frac{\omega-\omega_0}{[(\omega-\omega_0)^2+x^2]^{1/2}}\\ &\left.\times\left[1-\cos[(\omega-\omega_0)^2+x^2]^{1/2}\frac{z}{v}\right]\right\}dz\ .\end{aligned} \tag{44}$$

From the real part of Eq. (44), the amplitude of oscillation $E=x\hbar/\bar{\mu}$ can be obtained as

$$n/n_{th}=\theta^2/\sin^2\theta\ .$$

This is the same as Eq. (31), but now

$$\theta=[(\omega-\omega_0)^2+x^2]^{1/2}\,L/2v\ , \tag{45}$$

including the case when $\omega\not\fallingdotseq\omega_0$.
The imaginary part of Eq. (44) gives

$$\frac{\omega-\omega_0}{\omega_0}=2Q\,\frac{(v/L)}{\omega_0}\,\frac{1-\cos 2\theta}{1-\sin 2\theta/2\theta}\,\frac{\omega_c-\omega}{\omega_c}\ . \tag{46}$$

One-Center Molecular Orbital Wave Function for Methane

By Shoichiro KOIDE
Institute of Physics, College of General Education, University of Tokyo
Hisao SEKIYAMA and Toshio NAGASHIMA*
Department of Physics, Faculty of Science, University of Tokyo

(Received June 8, 1957)

The validity of the spherical approximation for the potential due to nuclei used in the calculation of molecules with good symmetry by means of one-center MO method is examined for methane molecule. Molecular orbital wave functions are set up as harmonic expansion about the central carbon nucleus, and energy expectation values are calculated with respect to the exact Hamiltonian. Results obtained by using various approximations are compared. It is shown that while the effect of the angular dependent part of the nuclear potential on the energy value is not so large as is expected, the electron charge distribution has fairly large directional dependence caused by the non-central part of the potential.

§ 1. Introduction

Most of the molecular orbital calculations heretofore performed have been based on the so-called LCAO approximation. The main difficulty of this method is that if we want to get sufficiently accurate results it requires extensive numerical work especially in the evaluation of many-center integrals. To avoid this difficulty, several attempts have been made concerning the one-center method[1] in which each molecular orbital is expressed as a series of spherical harmonics times a radial function about a single center. Thus

$$\psi(i)=\sum_{a} A_{a\alpha} r_i^{-1} P_{n_a l_a}(r_i) Y_{l_a m_a}(\theta_i, \phi_i) . \quad (1)$$

The most famous work in this direction is the self-consistent field calculation of methane molecule carried out by Buckingham, Massey and Tibbs[2]. Considering the high degree of symmetry of this molecule, they used spherically averaged nuclear potential and reduced the problem to the atomic one. The configuration used was $(1s)^2(2s)^2(2p)^6$, and this corresponds to the product of one-center molecular orbitals each of which is approximated by a single harmonic term in the expansion (1).

A similar calculation was made by Bernal using analytic radial functions[3]. In his calculation he took account of the exchange terms which were neglected in the calculation by Buckingham et al.

Quite recently, Carter has calculated the one-center molecular orbitals for methane and silane taking account of the higher harmonic terms in the expansion of the molecular orbitals[4]. According to his results, the total energy of the methane is predicted very well by taking just the first term in each series, but higher terms are important in the calculation of some other molecular quantities such as angular momentum and diamagnetic susceptibility.

If we use the one-center expansion of molecular orbitals, it will be difficult to obtain wave functions with uniform accuracy throughout all regions of the molecule. One cannot therefore expect good results for the calculation of such properties for which contribution from the outer atoms is considerable. Carter's result reveals this situation.

---

* Now at the Research Laboratory, Asahi Glass Company, LTD., Yokohama, Japan.

In all these calculations, the potential due to nuclei has been approximated by spherically smoothed one. By using this approximation, however, the effect of the attraction by the outer atomic nuclei will be considerably reduced. This defect of smoothing approximation has been revealed in the calculation of electron distribution in CCl_4 molecule carried through by March and his colaborators using the Thomas-Fermi method[5]. In their result, the electrons have an inclination to concentrate to the central carbon atom. The same tendency may occur in the calculation of wave functions. Of course, one can by no means calculate the directional variation of the valence electron distribution in this smoothing approximation.

In view of these circumstances, it may be highly desirable to consider the angular dependence of the nuclear potential in the calculation of the one-center molecular orbitals. In order to reflect this effect in the wave functions, we must take account of the higher harmonic terms of the expansion as far as possible.

In Bernal's calculation, the exchange terms lower the total energy of methane molecule by ca 0.9 a.u. which is comparable to the binding energy 0.74 a.u. observed for this molecule.

Although the numerical calculation of the self-consistent field would yield the best result, it requires a tremendous effort since the Hartree or the Hartree-Fock equations become a set of simultaneous equations coupled with each other in a complicated way.

In this paper, therefore, we will restrict the problem to the simplest one, i.e. that of methane, and simple analytic radial functions will be employed so as to enable us to estimate the effects of angular dependent nuclear potential by using the antisymmetrized total wave function.

§2. Nuclear Potential and Wave Functions

If we choose the coordinate axes as shown in Fig. 1, the potential energy of an electron due to all nuclei can be expanded as

$$V_n(r, \theta, \phi) = V_0(r) + V_c(r)A(\theta, \phi) + V_t(r)B(\theta, \phi) + V_h(r)C(\theta, \phi) + \cdots \, . \qquad (2)$$

The first term $V_0(r)$ is nothing but the spherically averaged potential used in the previous calculations. Here and in the following we use the atomic units, so the unit of length is the Bohr radius a_0. Since four protons are at a distance $2a_0$ from the central carbon nucleus, terms on the right hand side of Eq. (2) can be determined as

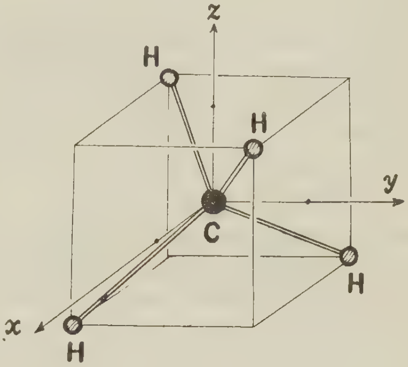

Fig. 1.

$$V_0(r) = \begin{cases} -2 - \dfrac{6}{r} & \text{if } r < 2 \, , \\ -\dfrac{10}{r} & \text{if } r > 2 \, , \end{cases} \qquad (3)$$

$$V_c(r) = \begin{cases} -\dfrac{(35\pi)^{1/2}}{42} r^3 & \text{if } r < 2 \, , \\ -\dfrac{64(35\pi)^{1/2}}{21} r^{-4} & \text{if } r > 2 \, , \end{cases} \qquad (4)$$

$$A(\theta, \phi) = -2^{-1/2} i \{ Y_{32}(\theta, \phi) - Y_{3-2}(\theta, \phi) \} \, , \qquad (4a)$$

$$V_t(r) = \begin{cases} -\dfrac{(21\pi)^{1/2}}{108} r^4 & \text{if } r < 2 \, , \\ -\dfrac{128(21\pi)^{1/2}}{27} r^{-5} & \text{if } r > 2 \, , \end{cases} \qquad (5)$$

$$B(\theta, \phi) = -\left(\frac{5}{24}\right)^{1/2} \{ Y_{44}(\theta, \phi) + Y_{4-4}(\theta, \phi) \} - \left(\frac{7}{12}\right)^{1/2} Y_{40}(\theta, \phi) \, , \qquad (5a)$$

$$V_h(r) = \begin{cases} -\dfrac{(26\pi)^{1/2}}{468} r^6 & \text{if } r < 2 \, , \\ -\dfrac{2048(26\pi)^{1/2}}{117} r^{-7} & \text{if } r > 2 \, , \end{cases} \qquad (6)$$

$$C(\theta, \phi) = -\left(\frac{7}{16}\right)^{1/2} \{ Y_{64}(\theta, \phi) + Y_{6-4}(\theta, \phi) \} + \left(\frac{1}{8}\right)^{1/2} Y_{60}(\theta, \phi) \, . \qquad (6a)$$

Corresponding to the atomic configuration $(1s)^2(2s)^2(2p_x)^2(2p_y)^2(2p_z)^2$, we may take the ground state configuration of our ten-electron system as

$$(1a_1)^2(2a_1)^2(2t_{2x})^2(2t_{2y})^2(2t_{2z})^2 .$$

Here a_1 and t_2 denote the irreducible representations A_1 and T_2 of the tetrahedral group corresponding to the respective molecular orbitals.

Since the influence of surrounding hydrogen atoms is considered to be small on the inner K-shell electrons of the carbon atom, $1a_1$ function may safely be assumed to be spherically symmetric; i.e.

$$(1a_1): \quad \psi_1(\boldsymbol{r})=C_1r^{-1}P_1(r)Y_{00}(\theta, \phi) . \tag{7}$$

In the molecular orbitals of the valence electrons, we will include the higher harmonic terms up to the third order ($l=3$). Then, by using the group character table, we can assume the following form for our $2a_1$ and $2t_2$ functions:

$$(2a_1): \quad \psi_2(\boldsymbol{r})=C_2r^{-1}P_2(r)Y_{00}(\theta, \phi) + C_3r^{-1}P_3(r)A(\theta, \phi) , \tag{8}$$

$$(2t_{2x}): \quad \psi_x(\boldsymbol{r})=C_4r^{-1}P_4(r)T_x^{(1)}(\theta, \phi) + C_5r^{-1}P_5(r)T_x^{(2)}(\theta, \phi) + C_6r^{-1}P_6(r)T_x^{(3)}(\theta, \phi) , \tag{9}$$

with similar expressions for $2t_{2y}$ and $2t_{2z}$. In these expressions, $A(\theta, \phi)\equiv f_{xyz}$ is the function defined by (4a) and is proportional to xyz/r^3, and

$$T_x^{(1)}=p_x , \quad T_x^{(2)}=d_{yz} , \quad T_x^{(3)}=f_{x(5x^2-3)} \tag{10}$$

are the functions proportional to x/r, yz/r^2 and $x(5x^2-3r^2)/r^3$ and they are expressed as proper linear combinations of the spherical harmonics $Y_{lm}(\theta, \phi)$ with $l=1, 2, 3$ respectively.

Since each of the angular and radial functions is taken to be normalized as

$$\iint|A|^2 \sin\theta \, d\theta d\phi = \iint|T_\xi^{(i)}|^2 \sin\theta \, d\theta d\phi = \int_0^\infty |P_i(r)|^2 dr=1 , \tag{11}$$

the coefficients C's must satisfy the conditions

$$C_1=1 , \quad C_2^2+C_3^2=C_4^2+C_5^2+C_6^2=1 . \tag{12}$$

For simplicity, the same functions as the Bernal's may be adopted as the radial functions of the leading terms in (7), (8) and (9):

$$P_1(r)=2\alpha^{3/2}re^{-\alpha r} \tag{13}$$

$$P_2(r)=\{12\beta^5/(\alpha^2-\alpha\beta+\beta^2)\}^{1/2} \times\{(\alpha+\beta)r/3-1\}re^{-\beta r} \tag{14}$$

$$P_4(r)=(4\gamma^5/3)^{1/2}r^2e^{-\gamma r} , \tag{15}$$

though the functions used by Carter appear to give somewhat better results.

As we know nothing in advance about the radial parts of the additional functions, some preliminary calculations about the Hartree equations for $P_3(r), P_5(r), P_6(r)$ were carried out using the initial fields obtained from numerical functions of Buckingham et al. As a result, it has been concluded that each of these functions seems to have a maximum in the neighborhood of the C–H bond length, i.e. $r=2$. Thus we may eventually assume the following form for these functions:

$$P_3(r)=(2048/315)^{1/2}r^4e^{-2r} \tag{16}$$

$$P_5(r)=(243/80)^{1/2}r^3e^{-3r/2} \tag{17}$$

$$P_6(r)=P_3(r) . \tag{18}$$

§ 3. Variation Calculations

The total energy of the molecule is the sum of the electronic energy E and the classical nuclear repulsion energy E_N:

$$E=\int\Psi^*\mathscr{H}\Psi d\boldsymbol{r}_1 d\boldsymbol{r}_2\cdots d\boldsymbol{r}_{10} , \tag{19}$$

$$E_N=\{40+3(3/2)^{1/2}\}/2 , \tag{20}$$

where $\mathscr{H}$ is the Hamiltonian of the electron system

$$\mathscr{H}=\sum_{i=1}^{10} H(i)+\sum_{i<j}^{10}\frac{1}{r_{ij}} , \tag{21}$$

$$H(i)=-\frac{1}{2}\Delta_i+V_n(r_i, \theta_i, \phi_i) , \tag{22}$$

and Ψ is the Slater determinant given by

$$\Psi=(10!)^{-1/2}\,\mathrm{Det}[\psi_1\bar{\psi}_1\psi_2\bar{\psi}_2\psi_x\bar{\psi}_x\psi_y\bar{\psi}_y\psi_z\bar{\psi}_z| , \tag{23}$$

where electrons in the orbitals with upper bar have an opposite direction of spin to those in the orbitals without bar.

The electronic energy E is expressed in terms of one- and two-electron integrals as follows:

$$\begin{aligned} E=&2I(1a_1)+2I(2a_1)+6I(2t_{2x})+F_0(11) \\ &+4F_0(12)C_2^2+4F_0(13)C_3^2+12F_0(14)C_4^2 \\ &+12F_0(15)C_5^2+12F_0(16)C_6^2+F_0(22)C_2^4 \\ &+2F_0(23)C_2^2C_3^2+F_0(33)C_3^4+\frac{4}{7}G_3(23)C_2^2C_3^2 \\ &+\frac{84}{1089}F_4(33)C_3^4+\frac{800}{20449}F_6(33)C_3^4 \\ &+12F_0(24)C_2^2C_4^2-\frac{48\sqrt{21}}{49}I_3(23:45)C_2C_3C_4C_5 \\ &+12F_0(25)C_2^2C_5^2+\frac{23}{7}I_3(23:56)C_2C_3C_5C_6 \end{aligned}$$

\end{aligned}
$$

where one-electron integrals are expressed as usual:

$$I(1a_1)=\iint\psi_1^*(\boldsymbol{r})H(\boldsymbol{r})\psi_1(\boldsymbol{r})d\boldsymbol{r}\ , \qquad (25a)$$

$$I(2a_1)=\int\psi_2^*(\boldsymbol{r})H(\boldsymbol{r})\psi_2(\boldsymbol{r})d\boldsymbol{r}\ , \qquad (25b)$$

$$I(2t_{2x})=\int\psi_x^*(\boldsymbol{r})H(\boldsymbol{r})\psi_x(\boldsymbol{r})d\boldsymbol{r}=I(2t_{2y})=I(2t_{2z})\ . \qquad (25c)$$

Since our orbital functions are not of single term, two-electron integrals have the following form in general

$$I_n(ij:kl)=\iint\frac{r_<^n}{r_>^{n+1}}P_i(r)P_j(r)P_k(r')P_l(r')drdr'\ , \qquad (26)$$

and F and G are the special cases of this general form

$$F_n(ij)=I_n(ii:jj)\ , \qquad (27a)$$

$$G_n(ij)=I_n(ij:ij)\ . \qquad (27b)$$

Following the variational method, the electronic energy E is minimized with respect to the parameters, α, β, γ, C_1, C_2, $\cdots$, C_6 under the condition of Eq. (12). The calculation of Buckingham et al shows that the $1a_1$ function does not differ much from the self-consistent function for the free carbon atom. For this reason, the minimization with respect to α was not carried out. Comparing the results of Buckingham et al and of Bernal, we took $\alpha=5.52$. For several sets of the values of β and γ numerical calculations of the one- and two-electron integrals were carried out, and the coefficient C's were determined so as to minimize the value of E for each set of β and γ.

§4. Results and Discussion

The results are listed in Table I. From these values, we can find that the minimum value of the total energy occurs at $\beta=1.73$ and $\gamma=1.3$, as

$$E+E_N=-39.64\ \text{a.u.}$$

The coefficients C's corresponding to this minimum energy value were found to be $C_2=0.9851$, $C_3=0.172$, $C_4=0.9718$, $C_5=0.227$ and $C_6=-0.064$.

A: values obtained by using spherical approximation (without exchange).
B: values obtained by using spherical approximation (with exchange).
C: values obtained by taking account of angular dependent terms of the nuclear potential (with exchange).
$\Delta E=B-C$.

If we take $C_2=C_4=1$ and $C_3=C_5=C_6=0$, contribution from the angular dependent terms of the nuclear potential vanishes because of the properties of the spherical harmonics, and the results thus obtained, which are also shown in Table I in the fourth column, column, coincide with those given by Bernal's approximation. In this table, we can see that our results are lower about 0.3 a.u. than those of Bernal's approximation.

According to Carter's estimation, even when C_5 and C_6 terms and the non-central part of the nuclear potential are neglected, the minimum energy can be lowered by ca 0.2 a.u. if we take account of the second term of Eq. (8). Thus we can see that the effect of the non-central part of the nuclear potential is not so large as we have expected, though our results would be improved further to some extent by using more appropriate form for the additional functions.

In Table II, energy values obtained by the various workers are tabulated with approximations involved. As is pointed out by Carter, there is a numerical error in the total energy value calculated by Buckingham et al. Hence the calculated binding energy, which is given by subtracting the total energy $E+E_N$ from that for C+4H calculated by Torrance⁶⁾, becomes slightly negative. Since Torrance's calculation is based on the numerical computation of the self-consistent field without exchange, it is of little meaning to compare it with the $E+E_N$ values obtained by using other approximations. If, however, the non-central terms of the nuclear potential were took into account in the calculation of Buckingham et al, their result would be improved

and, as we have seen in the above consideration, the calculated total energy of methane would be lowered by at least ca 0.3 a.u., yielding the positive binding energy of about 0.1 a.u. = 2.7 eV.

In order to see the effect of angular dependent part of the nuclear potential on the electron distribution, we may divide the whole space into eight regions by xy-, yz- and zx-planes, and calculate the number of electrons belonging to each of these divisions. As is seen in Fig. 1, protons are located in four of those, and the number of electrons lying in one of them can be easily calculated as

$$\begin{aligned} n_+ = \frac{10}{8} &+ 4C_2C_3(4\pi)^{-1/2}\int_0^{\pi/2}\int_0^{\pi/2} A(\theta, \phi)\sin\theta\, d\theta d\phi \int_0^\infty P_2P_3dr \\ &+ 12C_4C_5\int_0^{\pi/2}\int_0^{\pi/2} T_x^{(1)}T_x^{(2)}\sin\theta\, d\theta d\phi \int_0^\infty P_4P_5dr \\ &+ 12C_6C_6\int_0^{\pi/2}\int_0^{\pi/2} T_x^{(2)}T_x^{(3)}\sin\theta\, d\theta d\phi \int_0^\infty P_5P_6dr \\ &+ 12C_4C_6\int_0^{\pi/2}\int_0^{\pi/2} T_x^{(1)}T_x^{(3)}\sin\theta\, d\theta d\phi \int_0^\infty P_4P_6dr = 1.25+0.25\ . \end{aligned} \tag{28a}$$

Similarly, the number of electrons in one of the remaining four divisions is

$$n_- = 1.25 - 0.25\ . \tag{28b}$$

If we use the simplest Heitler-London method and neglect the non-orthogonality of the hydrogen atomic orbitals with each other and with carbon atomic orbitals, ten electrons are accommodated as $(1s)^2 \cdot \phi_1 : h_1 \cdot \phi_2 : h_2 \cdot \phi_3 : h_3 \cdot \phi_4 : h_4$. Here ϕ_i denotes one of the sp^3 hybridized orbitals which points to the i-th hydrogen atom whose atom orbital is expressed by h_i; e.g.

$$\phi_1 = [(2s) + \{(2p_x) + (2p_y) + (2p_z)\}]/2\ ,$$

and the colons express the bondings between the orbitals connected by them. In this rough approximation, electron distribution is given by

$$\begin{aligned} \rho(\boldsymbol{r}) = 2(1s)^2 &+ (2s)^2 + (2p_x)^2 + (2p_y)^2 + (2p_z)^2 \\ &+ h_1^2 + h_2^2 + h_3^2 + h_4^2\ . \end{aligned}$$

Since the first five terms give the charge distribution of spherical symmetry, angular dependence comes only from the last four terms. Then

$$n_+ = \frac{6}{8} + \int_0^\infty\int_0^\infty\int_0^\infty (h_1^2 + h_2^2 + h_3^2 + h_4^2)dxdydz\ ,$$

and

$$n_- = \frac{6}{8} + \int_0^\infty\int_0^\infty\int_0^{-\infty} (h_1^2 + h_2^2 + h_3^2 + h_4^2)dxdydz\ .$$

If the hydrogen atomic orbital is confined only in one of the eight divisions defined above, $n_+ = 0.75 + 1$ and $n_- = 0.75 + 0$. The numbers given by (28a) and (28b) correspond to $n_+ = 0.75 + 0.75$ and $n_- = 0.75 + 0.25$. If we think about the fairly large extension of hydrogen atomic orbital, our results (28a) and (28b) seem to express the electron distribution with fairly large directional dependence.

In conclusion, the authors wish to express their sincere thanks to Professor M. Kotani and the members of his laboratory for their continuous encouragement during the course of this work, and to Mrs. H. Komuro and Mrs. M. Sekiyama for their help in troublesome computations. A part of this work was supported financially by Scientific Expenditure of the Educational Ministry.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 9, SEPTEMBER, 1957

On the Radio Wave Propagation in a Stratified Atmosphere II

By Ryozo YAMADA

Faculty of Science and Engineering Meijo University, Nagoya

(Received April 5, 1957)

In this paper a method is developed for determining the electromagnetic field produced by a microwave antenna. The theory is developed for the condition that the index of refraction of the atmosphere varies with height as $A+Bh+Ch^2$, for the flattened earth. From the rigorous solution the geometrical-optical description is derived. The Hertzian vector is split into the geometrical series, each term of which corresponds to the rays reflected 1, 2, 3, $\cdots$ times by the earth, when the "duct" is formed. Among these rays there are the rays whose propagation constants are complex number. The existence of these rays explains the "radio duct phenomena" in the cases when the transmitter and the receiver are located both out of the "duct", and when they are in and out of the "duct", respectively. For the field strength in the vicinity of the cusp of caustic, we use the original integral and calculate by numerical integration. The field strength of the reflected rays at the cusp of caustic is 3.2 times that of free space for $\lambda=2\pi$ cm, $b=5\times10^{-5}$/m, $z_0=100$ m, $z_1=z_2=60$ m, $r=62.8$ km. The interference of this strong field of these reflected rays with the weak field of the diverged direct ray may be the cause of the large fading range when the "duct" is formed.

§ 1. Introduction

In the Part I of this paper[5)] the field from a dipole is expressed in the form of the residue series which converges rapidly when the distance is large. While the convergence is not appropriate for numerical evaluation when the distance is small. In this paper we deal with this problem by ray method starting with the integral (15) of Part I of this paper. The integral (15) is split into two exponential integrals which correspond to the direct ray and the reflected ray by the earth in the case when the "duct" is not formed. In the case when the "duct" is formed, the integral (15) is split into a geometrical series, and each term of this series has the form of an exponential integral and corresponds to the ray reflected 1, 2, 3, $\cdots$ times by the earth. And if a source is located in the "duct", the rays rediated with real angle and once reflected totally by the inhomogeneity of the atmosphere never get out of the "duct". In the cases when the transmitter and the receiver are both located out of the "duct" and when they are in and out of the "duct", respectively, the saddle points of these integrals become complex and these correspond to the rays which start with complex angle and reach the receiver. This explains the "radio duct phenomena" in these cases.

In the case when the "duct" is formed and the source is in the "duct", the ray leaving horizontally has the smallest range between successive reflections at the surfoce of the earth (let this range be $2R$) among the rays leaving the source, as shown in Fig. 1. A ray leaving the source at a negative inclination α has its first reflection at a horizontal distance less than R and its range between successive reflections is $2R+O(\alpha^2)$, hence such rays must form one of a caustic. And the rays leaving the source at positive inclinations may form the second branch of a caustic. The field distribution in the neighbourhood of a caustic can be calculated by Airy's integral, but this treatment does not apply in the neighbourhood of the cusp of caustic. The

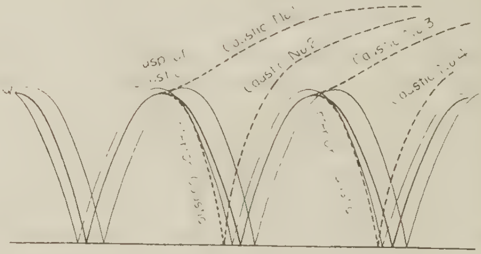

Fig. 1.

field in this neighbourhood was evaluated by D. R. Hartree, Michel and Nicholson[7]. The theory developed here is intrinsically most accurate in this neighbourhood and is less accurate as one recedes from the cusp of caustic. The rays once reflected converge and the field strength at the cusp of caustic due to once reflected rays is large. The interference of this reflected rays with the diverged direct ray in this neighbourhood may be the cause of the large fading range due to the "duct" when the reflection coefficient of the earth is small.

§ 2. Ray Theory

In this section we shall derive from our solution (15) of Part I the geometrical- optical approximation which is valied for short wave length. The procedure has been developed by many writers[1)2)3)4)9)]; we apply this method to our case. By the aid of the asymptotic approximations given in § 3. b), c), d) of Part I for large x, we have the asymptotic expressions for the integrand in (15), and find the value of γ_0 for which the phase of the integrand is stationary, if such point exists, and evaluate the integral around the point of stationary phase. This procedure corresponds to to find the path and the amplitude of the ray.

We rewrite the integral representation (15) of the Hertzian vector in the form

$$\psi=\frac{i}{2H}\int_{\infty}^{-\infty}H_0^{(1)}(k_0r\sqrt{1-4b^2H^2\gamma})v(\gamma)\,d\gamma \qquad (15)$$

$$=\frac{i}{2H}\int_{\infty}^{-\infty}H_0^{(1)}(k_0r\sqrt{1-4b^2H^2\gamma})[U(\gamma)-V(\gamma)]u_2(x_1,\gamma)u_2(x_2,\gamma)\,d\gamma\ , \qquad (2.1)$$

where

$$U(\gamma)=\frac{u_1'(x_0,\gamma)-Hpu_1(x_0,\gamma)}{u_2'(x_0,\gamma)-Hpu_2(x_0,\gamma)} \qquad (2.2)$$

$$V(\gamma)=\frac{u_1(x_1,\gamma)}{u_2(x_1,\gamma)}\quad x_2\geqslant x_1$$

$$V(\gamma)=\frac{u_1(x_2,\gamma)}{u_2(x_1,\gamma)}\quad x_2\leqslant x_1\ . \qquad (2.3)$$

And u_1 and u_2 are expressed in terms of Weber's functions [cf. (9), (10) (I)].

According to the result of Part I of this paper, Weber's functions are expressed as follows: We divide γ-plane into four subdomains corresponding to the four subdomains of w_0-plane (Fig. 1 of Part I), and the corresponding subdomains for the complex $\gamma+i/2=(x_2/4)\sinh^2 w_0$ have the same numbers as shown in Fig. 2. When x is large and positive and γ is large, $D_{-i\gamma-1/2}(e^{i\pi/4}x)$ and $D_{i\gamma-1/2}(e^{-i\pi/4}x)$ are expressed in terms of (w_1), $(w_1+2\pi i)$ and (w_2) in Table I of Part I, and (w_1), $(w_1+2\pi i)$, (w_2) are approximated by their asymptotic expansions as follows,

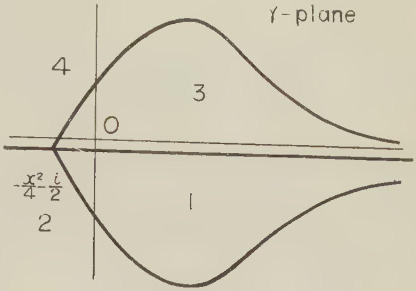

Fig. 2. γ-plane.

$$(w_1)\sim-\sqrt{2\pi}\frac{e^{-5\pi(\gamma-i/2)/4}}{\sqrt[4]{x^2+4(\gamma+i/2)}}\exp i\left\{\frac{\gamma+i/2}{2}+\frac{x}{4}\sqrt{x^2+4(\gamma+i/2)}+\gamma\log\frac{x+\sqrt{x^2+4(\gamma+i/2)}}{2}-\gamma\log(\gamma+i/2)\right\}, \qquad (2.4)$$

$$(w_2)\sim-\sqrt{2\pi}\frac{e^{-\pi(\gamma-i/2)/4}}{\sqrt[4]{x^2+4(\gamma+i/2)}}\exp -i\left\{-\frac{\gamma+i/2}{2}+\frac{x}{4}\sqrt{x^2+4(\gamma+i/2)}+\gamma\log\frac{x+\sqrt{x^2+4(\gamma+i/2)}}{2}\right\}, \qquad (2.5)$$

$$(w_1+2\pi i)\sim-\sqrt{2\pi}\frac{e^{3\pi(\gamma-i/2)/4}}{\sqrt{x^2+4(\gamma+{}^{i}/2)}}\times\exp i\left\{\frac{\gamma+i/2}{2}+\frac{x}{4}\sqrt{x^2+4(\gamma+i/2)}+\gamma\log\frac{x+\sqrt{x^2+4(\gamma+i/2)}}{2}-\gamma\log(\gamma+i/2)\right\}. \qquad (2.6)$$

and $\Gamma(i\gamma+1/2)$, when γ is large, is approximated by

$$\Gamma(i\gamma+1/2)\sim\sqrt{2\pi}\exp\{-i\gamma-1/2+i\gamma\log(\gamma-i/2)-\gamma\pi/2\}\ . \qquad (2.7)$$

When x is large and positive, and γ is small, we use Weber's functions the asymptotic expansions given in § 3. b) of Part I[6)].

For the transitional region, the asymptotic expansions given in § 3. d) are used.

As for negative values of x, $D_{-i\gamma-1/2}$ and $D_{i\gamma-1/2}$ are given by the circuit relations[6];

$$D_n(-e^{i\pi/4}x)=e^{-n\pi i}D_n(e^{i\pi/4}x)+\frac{\sqrt{2\pi}}{\Gamma(-n)}e^{-i(n+1)\pi/2}D_{-n-1}(e^{-\pi/4}x) \tag{2.8}$$

$$D_{-n-1}(-e^{-i\pi/4}x)=\frac{\sqrt{2\pi}}{\Gamma(n+1)}e^{-n\pi i/2}D_n(e^{i\pi/4}x)-e^{-n\pi i}D_{-n-1}(e^{-i\pi/4}x)\,. \tag{2.9}$$

Thus the asymptotic expansions of Weber's functions are different accordings to the sign x and the value of γ in relation to x; the asymptotic expression of (2.1) has the different form according to the signs of x_0, x_1, x_2. We divide this into four cases:

i) $x_0>0,\quad x_1>0,\quad x_1>0.$

ii) $x_0<0,\quad x_1>0,\quad x_2>0.$

iii) $x_0<0,\quad x_1>0,\quad x_2<0,$

or $x_0<0,\quad x_1<0,\quad x_2>0.$

iv) $x_0<0,\quad x_1<0,\quad x_2<0.$

For these four cases the different terms appear in (2.1), and the corresponding ray configurations are different. But as the method of deducing the corresponding rays from these different terms is quite similar, we illustrate this by the example of the case ii) $x_0<0$, $x_1>0$, $x_2>0$, $(x_1>x_2)$ in this section.

To begin with, we divide γ-plane into the sub-subdomains in relation to x_0, x_1, x_2 as follows: We write

$$\gamma+\frac{i}{2}=\frac{x_0^2}{4}\sinh^2 w_{00}=\frac{x_1^2}{4}\sinh^2 w_{01}=\frac{x_2^2}{4}\sinh^2 w_{02}\,,$$

and when w_{00} lies in the subdomain 3, w_{01} in the subdomain 3, w_{02} in subdomain 4, γ lies in the sub-subdomain 3_0, 3_1, 4_2 as shown in Fig. 3. We write the asymptotic expression of (2.1) in these sub-subdomains and evaluate this integral by the method of steepest descents.

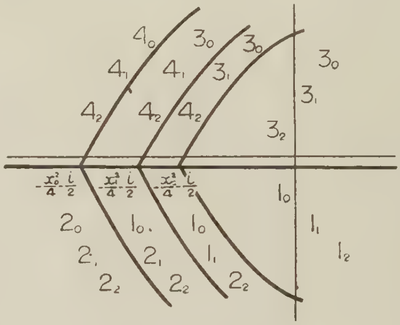

Fig. 3. γ-plane.

In the limit of large r (in comparison with λ) we have

$$H_0^{(1)}(k_0r\sqrt{1-4b^2H^2\gamma}\sim\left(\frac{2}{\pi k_0r\sqrt{1-4b^2H^2\gamma}}\right)^{1/2}\exp(ik_0r\sqrt{1-4b^2H^2\gamma}-i\pi/4)\,.$$

When γ lies in the 3_0, 3_1, 3_2 sub-subdomain, the second term of the right-hand side of (2.1) can be written as

$$-\frac{i}{2H}\int_{\infty}^{-\infty}H_0^{(1)}(k_0r\sqrt{1-4b^2H^2\gamma})\frac{u_1(x_2,\gamma)}{u_2(x_2,\gamma)}u^2(x_2,\gamma)\,u_2(x_1,\gamma)\,d\gamma$$

$$\sim\frac{e^{i\pi/4}}{H\sqrt{2\pi k_0r}}\int_{-\infty}^{\infty}[(1-4b^2H^2\gamma)\{x_1^2+4(\gamma+i/2)\}\{x_2^2+4(\gamma+i/2)\}]^{-1/4}\{\exp iq(\gamma)\}\,d\gamma\,, \tag{2.10}$$

where

$$q(r)=k_0r\sqrt{1-4b^2H^2\gamma}+\frac{x_1}{4}\sqrt{x_1^2+4(\gamma+i/2)}-\frac{x_2}{4}\sqrt{x_2^2+4(\gamma+i/2)}$$
$$+\gamma\log[\{x_1+\sqrt{x_1^2+4(\gamma+i/2)}\}/\{x_2+\sqrt{x_2^2+4(\gamma+i/2)}\}]\,.$$

And when γ and $x_1^2+4\gamma$ are large in comparison with 1/2, we have

$$q(r)=k_0r\sqrt{1-4b^2H^2\gamma}+\frac{x_1}{4}\sqrt{x_1^2+4\gamma}-\frac{x_2}{4}\sqrt{x_2^2+4\gamma}+\gamma\log\frac{x_1+\sqrt{x_1^2+4\gamma}}{x_2+\sqrt{x_2^2+4\gamma}}\,.$$

The point of stationary phase of this integrand is determined from

$$\partial q(r)/\partial\gamma=-(br/\sqrt{1-4b^2H^2\gamma}+\log\{(x_1+\sqrt{x_1^2+4\gamma})/(x_2+\sqrt{x_2^2+4\gamma})\}=0\,. \tag{2.11}$$

The saddle point γ_0 can exist in this sub-subdomain, if $br<(1+b^2H^2x_2^2)^{1/2}\log\{x_1+\sqrt{x_1^2-x_2^2}/x_2\}$, and the value of this γ_0 is real and $\gamma_0>-x_2^2/4$ as shown in Appendix. This saddle point gives a ray which directly reaches the receiver and satisfies the Fermat's principle; a brief calculation gives (2.11) an integral form

$$r=\int_{z_2}^{z_1}\frac{N(z_1)\cos\alpha\,dz}{\sqrt{N^2(z)-N^2(z_1)\cos^2\alpha}}\ ,$$

where α is the inclination with which the ray leaves the source, and $N(z_1)\cos\alpha/N_0=\sqrt{1-4b^2H^2\gamma_0}$. The Hertzian vector due to this ray is calculated by the method of steepest descents, and is given by

$$\begin{aligned}\Psi_{01}\sim\frac{1}{r}\{\exp iq(\gamma_0)\}\Bigg\{&\frac{\sqrt{1-4b^2H^2\gamma_0}}{br}\left(\frac{\sqrt{x_1^2+4\gamma_0}}{x_2+\sqrt{x_2^2+4\gamma_0}}-\frac{\sqrt{x_2^2+4\lambda_0}}{x_1+\sqrt{x_1^2+4\gamma_0}}\right)\\&+\frac{b^2H^2\sqrt{x_1^2+4\gamma_0}\sqrt{x_2^2+4\gamma_0}}{1-4b^2H^2\gamma_0}\Bigg\}^{-1/2}=\alpha_{01}\frac{1}{r}\exp iq(\gamma_0)\ ,\end{aligned}\tag{2.12}$$

where α_{01} is the divergence factor of direct ray due to the inhomogeneity of the atmosphere, and the value of α_{01} is nearly 1 when the distance is small. Further investigation shows that there is no saddle point in the other sub-subdomains, so the contribution of the integral in these sub-subdomains is small.

Next we shall evaluate the Hertzian vector due to $U(\gamma)$. In our case x_0 is negative, we use the circuit relations (2.8), (2.9) and we have

$$\begin{aligned}U(\gamma)&=e^{i\pi/4}\frac{\{(\partial/\partial x)D_{-i\gamma-1/2}(xe^{i\pi/4})\}_{x=x_0}-HpD_{-i\gamma-1/2}(x_0e^{i\pi/4})}{\{(\partial/\partial x)D_{i\gamma-1/2}(xe^{-i\pi/4})\}_{x=x_0}-HpD_{i\gamma-1/2}(x_0e^{i\pi/4})}=e^{i\pi/4}\Bigg[\frac{\Gamma(-i\gamma+1/2)}{\sqrt{2\pi}}e^{-(\gamma-i/2)\pi/2}\\&-\frac{\Gamma(-i\gamma+1/2)}{\sqrt{2\pi}}e^{(\gamma-i/2)\pi/2}\frac{\{(\partial/\partial x)D_{i\gamma-1/2}(xe^{-i\pi/4})\}_{x=|x_0|}+HpD_{i\gamma-1/2}(|x_0|e^{-i\pi/4})}{\{(\partial/\partial x)D_{i\gamma-1/2}(xe^{-i\pi/4})\}_{x=x_0}-HpD_{i\gamma-1/2}(x_0e^{-i\pi/4})}\Bigg].\end{aligned}\tag{2.13}$$

Further the second term of the right-hand side of (2.13) becomes

$$\begin{aligned}&-e^{(\gamma-i/2)\pi/2}\frac{\Gamma(-i\gamma+1/2)}{\sqrt{2\pi}}D_{i\gamma-1/2}(|x_0|e^{-i\pi/4})\left[\left\{\frac{\partial}{\partial x}\log D_{i\gamma-1/2}(xe^{-i\pi/4})\right\}_{x=|x_0|}+Hp\right]\Bigg/\\&\quad-\frac{\sqrt{2\pi}}{\Gamma(-i\gamma+1/2)}e^{-(\gamma-i/2)\pi/2}D_{-i\gamma-1/2}(|x_0|e^{i\pi/4})\left[\left\{\frac{\partial}{\partial x}\log D_{-i\gamma-1/2}(xe^{i\pi/4})\right\}_{x=|x_0|}+Hp\right]\\&\quad+e^{-(\gamma-i/2)\pi}D_{i\gamma-1/2}(|x_0|e^{-i\pi/4})\left[\left\{\frac{\partial}{\partial x}\log D_{i\gamma-1/2}(xe^{-i\pi/4})\right\}_{x=|x_0|}+Hp\right]=e^{\pi(\gamma-i/2)}\left\{\frac{\Gamma(-i\gamma+1/2)}{\sqrt{2\pi}}\right\}^2\\&\quad\times\frac{D_{i\gamma-1/2}(|x_0|e^{-i\pi/4})}{D_{-i\gamma-1/2}(|x_0|e^{i\pi/4})}\left(\frac{B}{C}\right)\left[1-\frac{\Gamma(-i\gamma+1/2)}{\sqrt{2\pi}}e^{-(\gamma-i/2)\pi/2}\frac{D_{i\gamma-1/2}(|x_0|e^{-i\pi/4})}{D_{-i\gamma-1/2}(|x_0|e^{i\pi/4})}\left(\frac{B}{C}\right)\right]^{-1},\end{aligned}\tag{2.14}$$

where

$$B=\left\{\frac{\partial}{\partial x}\log D_{i\gamma-1/2}(xe^{-i\pi/4})\right\}_{x=|x_0|}+Hp\ ,\tag{2.15}$$

$$C=\left\{\frac{\partial}{\partial x}\log D_{-i\gamma-1/2}(xe^{i\pi/4})\right\}_{x=|x_0|}+Hp\ .\tag{2.16}$$

In the domain of γ which satisfies the following relation

$$\left|\frac{\Gamma(-i\gamma+1/2)}{\sqrt{2\pi}}e^{-(\gamma-i/2).\pi/2}\frac{D_{i\gamma-1/2}(|x_0|e^{-i\pi/4})}{D_{-i\gamma-1/2}(|x_0|e^{i\pi/4})}\left(\frac{B}{C}\right)\right|<1\ ,$$

(2.14) can be expanded in the geometrical series. By the similar method that we used when we investigated the residue series in Part I, in the case $Hp=\infty$ this is the domain of γ which satisfies the following relation, if we write $\gamma+i/2=(x_0^2/4)\sinh^2(\alpha_0+i\beta_0)$,

$$\sinh\alpha_0\sin\beta_0-\frac{\sinh 2\alpha_0\sin 2\beta_0}{4}\log\frac{\cosh\alpha_0+\cos\beta_0}{\cosh\alpha_0-\cos\beta_0}-\frac{\cosh 2\alpha_0\sin 2\beta_0-1}{2}\left(\tan^{-1}\frac{\sin\beta_0}{\sinh\alpha_0}-\frac{\pi}{2}\right)>0$$

as is shown in Fig. 4. We write (2.14) in this domain in the form

$$\frac{\Gamma(-i\gamma+1/2)}{\sqrt{2\pi}}e^{3\pi(\gamma-i/2)/2}\sum_{n=1}^{\infty}\left[\frac{\Gamma(-i\gamma+1/2)}{\sqrt{2\pi}}e^{-(\gamma-i/2).\pi/2}\frac{D_{i\gamma-1/2}(|x_0|e^{-i\pi/4})}{D_{-i\gamma-1/2}(|x_0|e^{i\pi/4})}\left(\frac{B}{C}\right)\right]^n . \tag{2.17}$$

Using this result, we write $U(\gamma)$ in (2.2) in the form

$$U(\gamma)=U_0(\gamma)+\sum_{n=1}^{\infty}U_n(\gamma) .$$

At first we consider the Hertzian vector due to $U_0(\gamma)$. When x_0, x_1, x_2, γ are large and γ lies in the 3_0, 3_1, 3_2, sub-subdomain, and γ and $x_1^2+4\gamma$ are large in comparison with 1/2, we have

$$\frac{i}{2H}\int_{-\infty}^{\infty}H_0^{(1)}(k_0r\sqrt{1-4b^2H^2\gamma})U_0(\gamma)u_2(x_1,\gamma)u_2(x_2,\gamma)d\gamma ,$$

$$\sim\frac{e^{-\pi i/4}}{H\sqrt{2\pi k_0r}}\int_{-\infty}^{\infty}\{(1-4b^2H^2\gamma)(x_1^2+4\gamma)(x_2^2+4\gamma)\}^{-1/4}\exp ip_0(\gamma)d\gamma , \tag{2.18}$$

where

$$p_0(\gamma)=k_0r\sqrt{1-4b^2H^2\gamma}+\frac{x_1}{4}\sqrt{x_1^2+4\gamma}+\frac{x_2}{4}\sqrt{x_2^2+4\gamma}+\gamma\log\frac{(x_1+\sqrt{x_1^2+4\gamma})(x_2+\sqrt{x_2^2+4\gamma})}{4\gamma} ,$$
$$+i\pi\gamma , \tag{2.19}$$

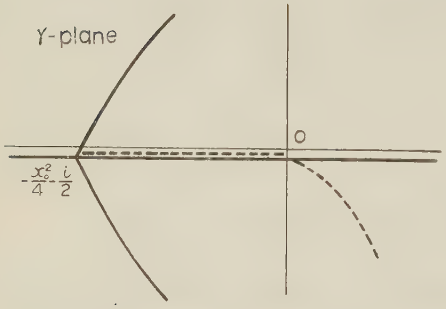

Fig. 4. $\left|e^{-(\gamma-i/2)\pi/2}\frac{\Gamma(-i\gamma+1/2)}{\sqrt{2\pi}}\frac{D_{i\gamma-1/2}}{D_{-i\gamma-1/2}}\right|<1$ in the domain above the dotted line.

and the point of stationary phase of this integrand is determined from

$$\frac{\partial p_0(\gamma)}{\partial\gamma}=-br/\sqrt{1-4b^2H^2\gamma}$$
$$+\log\frac{(x_1+\sqrt{x_1^2+4\gamma})(x_2+\sqrt{x_2^2+4\gamma})}{4\gamma}$$
$$+i\pi=0 . \tag{2.20}$$

The saddle point γ_0 can exist in this sub-subdomain, if

$$br>\sqrt{1+4b^2H^2x_2}\log\{(x_1+\sqrt{x_1^2-x_2^2})/x_2\},$$

and the value of this γ_0 is real and $-x_2^2/4<\gamma_0<0$. This defines the direct ray totally reflected by the inhomogeneity of the atmosphere. The contribution from this ray to the Hertzian vector is evaluated by the saddle point integral, and is given by

$$\Psi_{02}\sim\frac{1}{r}\exp ip_0(\gamma_0)$$
$$\times\left[\frac{\sqrt{1-4b^2H^2\gamma_0}}{br}\left(\frac{\sqrt{x_2^2+4\gamma_0}}{x_1+\sqrt{x_1^2+4\gamma_0}}+\frac{\sqrt{x_1^2+4\gamma_0}}{x^2-\sqrt{x_2^2+4\gamma_0}}\right)-\frac{b_2H^2\sqrt{x_1^2+4\gamma_0}\sqrt{x_2^2+4\gamma_0}}{1-4b^2H^2\gamma_0}\right]$$
$$=\alpha_{02}\frac{1}{r}\exp ip_0(\gamma_0) , \tag{2.21}$$

where α_{02} is the divergence factor of this ray. The point of sationary phase does not exist in the other sub- subdomains of γ. When γ is small in comparison with x_1^2, we use the asymptotic expansions of Weber's function in § 3. b), and we obtain corresponding to (2.21)

$$\Psi_{02}\sim\frac{1}{r}\sqrt{2br}\,\exp\left(-\frac{br}{2}\right)\exp i\left(k_0r+\frac{x_1^2}{4}+\frac{x_2^2}{4}+\gamma_0\right), \tag{2.21'}$$

where

$$-\gamma_0=(x_1x_2)^{1/2}\exp(-br).$$

Next we consider the Hertzian vector due to $U_1(\gamma)$. When x_0, x_1, x_2, γ are large and γ lies in the 3_0, 3_1, 3_2 sub-subdomain, and γ and $x_i^2+4\gamma$ $(i=0, 1, 2)$ are large in comparison with 1/2, we have

$$\frac{i}{2H}\int_{\infty}^{-\infty}H_0^{(1)}\left(k_0r\sqrt{1-4b^2H^2\gamma}\right)U_1(\gamma)u_2(x_1,\gamma)u_2(x_2,\gamma)d\gamma$$
$$\sim\frac{e^{i\pi/4}}{H\sqrt{2\pi k_0r}}\int_{-\infty}^{\infty}\left(\frac{B}{C}\right)\{(1-4b^2H^2\gamma)(x_1^2+4\gamma)(x_2^2+4\gamma\}^{-1/4}\exp ip_1(\gamma)\,d\gamma\,, \tag{2.22}$$

where

$$p_1(\gamma)=k_0r\sqrt{1-4b^2H^2\gamma}+\frac{|x_0|}{2}\sqrt{x_0^2+4\gamma}+\frac{x_1}{4}\sqrt{x_1^2+4\gamma}+\frac{x_2}{4}\sqrt{x_2^2+4\gamma}$$
$$+\gamma\log\frac{(|x_0|+\sqrt{x_0^2+4\gamma})^2(x_1+\sqrt{x_1^2+4\gamma})(x_2+\sqrt{x_2^2+4\gamma})}{16\gamma^2}.$$

And the saddle point is determined by

$$\frac{\partial p_1(\gamma)}{\partial\gamma}=-br/\sqrt{1-4b^2H^2\gamma}+\log\left(\frac{(|x_0|+\sqrt{x_0^2+4\gamma})^2(x_1+\sqrt{x_1^2+4\gamma})(x_2+\sqrt{x_2^2+4\gamma})}{16\gamma^2}\right)=0\,. \tag{2.23}$$

The saddle point lies on the real axis and $\gamma_0>0$. This defines the reflected ray by the earth. And the contribution of this ray to the Hertzian vector is

$$\Psi_1\sim-\left(\frac{B}{C}\right)\frac{1}{r}\{\exp ip_1(\gamma_0)\}\Bigg[\frac{\sqrt{1-4b^2H^2\gamma_0}}{br}\left(\frac{\sqrt{x_2^2+4\gamma_0}}{\sqrt{x_1^2+4\gamma_0}-x_1}+\frac{\sqrt{x_1^2+4\gamma}}{\sqrt{x_2^2+4\gamma_0}-x_2}\right)$$
$$+\left(\frac{b^2H^2}{1-4b^2H^2\gamma_0}-\frac{\sqrt{1-4b^2H^2\gamma_0}}{br\sqrt{x_0^2+4\gamma_0}\,(|x_0|+\sqrt{|x_0|^2+4\gamma_0})}\right)\sqrt{x_1^2+4\gamma_0}\sqrt{x_2^2+4\gamma_0}\Bigg]^{-1/2}. \tag{2.24}$$

By the appropriate approximation, we find

$$-\left(\frac{B}{C}\right)\sim\frac{-(i/2)\sqrt{x_0^2+4\gamma_0}-Hp}{(i/2)\sqrt{x_0^2+4\gamma_0}-Hp}=\frac{(k_2^2/k_0^2)\cos\theta-\sqrt{(k_2^2/k_0^2)-\sin^2\theta}}{(k_2^2/k_0^2)\cos\theta+\sqrt{(k_2^2/k_0^2)-\sin^2\theta}}$$

for a vertical electric dipole

$$=\frac{\cos\theta-\sqrt{(k_2^2/k_0^2)-\sin^2\theta}}{\cos\theta-\sqrt{(k_2^2/k_0^2)-\sin^2\theta}}$$

for a vertical magnetic dipole

where θ is the angle of reflection, and this is the reflection coefficient of the earth. There is no point of stationary phase of this term in the other sub-subdomains. When γ is small in comparison with x_0, x_1, x_2, we obtain corresponding to (2.24)

$$\Psi_1\sim\frac{\sqrt{br}}{r}\sqrt[4]{\frac{|x_0^2|}{x_1x_2}}\exp\left(\frac{-br}{4}\right)\exp i\left(k_0r+\frac{x_0^2}{2}+\frac{x_1^2}{4}+\frac{x_2^2}{4}+2\gamma_0\right), \tag{2.24'}$$

where

$$\gamma_0=|x_0|\sqrt{x_1x_2}\exp\left(\frac{-br}{2}\right)$$

At last we consider the Hertzian vector due to $U_n(\gamma)$. When x_0, x_1, x_2, γ are large and γ lies in the 3_0, 3_1, 3_2 sub-subdomain, and if γ and $x_i^2+4\gamma$ $(i=0, 1, 2)$ are large in comparison with 1/2, we have

$$\frac{i}{2H}\int_{\infty}^{-\infty} H_0^{(1)}\left(k_0 r\sqrt{1-4b^2H^2\gamma}\right)U_n(\gamma)u_2(x_1,\gamma)u_2(x_2,\gamma)d\gamma$$

$$\sim\frac{e^{i\pi/4}}{H\sqrt{2\pi k_0 r}}\int_{-\infty}^{\infty}\left(\frac{B}{C}\right)^n\{(1-4b^2H^2\gamma)(x_1^2+4\gamma)(x_2^2+4\gamma)\}^{-1/4}\exp ip_n(\gamma)\,d\gamma\ , \tag{2.25}$$

where

$$p_n(\gamma)=k_0 r\sqrt{1-4b^2H^2\gamma}+i(n-1)\pi\gamma+\frac{n-1}{2}\pi+\frac{n|x_0|}{2}\sqrt{|x_0|^2+4\gamma}+2n\gamma\log\frac{|x_0|+\sqrt{|x_0|^2+4\gamma}}{2}$$

$$-(n+1)\gamma\log\gamma+\frac{x_1}{4}\sqrt{x_1^2+4\gamma}+\frac{x_2}{4}\sqrt{x_2^2+4\gamma}+\gamma\log\frac{(x_1+\sqrt{x_1^2+4\gamma})(x_2+\sqrt{x_2^2+4\gamma})}{4}=0\,. \tag{2.26}$$

And the saddle point is given by

$$\frac{\partial p_n(\gamma)}{\partial\gamma}=\frac{-br}{\sqrt{1-4b^2H^2\gamma}}+\log\frac{(|x_0|+\sqrt{x_0^2+4\gamma})^{2n}(x_1+\sqrt{x_1^2+4\gamma})(x_2+\sqrt{x_2^2+4\gamma})}{(4\gamma)^{n+1}}+i(n-1)\pi=0\,. \tag{2.27}$$

In this case, the saddle point does not lie on the real axis but γ_0 has the complex value and its imaginary part is positive (as shown in Appendix). This defines the ray which reflects n times from the earth, and is totally reflected and attenuated by the inhomogeneity of the atmosphere. The contribution of this ray to the Hertzian vector is

$$\Psi_n\sim\frac{-1}{r}\left(\frac{B}{C}\right)^n\{\exp ip_n(\gamma_0)\}[(1-4b^2H^2\gamma_0)^{1/2}(x_1^2+4\gamma_0)^{1/2}(x_2^2+4\gamma_0)^{1/2}(1/2br)(-\partial p_n(\gamma_0)/\partial\gamma)]^{-1/2}\,. \tag{2.28}$$

There is no point of stationary phase in the other sub-subdomains of γ. When γ is small in comparison with x_0, x_1, x_2, but is large compared with 1/2, we obtain corresponding to (2.28)

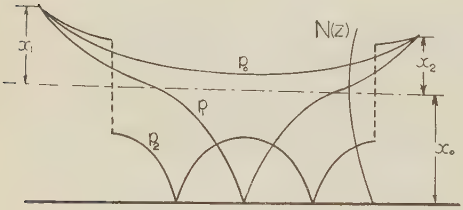

Fig. 5. $x_0<0$, $x_1>x_2>0$.

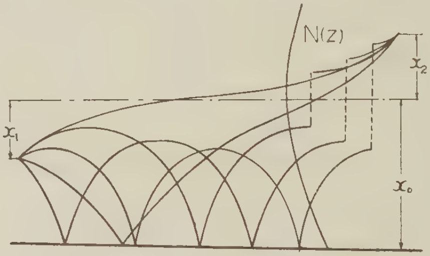

Fig. 7. $x_0<0$, $x_1<0$, $x_2>0$.

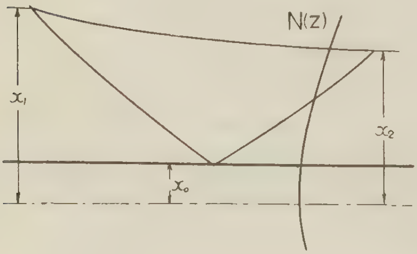

Fig. 6. $x_0>0$, $x_1>0$, $x_2>0$.

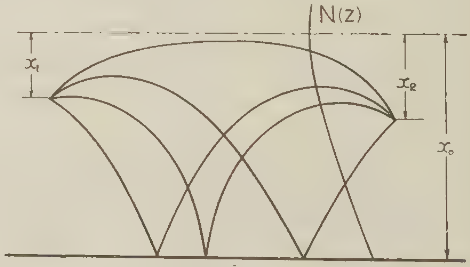

Fig. 8. $x_0<0$, $x_1<0$, $x_2<0$.

$$\Psi_n\sim-\frac{\sqrt{2br}}{r}\left(\frac{B}{C}\right)^n\frac{|x_0|^{n/(n+1)}(x_1x_2)^{-1/2(1-1/(n+1))}}{(n+1)^{1/2}}\exp\frac{-br+i(n-1)\pi}{2(n+1)}\exp i\Big\{k_0r+\gamma_0(n+1)$$

$$+\frac{(n-1)\pi}{2}+\frac{nx_0^2}{2}+\frac{x_1^2}{4}+\frac{x_2^2}{4}\Big\}\,, \tag{2.28'}$$

where

$$\gamma_0=(x_0^{2n}x_1x_2)^{1/(n+1)}\exp\left(\frac{-br}{n+1}+\frac{i(n-1)\pi}{n+1}\right).$$

This shows us that the attenuation of this ray becomes small as n becomes large. The field due to these multi-reflected rays explains the "radio duct phenomena" ray-theoretically in our case. The rays derived above are shown in Fig. 5.

And the rays in the cases i), ii), iv) are shown in Fig. 6, 7, 8, respectively.

§3. The Field in the Vicinity of the Cusp of Caustic

As mentioned in §1, there are the caustic and the cusp of caustic, when the "duct" is formed. The treatment of the field distribution in the neighbourhood of a caustic, away from the cusp, is due to Airy and is classical. This treatment does not apply in the immediate neighbourhood of the cusp of caustic, where three rays of the system pass through each point between the branches which meet in the cusp. The points of the cusp of caustic are, in our case, $x_0<0$, $x_1=x_2<0$ and $br=2n\sqrt{1+b^2H^2x_1^2}\log(|x_0|+\sqrt{x_0^2-x_1^2}/|x_2|)$. In the vicinity of the cusp, the saddle points of the terms in (2,1) corresponding to the reflected rays become nearly to $-x_1^2/4$, and in this transitional region $D_{-i\gamma-1/2}$ and $D_{i\gamma-1/2}$ lose their exponential character, and we can not evaluate the integral by the method of steepest descents. We evaluate the original integral by the numerical integration[10) using the $H_{1/3}$ approximations[8) for $D_{-i\gamma-1/2}$ and $D_{i\gamma-1/2}$, and calculate the field at $x_1=x_1$, $r\sim2\sqrt{1+b^2H^2x_1^2}\log\{(|x_0|+\sqrt{x_0^2-x_1^2})/|x_1|)$, due to the once reflcted rays from the earth.

The Hertzian vector due to the rays reflected once is given

$$\Psi_1\sim\frac{\sqrt{\pi}\,e^{i\pi/12}}{4\sqrt{2}\,H}\int_{-\infty}^{\infty}\frac{Re^{i\phi(\gamma)}\zeta\{H_{1/3}^{(1)}(\zeta e^{-i\pi})\}^2d\gamma}{(k_0r\sqrt{1-4b^2H^2\gamma})\sqrt{x_1^2/4+\gamma}}\,, \tag{2.29}$$

where

$$\phi(\gamma)=k_0r\sqrt{1-4b^2H^2\gamma}+\frac{|x_0|}{2}\sqrt{x_0^2+4\gamma}+2\gamma\log(|x_0|+\sqrt{x_0^2+4\gamma})-\gamma\log(-4\gamma)\,,$$

$$\zeta\equiv\frac{|x_1|}{4}\sqrt{x_1^2+4\gamma}+\gamma\log(|x_1|+\sqrt{x_1^2+4\gamma})-\frac{\gamma}{2}\log(-4\gamma)\,.$$

And we write $\varepsilon\equiv\gamma+x_1^2/4\equiv\gamma-\gamma_0$, then in this transitional region $\zeta\sim4\varepsilon^{3/2}/3x$ for $|4\varepsilon/x_1^2|<1$.

Using these we write (2.29) in the form

$$\psi_1\sim\frac{\sqrt{\pi}\,e^{i\pi/12}}{4\sqrt{2}\,H}\int_{-\infty}^{\infty}\frac{R\exp\{i\phi(\gamma_0)+i\varepsilon\phi'(\gamma_0)+i(\varepsilon^2/2)\phi''(\gamma_0)\}}{(k_0r\sqrt{1-4b^2H^2\gamma})^{1/2}}\left(\frac{4\varepsilon}{3x}\right)\left\{H_{1/3}^{(1)}\left(\frac{4\varepsilon^{3/2}}{3x}e^{-i\pi}\right)\right\}^2d\varepsilon\,. \tag{2.30}$$

Using the relation

$$H_{1/3}^{(1)}(xe^{-i\pi})=H_{1/3}^{(1)}(x)+e^{-i\pi/3}H_{1/3}^{(2)}(x)\,,$$

(2.30) can be written as

$$\begin{aligned}\psi_1\sim&\frac{\sqrt{\pi}\,R\exp i\{\pi/12+\phi(\gamma_0)\}}{4\sqrt{2}\,H(k_0r\sqrt{1-4b^2H^2\gamma_0})^{1/2}}\left[\int_{-\infty}^{\infty}\left\{\exp i\varepsilon\phi'(\gamma_0)+i\frac{\varepsilon^2}{2}\phi''(\gamma_0)\right\}\left(\frac{4\varepsilon}{3x}\right)\left\{H_{1/3}^{(1)}\left(\frac{4\varepsilon^{3/2}}{3x}e^{-i\pi}\right)\right\}^2d\varepsilon\right.\\&+\int_0^{\infty}\left\{\exp i\varepsilon\phi'(\gamma_0)+i\frac{\varepsilon^2}{2}\phi''(\gamma_0)\right\}\left(\frac{4\varepsilon}{3x}\right)\left[\left\{H_{1/3}^{(1)}\left(\frac{4\varepsilon^{3/2}}{3x}\right)\right\}^2+2e^{-i\pi/3}H_{1/3}^{(1)}\left(\frac{4\varepsilon^{3/2}}{3x}\right)H_{1/3}^{(2)}\left(\frac{4\varepsilon^{3/2}}{3x}\right)\right.\\&\left.\left.+e^{-2\pi i/3}\left\{H_{1/3}^{(1)}\left(\frac{4\varepsilon^{3/2}}{3x}\right)\right\}^2\right]d\varepsilon\right]=\frac{\sqrt{\pi}\,R\exp i\{\pi/12+\phi(\gamma_0)\}}{4\sqrt{2}\,H(k_0r\sqrt{1-4b^2H^2\gamma_0})^{1/2}}\int_0^{\infty}\left[\left\{\exp i\varepsilon\phi'(\gamma_0)+i\frac{\varepsilon^2}{2}\phi''(\gamma_0)\right.\right.\\&\left.-i\frac{\pi}{3}\right\}\left(\frac{2}{\pi}\right)^2\left(\frac{4\varepsilon}{3x}\right)\left\{K_{1/3}\left(\frac{4\varepsilon^{3/2}}{3x}\right)\right\}^2+\left\{\exp i\varepsilon e^{i\pi/3}\phi'(\gamma_0)+i\frac{\varepsilon^2}{2}e^{i2\pi/3}\phi''(\gamma_0)-i\frac{2\pi}{3}\right\}\left(\frac{2}{\pi}\right)^2\left(\frac{4\varepsilon}{3x}\right)\\&\times\left\{K_{1/3}\left(\frac{4\varepsilon^{3/2}}{3x}\right)\right\}^2+2\left\{\exp i\varepsilon\phi'(\gamma_0)+i\frac{\varepsilon^2}{2}\phi''(\gamma_0)-i\frac{\pi}{3}\right\}\left(\frac{4\varepsilon}{3x}\right)H_{1/3}^{(1)}\left(\frac{4\varepsilon^{3/2}}{3x}\right)H_{1/3}^{(2)}\left(\frac{4\varepsilon^{3/2}}{3x}\right)\\&\left.+\left\{\exp i\varepsilon e^{-i\pi/3}\phi'(\gamma_0)+i\frac{\varepsilon^2}{2}e^{-2\pi i/3}\phi''(\gamma_0)\right\}\left(\frac{2}{\pi}\right)^2\left(\frac{4\varepsilon}{3x}\right)\left\{K_{1/3}\left(\frac{4\varepsilon^{3/2}}{3x}\right)\right\}^2\right]d\varepsilon\,.\end{aligned} \tag{2.31}$$

Among the terms of this integrand, the term containing $H_{1/3}^{(1)}$ and $H_{1/3}^{(2)}$ gives the largest contribution to the Hertzian vector. And this term corresponds to the rays which form the caustic.

We obtain $\Psi_1=3.2/r$ for the case $\lambda=2\pi\,cm$, $b=5\times10^{-6}/m$, $z_0=z_2=60$ m, $r=62.8km$, the reflection coefficient of the earth -1.

The interference of this converged reflected rays and the diverged direct ray which distance as (2.21′) may be the cause of the large fading range when the " duct " is formed and the refliction coefficient is small.

§ 4. Conclusion

In this paper we developed a method to calculate the field strength when the modified index of refraction varies with height as $A+Bh+Ch^2$. By this method, the electromagnetic field produced by a microwave antenna may be calculated except the cases when x_0, x_1, x_2, γ are small. The field in these regions may be extrapolated from the other region. This method is useful to evaluate the field in the lit region when the " duct " is not formed. But when the distance is large, the calculation of the field due to the rays reflected 1, 2, 3, times becomes tedious in the case when the " duct " is formed, and the calculation by the mode theory may be useful in the lit region.

Appendix. Determination of the Point of Stationary Phase

To determine the point where $\partial p(\gamma)/\partial\gamma=0$, we consider the locus of $\partial p/\partial\gamma$ in the complex plane, when γ lies along the real axis, except it shall include a small semicircular detour in the upper half plane about the singular points on the real axis, and a large semicircular path in the upper half plane as shown in Fig. 10 (we seek the saddle point in the upper half plane). In our case there are no poles in the domain encircled by this contour, if this contour encircles in a positive sense Z zeros, the corresponding contour of $\partial p/\partial\gamma$ encircles the origin Z times in a positive sense. Furthermore from this contour, we are able to determine the point γ, in whose vicinity $\partial p/\partial\gamma=0$ exists. In our case we find the asymptotic expansion of Ψ in certain sub-subdomain, and determine the point of stationary phase of each term by above procedure. If such point exists and this point lies in this sub-subdomain, this is the point of stationary phase of the term of Ψ and this defines the real ray. In our case this is shown for $p_0(\gamma)$ and $p_n(\gamma)$ in Fig. 9, and 10, respectively.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 9, SEPTEMBER 1957

On the Two-dimensional Compressible Flow over a Thin Symmetric Obstacle with Sharp Shoulders Placed in an Unbounded Fluid and in a Choked Wind Tunnel

By Ken-ichi KUSUKAWA

Department of Physics, Faculty of Science, Tokyo Metropolitan University

(Received May 11, 1957)

The transonic flow past a two-dimensional symmetric body with sharp shoulders placed in an unbounded compressible fluid and in a choked wind tunnel is studied by the use of the model flow, where the flow is assumed to separate from the surface of the body at the shoulder instead of performing the Prandtl-Meyer expansion. Applying this model flow method to the flow past a finite wedge, and comparing with the more accurate solutions derived by Guderley, Cole, Hida and Marschner, it is found that the accuracy of the predicted values of the pressure distribution over the surface or the head drag coefficient is fairly good, but that as for the choking Mach number this model flow gives a rather different value from that of the real flow. The pressure distributions over the surface of the several symmetric profiles with sharp shoulders are calculated by this model flow method.

§1. Introduction

We shall consider the two-dimensional transonic flow of a compressible fluid past a thin obstacle which is symmetric with repect to the uniform velocity vector and has sharp shoulders at the position of maximum thickness. According to the transonic approximation originally due to von Kármán[1], the fundamental equation can be transformed to Tricomi's differential equation in the hodograph plane. In such a case as a wedge profile, the boundary curve can be explicitly determined in the hodograph plane as well as in the physical plane. The flow can be found by solving Tricomi's equation subject to the given boundary conditions. Thus, Guderley and Yoshihara[2] obtained the solutions for the flow over a wedge at Mach number 1, and Cole[3] and Trilling and walker[4] obtained the solutions at high subsonic speeds. Marschner,[5] Hashimoto[6] and Hida[7] studied the flow past the wedge placed along the center line between the two plane walls. Since the boundary curve in the hodopraph plane cannot be explicitly determined in more general cases, it is not convenient to deal with the problem by the hodograph equation.

On the other hand, the pure subsonic flow can be very easily dealt with by the simplified W. K. B. method,[8],[9] provided the corresponding incompressible flow can be known. In our cases, the surface velocity attains the local sound velocity at the shoulder. If we make use of an appropriate incompressible flow, the velocity of which becomes a corresponding value to the sonic velocity of the compressible flow at the shoulder and on the same curve as the sonic line of the compressible flow, we can find the velocity distribution of the compressible fluid on the surface of the front part of the given body (the region from the nose to the shoulder). In this paper we shall restrict the analysis to find the solution in the forward subsonic region, but the solution in the supersonic region can be given by the method of characteristics, if it is desired.

As the sonic line cannot be known a priori, we must assume it. In this paper we shall use a flow with free streamlines as a model. It is assumed that the flow separates from the surface of the body at the shoulder, and that along the free streamlines the fluid velocity continues to be sonic to the point where the inclination θ of the velocity vector vanishes, and behind this point θ continues to be zero.

This assumption was used by Roshko[10] to estimate the drag of a bluff body in an incompressible fluid. By the use of this model flow, we can study the forward subsonic region in the flow past a thin symmetric obstacle with sharp shoulders by the W.K.B. method.[8),9)]. Especially in the case of the flow past a finite wedge at sonic and high subsonic speeds, the pressure distributions on the surface derived by this model flow method will be compared with the exact solutions due to Guderley and Yoshihara[2)] and Cole[3)]. This model can be modified to treat the flow past the obstacle placed along the centre line between the two parallel plane walls. Also in this case, the pressure distribution past the wedge derived by this model will be compared with that obtained by the more accurate methods due to Marschner[5)] and Hida[7)]. As the numerical examples we evaluate the pressure distributions on the front surface of several thin obstacles with curved walls and sharp shoulders placed in an unbounded fluid and in a choked wind tunnel.

§ 2. Outline of W.K.B. Method

Applying the K.W.B. method derived by Imai[8),9)] to the thin obstacle in the transonic flow, and neglecting the higher order terms of perturbation, we can obtain the following simple relation between the magnitudes q, Q of the velocity of a compressible and an incompressible fluids on the surface of the same obstacle:

$$\varepsilon=(9/8\Gamma)^{1/3}\eta^{2/3}, \qquad (2.1)$$

with

$$\varepsilon=1-q\,, \qquad (2.2)$$

$$\eta=1-Q\,, \qquad (2.3)$$

$$\Gamma=(\gamma+1)/2\,, \qquad (2.4)$$

where the sonic velocity and the corresponding velocity of an incompressible flow are taken to be the units of the velocity of the compressible and the incompressible fluids respectively.

Defining the pressure coefficient C_p by

$$C_p=(p-p_\infty)\Big/\frac{1}{2}\rho_\infty q_\infty^2, \qquad (2.5)$$

where p and ρ denote the pressure and the density respectively, and suffix ∞ refers to the quantity at infinity upstream, the surface pressure coefficient can be given as follows within the accuracy of the approximation considered here:

$$C_p=2(\varepsilon-\varepsilon_\infty)=(9/\Gamma)^{1/3}\{\eta^{2/3}-\eta_\infty^{2/3}\}$$

$$=t^{2/3}\Gamma^{-1/3}[9^{1/3}(\eta/t)^{2/3}-2K_1]\,, \qquad (2.6)$$

in which

$$K_1=(1-M_1)t^{-2/3}\Gamma^{-2/3}\,, \qquad (2.7)$$

and t and M_1 denote the half thickness ratio of the body and the free stream Mach number respectively.

As the non-dimensional perturbation velocity η of an incompressible flow is proportional to the half thickness ratio t in the first approximation of the thin wing expansion theory, the expression (2.6) can satisfy the Kármán's transonic similarity law[1)]. Introducing the usual transonic parameter ξ_0 and the reduced pressure coefficient $\tilde{C}_p$ defined by

$$\xi_0=(1-M_1^2)/t^{2/3}(1+\gamma)^{2/3}=2^{1/3}K_1\,, \qquad (2.8)$$

and

$$\tilde{C}_p=(1+\gamma)^{1/3}t^{-2/3}C_p\,, \qquad (2.9)$$

respectively, Eq. (2.6) is expressed as

$$\tilde{C}_p=18^{1/3}(\eta/t)^{2/3}-2\xi_0\,. \qquad (2.10)$$

When we consider the flow of a compressible fluid past the obstacle placed along the centre line between the two parallel plane walls γ distance $2L$ apart, the corresponding incompressible flow may be taken to be the flow past the same body placed in the similar wind tunnel, but with the corresponding width $2L_0$.

As the flow is almost parallel and uniform at a great distance upstream, the W. K. B. method can be reduced to the usual Prandtl-Glauert's law. Thus there exists the following relation between the distances L and L_0:

$$L/L_0=1/\sqrt{1-M_1^2}\,. \qquad (2.11)$$

§ 3. Flow Past an Obstacle in an Unbounded Fluid

We shall consider the flow with separation of an incompressible fluid past a thin symmetric obstacle with a flat base. We shall introduce the complex coordinate $z=x+iy$, and the complex velocity potential $\omega=\varphi+i\psi$, where x and y denote the Cartesian coordinates of physical plane, and φ and ψ denote the velocity potential and the stream function respectively. Owing to the theory of the incompressible flow, ω should be an analytic function of z. It is convenient to introduce a new analytic function f of z such that

$$f=\log\left(\frac{dz}{d\omega}\right)=r+i\theta\ , \qquad (3.1)$$

where

$$r=\log(1/Q)\ , \qquad (3.2)$$

and Q and θ denote the magnitude and the inclination of the velocity vector of an incompressible fluid. Denoting the half thickness ratio by t, and taking the chord length to be unity, the profile may be expressed as

$$y=\pm tH(x)\ ,\quad 0\leqq x\leqq 1\ . \qquad (3.3)$$

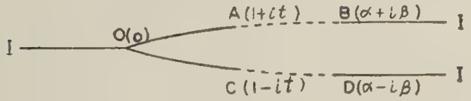
The magnitude of the velocity at the shoulder being taken to be the unit of the velocity, the analytic function f should satisfy the following boundary conditions in the z-plane (cf. Fig. 1(a)):

along $\psi=\pm 0$;

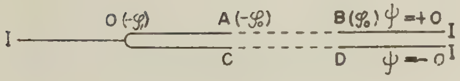
$$\left.\begin{array}{lll} \text{for} & -\infty\leqq x<0, & \theta=0, \\ \text{for} & 0\leqq x<1, & \theta=\pm tH'(x), \\ \text{for} & 1\leqq x<\alpha, & r=0, \\ \text{for} & \alpha\leqq x\leqq\infty, & \theta=0, \end{array}\right\} \qquad (3.4)$$

where α denotes an undermined constant.

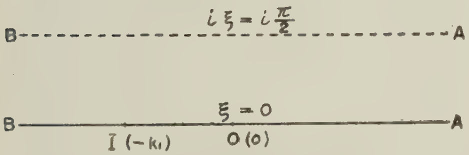
These boundary conditions (3.4) are originally given by Roshko[10] as a modified Helmholtz flow for an incompressible fluid.



(a) Z − Plane



(b) ω−Plane



(c) ζ − Plane

Fig. 1. Boundary conditions for the flow past a body in an unbounded fluid.

In the ω-plane the boundary conditions (3.4) are transformed as follows (cf. Fig. 1 (b)):

along $\psi=\pm 0$;

$$\left.\begin{array}{lll} \text{for} & -\infty\leqq\varphi<-\varphi_1, & \theta=0, \\ \text{for} & -\varphi_1\leqq\varphi<-\varphi_0, & \theta=\pm tH'(x), \\ \text{for} & -\varphi^0\leqq\varphi<\varphi_0, & r=0, \\ \text{for} & \varphi_0\leqq\varphi\leqq\infty, & \theta=0, \end{array}\right\} \qquad (3.5)$$

where φ_0 and φ_1 denote undetermined positive constants.

Now, an auxiliary plane $\zeta=\delta+i\xi$ is introduced such that

$$\zeta=\delta+i\xi=\frac{1}{2}\log\left(\frac{\omega-\varphi_0}{\omega+\varphi_0}\right)-k_1\ , \qquad (3.6)$$

with

$$k_1=\frac{1}{2}\log\left(\frac{\varphi_1+\varphi_0}{\varphi_1-\varphi_0}\right). \qquad (3.7)$$

The upper half part of the ω-plane is mapped onto the strip

$$-\infty\leqq\delta\leqq\infty,\quad 0\leqq\xi\leqq\pi/2$$

i.e., the intervals of the bounding streamlines on which θ is known correspond to $\xi=0$, $-\infty\leqq\delta\leqq\infty$: while the remaining interval corresponds to $\xi=\pi/2$, $-\infty\leqq\delta\leqq\infty$. (cf. Fig. 1 (c))

Since $f(\omega)$ is analytic, so also is $f(\zeta)$ and boundary conditions (3.5) can be transformed to the following form in the ζ-plane:

$$\left.\begin{array}{ll} \text{along } \xi=0; & \\ \quad\text{for } -\infty\leqq\delta<0, & \theta=\theta_0=0, \\ \quad\text{for } 0\leqq\delta\leqq\infty, & \theta=\theta_0=tH'(x), \\ \text{along } \xi=\pi/2; & \\ \quad\text{for } -\infty\leqq\delta\leqq\infty, & r=r_0=0, \end{array}\right\} \qquad (3.8)$$

where θ_0 and r_0 are known functions of δ.

Woods[11] found the form of the analytic function $f(\zeta)$ subject to the boundary conditions (3.8) as follows:

$$f(\delta,\ \xi)=\frac{1}{\pi}\int_{-\infty}^{\infty}[\theta_0(\delta^*)\operatorname{cosech}\{\delta^*-(\delta+i\xi)\}$$
$$+r_0(\delta^*)\operatorname{sech}\{\delta^*-(\delta+i\xi)\}]d\delta^*\ . \qquad (3.9)$$

In our case, according to the conditions (3.8), Eq. (3.9) can be reduced to

$$f(\delta,\ \xi)=\frac{1}{\pi}\int_0^{\infty}tH'(x)\operatorname{cosech}\{\delta^*-(\delta+i\xi)\}d\delta^* \qquad (3.10)$$

Putting $\xi=0$ in Eq. (3.10), the value of r on the real axis of the ζ-plane is given by

$$r=\frac{t}{\pi}\int_0^{\infty}H'(x)\operatorname{cosech}(\delta^*-\delta)d\delta^*. \qquad (3.11)$$

As the body is very thin, we can obtain

$$x=(e^{2\delta}-1)/(e^{2\delta}-e^{-2k_1})+O(t). \qquad (3.12)$$

Substituting Eq. (3.12) into Eq. (3.11), and remembering Eq. (2.3), we can obtain

$$\eta=\frac{t}{\pi}\int_0^\infty H'\left(\frac{e^{2\delta^*}-1}{e^{2\delta^*}-e^{-2k_1}}\right)\operatorname{cosech}(\delta^*-\delta)d\delta^* +\mathrm{O}(t^2)\,, \tag{3.13}$$

where H' denotes the derivative of H with respect to the argument x.

Introducing new variables such that

$$u=e^{\delta^*},\quad v=e^{\delta}, \tag{3.14}$$

Eq. (3.13) can be transformed to a more convenient form:

$$\eta=\frac{2tv}{\pi}\int_1^\infty H'\left(\frac{u^2-1}{u^2-e^{-2k_1}}\right)\frac{du}{u^2-v^2}\,, \tag{3.15}$$

with

$$v=\left\{\frac{1-xe^{-2k_1}}{1-x}\right\}^{1/2},\quad -\infty\leqq x\leqq 1. \tag{3.16}$$

For a given profile, Eq. (3.15) with Eq. (3.16) gives the non-dimensional perturbation velocity of an incompressible fluid on the surface of the body.

As

$$x\to-\infty,\quad v\to e^{-k_1}$$

and

$$\eta_\infty=\lim_{v\to e^{-k_1}}\left[\frac{2tv}{\pi}\int_1^\infty H'\left(\frac{u^2-1}{u^2-e^{-2k_1}}\right)\frac{du}{u^2-v^2}\right]. \tag{3.17}$$

Combining Eq. (3.17) with Eq. (2.6), we can obtain the relation between the transonic parameter K_1 and an undetermined constant k_1.

Thus substitutions of Eq. (3.15) into Eqs. (2.6) and (2.10) give pressure- and the reduced pressure coefficients of a compressible fluid on the surface of the given profile for a given transonic parameter K_1.

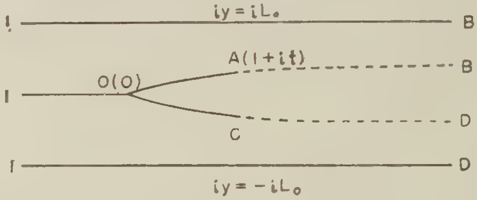
Especially putting $k_1=\infty$ in Eq. (3.17), the transonic parameter K_1 vanishes, and this is the case for the flow at Mach number 1.

§ 4. The Flow Past an Obstacle in a Choked Wind Tunnel

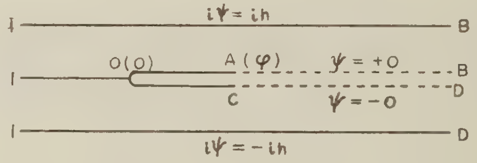
We shall consider the transonic flow past a thin symmetric obstacle with a flat base placed along the centre line between the two parallel plane walls a distance $2L$ apart under the choking conditions. For the model flow, the choking conditions may be given by putting the magnitude of the velocity along the free streamlines to be sonic. Thus the boundary conditions are given by (cf. Fig. 2 (a))

$$\left.\begin{array}{lll} \text{along } \psi=\pm 0; & & \\ \quad\text{for} & -\infty\leqq x<0, & \theta=0, \\ \quad\text{for} & 0\leqq x<1, & \theta=\pm tH'(x), \\ \quad\text{for} & 1\leqq x\leqq\infty, & r=0, \\ \text{along } y=\pm L_0; & & \\ \quad\text{for} & -\infty\leqq x\leqq\infty, & \theta=0, \end{array}\right\} \tag{4.1}$$

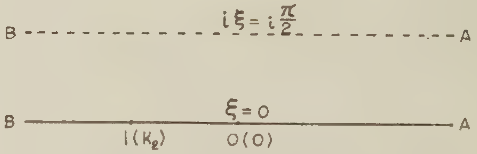
where $2L_0$ and $2t$ denote the corresponding width of tunnel of the incompressible flow and the thickness ratio of the body respectively and the profile is represented by Eq. (3.3).



(a) z-plane



(b) w-plane



(C) ζ-plane

Fig. 2. Boundary conditions for the flow past a body in a choked wind tunnel.

In the ω-plane, the boundary conditions (4.1) are transformed as follows (cf. Fig. 2 (b))

$$\left.\begin{array}{lll} \text{along } \psi=\pm 0; & & \\ \quad\text{for} & -\infty\leqq \varphi<0, & \theta=0, \\ \quad\text{for} & 0\leqq \varphi<\varphi_2, & \theta=\pm tH'(x), \\ \quad\text{for} & \varphi_2\leqq \varphi\leqq\infty, & r=0, \\ \text{along } \psi=\pm h & & \\ \quad\text{for} & -\infty\leqq \varphi\leqq\infty, & \theta=0, \end{array}\right\} \tag{4.2}$$

where φ_2 and h denote undetermined constants.

Now an auxiliary plane $\zeta=\delta+i\xi$ is introduced such that

$$\exp\left\{2\left(k_2+\frac{\pi}{2}i-\zeta\right)\right\}+1=\exp\{(\pi/h)(\omega-\varphi_2)\}, \tag{4.3}$$

with

$$2k_2=\log\left(1-e^{-\pi\varphi_2/h}\right) \tag{4.4}$$

The strip $-\infty\leqq\varphi\leqq\infty$, $0\leqq\psi\leqq h$ in the ω-plane is mapped onto the strip $-\infty\leqq\delta\leqq\infty$, $0\leqq\xi\leqq\pi/2$ in the ζ-plane, (cf. Fig. 2 (c)). In the ζ-plane, the boundary conditions (4.2) for the function f can be transformed to the form expressed by Eq. (3.8). Thus the problem can be reduced to the same form as that for the case of the flow in an unbounded fluid.

Considering the relation between x and δ along the surface of the body, Eq. (3.11) may be reduced to the following convenient form:

$$\eta=\frac{2tv}{\pi}\int_1^\infty H'\left(1+\frac{h}{\pi}\right.$$

$$\left.\times\log\{1-[1-e^{-\pi/h}]u^{-2}\}\right)\frac{du}{u^2-v^2}, \tag{4.5}$$

where

$$v=(1-e^{-\pi/h})^{1/2}/\{1-e^{(\pi/h)(x-1)}\}^{1/2}. \tag{4.6}$$

Performing the integral (4.5) and putting $x=-\infty$ in Eqs. (4.5) and (4.6), we can obtain the relation between η_∞ and h. Remembering Eq. (2.6), the undetermined constant h can be related to the transonic parameter K_1.

Next, we shall find the relation between the width $2L$ of tunnel, the thickness ratio $2t$ of the body and the transonic parameter K_1 under the choking state. As the flow becomes uniform at infinity upstream, we obtain the relation in the first approximation:

$$\int_0^{L_0}Q_\infty dy=\int_0^h d\psi$$

or

$$h=L_0Q_\infty=L_0(1-\eta_\infty)\doteqdot L_0\,, \tag{4.7}$$

where Q_∞ denotes the magnitude of the velocity of the incompressible flow at infinity upstream. Combining Eq. (4.7) with Eq. (2.11), we obtain

$$h/L=\sqrt{1-M_1{}^2}+\text{higher oder terms.} \tag{4.8}$$

Remembering Eq. (2.7), Eq. (4.8) can be transformed to

$$Lt^{1/3}\Gamma^{1/3}=2^{-1/2}hK_1{}^{-1/2}. \tag{4.9}$$

Since h is a function of K_1, $Lt^{1/3}\Gamma^{1/3}$ can be expressed as a function of the transonic parameter K_1. Hashimoto[6)] studied the flow past a finite wedge placed in the choked wind tunnel by solving Tricomi's equation in the hodograph plane, and assured that $Lt^{1/3}\Gamma^{1/3}$ can be expressed as a function of the transonic parameter K_1 or ξ_0.

§ 5. Examples

We shall first apply the present method of simple model flow to the transonic flow past a finite wedge in an unbounded fluid and in the choked wind tunnel, and examine the accuracy of this method by comparing the results with the more accurate solutions derived by Guderley and Yoshihara[2)], Cole[3)], Marschner[5)] and Hida[7)]. Then we shall apply the present method to the flow past a body with curved walls and a flat base.

(I) Wedge

(A) In an unbounded fluid

As a wedge of unit length is represented by

$$y=\pm tx \qquad 0\leqq x\leqq 1, \tag{5.1}$$

the integrals (3.15) and (3.17) are evaluated as follows:

$$\eta=\frac{t}{\pi}\log\left|\frac{v+1}{v-1}\right|, \tag{5.2}$$

and

$$\eta_\infty=\frac{t}{\pi}\log\left|\frac{1+e^{-k_1}}{1-e^{-k_1}}\right|, \tag{5.3}$$

where v is given by Eq. (3.16). The relation between k_1 and ξ_0 is given by

$$e^{-2k_1}=\tanh^2(\pi\xi_0{}^3/3)\,. \tag{5.4}$$

Substitution of Eq. (5.2) into Eq. (2.10) gives the reduced pressure coefficient $\tilde{C}_p$ on the surface of the body. It is expanded in the power series in ξ_0 such that

$$\tilde{C}_p=\tilde{C}_p{}^*-2\xi_0 \tag{5.5}$$

with

$$\tilde{C}_p{}^*=18^{1/3}(\eta/t)^{2/3}=P(x)+2N(x)\xi_0{}^3\cdots, \tag{5.6}$$

$$P(x)=\left(\frac{18}{\pi^2}\right)^{1/3}\log^{2/3}\left|\frac{1+\sqrt{1-x}}{1-\sqrt{1-x}}\right|, \tag{5.7}$$

$$N(x)=\frac{1}{3}\left(\frac{18}{\pi^2}\right)^{1/3}\left(\frac{\pi}{3}\right)^2(1-x)^{1/2}$$

$$\cdot\log^{-1/3}\left|\frac{1+\sqrt{1-x}}{1-\sqrt{1-x}}\right|, \tag{5.8}$$

where the functions $P(x)$ and $N(x)$ are shown in Figs. 3 and 4.

Within the accuracy of the approximation considered here, the left hand side of Eq. (5.6) denotes the reduced pressure coefficient with respect to the sonic point defined by

$$\tilde{C}_p{}^* = t^{-2/3}(\gamma+1)^{1/3}C_p{}^*, \tag{5.9}$$

with

$$C_p{}^* = (p-p^*)\Big/\frac{1}{2}\rho^* q^{*2}, \tag{5.10}$$

where the asterisk refers to the quantity at the sonic point.

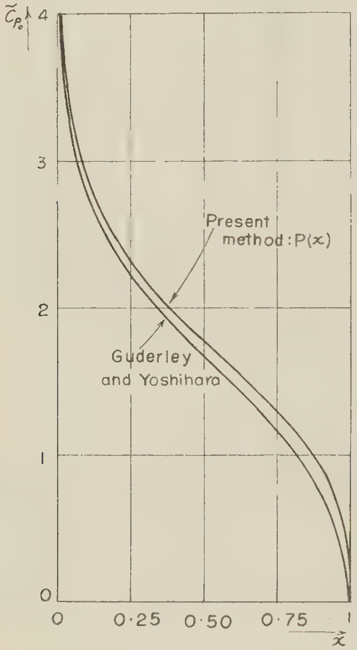


Fig. 3. The reduced pressure distribution on the surface of a wedge of unit length at $M_1=1$.

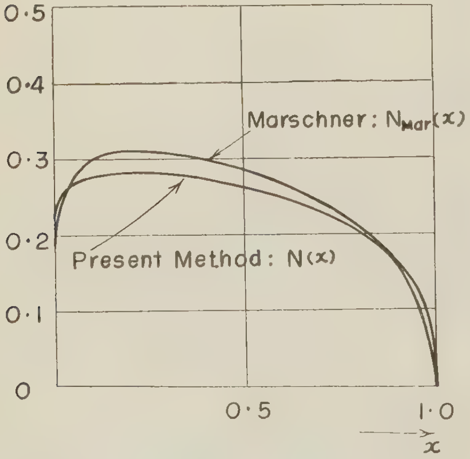

Fig. 4. The perturbation function $N(x)$.

The function $P(x)$ represented by Eq. (5.7) should be compared with the exact solution derived by Guderley and Yoshihara[2], which is also shown in Fig. 3.

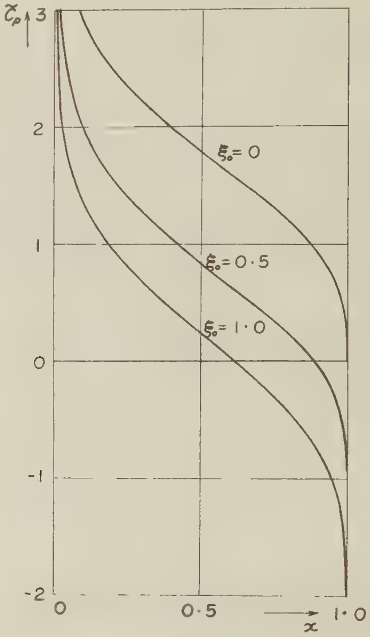

Fig. 5. The distributions of $\tilde{C}_p$ on the surface of a finite wedge in an unbounded fluid.

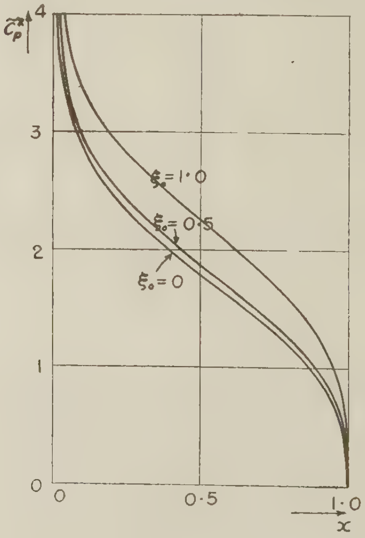

Fig. 6. The distributions of $\tilde{C}_p{}^*$ on the surface of a finite wedge in an unbounded fluid.

For several values of ξ_0, the surface distributions of $\tilde{C}_p$ and $\tilde{C}_p{}^*$ past the wedge are calculated by the present method, and they are shown in Figs. 5 and 6 respectively.

The head drag coefficient is obtained by integrating the horizontal component of the pressure coefficient on the front surfaces of the body or

$$C_d = t\int_0^1 C_p H'(x)dx\,. \tag{5.11}$$

Defining the reduced head drag coefficients $\tilde{C}_d$, $\tilde{C}_d^*$ with respect to the uniform- and the sonic velocities respectively by

$$\tilde{C}_d = t^{-5/3}(\gamma+1)^{1/3}C_d\,, \tag{5.12}$$

$$\tilde{C}_d^* = t^{-5/3}(\gamma+1)^{1/3}C_d^*\,, \tag{5.13}$$

and integrating Eqs. (5.5) and (5.6), we obtain

$$\tilde{C}_d = \tilde{C}_d^* - 2\xi_0\,, \tag{5.14}$$

$$\tilde{C}_d^* = \tilde{C}_{d_0} + B_{fr}\xi_0^3 + \cdots, \tag{5.15}$$

where

$$\tilde{C}_{d_0} = \int_0^1 P(x)dx\,, \tag{5.16}$$

$$B_{fr} = 2\int_0^1 N(x)dx\,. \tag{5.17}$$

Cole[3)] and Hida[7)] studied the flow past a wedge at high subsonic speeds by solving Tricomi's equation subject to the somewhat approximated boundary conditions in the hodograph plane. Their results, together with the exact values of $\tilde{C}_{d_0}$ derived by Guderley and Yoshihara[2)], are given and compared with the values obtained by the present method in Table I. (Hida[7)] estimated the value of $\tilde{C}_{d_0}$ by the same method as Cole's[3)] and revised it.)

(B) In the choked wind tunnel

Integrating Eq. (4.5), η is evaluated and we can obtain the pressure coefficient by the use of Eq. (2.6) or Eq. (2.10). The relation between h and ξ_0 is obtained as

$$\pi/h = 2\log\cosh\left(\frac{\pi}{3}\xi_0^{3/2}\right). \tag{5.18}$$

By the use of Eq. (5.18), the reduced pressure coefficient $\tilde{C}_p^*$ with respect to the sonic point can be expressed as follows:

$$C_p^* = P(x) + N(x)\xi_0^3 + \cdots \tag{5.19}$$

where the functions $P(x)$ and $N(x)$ are given by Eqs. (5.7) and (5.8).

Marschner[5)] studied the flow past a double wedge in a choked wind tunnel by the perturbation method applied to the Guderley's[2)] solution at Mach number 1. After him the reduced pressure coefficient is

$$\tilde{C}_p^* = \tilde{C}_{p_0} + N_{Mar}(x)\xi_0^3, \tag{5.20}$$

$$N_{Mar}(x) = 2(2/3)^{4/3}\frac{0.611}{0.586}F(x) \tag{5.21}$$

where $\tilde{C}_{p_0}$ was given by Guderley and Yoshihara and $F(x)$ was shown in Fig. 10 of reference [5]. The function $N_{Mar}(x)$ is also shown in Fig. 4.

For several values of ξ_0, the distributions of $\tilde{C}_p$ and $\tilde{C}_p^*$ over the surface of the wedge are obtained by the present method and they are shown in Figs. 7 and 8 respectively.

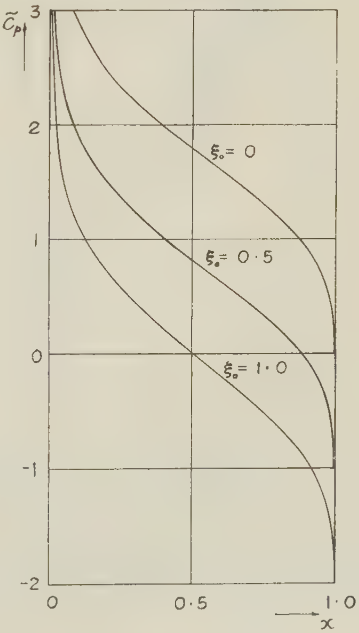

Fig. 7. The distributions of $\tilde{C}_p$ on the surface of a finite wedge in a choked wind tunnel.

The reduced head drag coefficient with respect to the sonic point is given by integrating Eq. (5.19) or (5.20) as follows:

$$\tilde{C}_d^* = \tilde{C}_{d_0} + B_{ch}\xi_0^3 + \cdots \tag{5.22}$$

where the coefficient B_{ch} is gigen by integrating $N(x)$ or $N_{Mar}(x)$. Hida[7)] also estimated the head drag coefficient of the finite wedge in the choked wind tunnel by an approximate treatment, and obtained the reduced head drag coefficient expressed in the same form as Eq. (5.22). The values of the coefficient B_{ch} evaluated by these authors are given in Table I.

Table I and Figs. 3 and 4 show that this simple model flow method gives a fairly good approximation for the pressure coefficient and the head drag coefficient of the finite wedge in the choked wind tunnel as well as in an unbounded fluid. Especially in the case of choked wind tunnel the present method seems to be very reliable.

Next, we shall consider the relation under the choking state. Substituting Eq. (5.18) into Eq. (4.9), and remembering Eq. (2.8), we obtain the relation:

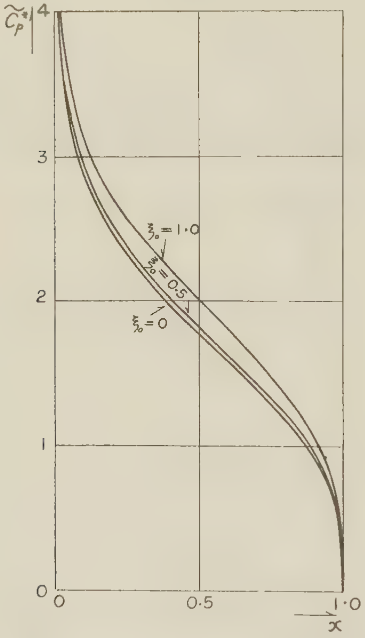

Fig. 8. The distributions of $\tilde{C}_p^*$ on the surface of a finite wedge in a choked wind tunnel.

$$L^{-1}(\gamma+1)^{-1/3}t^{-1/3}$$
$$=\left(\frac{2}{\pi}\right)\xi_0{}^{1/2}\log\cosh\left(\frac{\pi}{3}\xi_0{}^{3/2}\right). \quad (5.23)$$

For the small value of ξ_0, Eq. (5.23) is reduced to

$$L^{-1}(\gamma+1)^{-1/3}t^{-1/3}=(\pi/9)\xi_0{}^{7/2} \quad (5.24)$$

This result should be compared with the exact relation derived by Marschner⁵⁾:

$$L^{-1}(\gamma+1)^{-1/3}t^{-1/3}$$
$$=(1.235\times0.586)\times\left(\frac{2}{3}\right)^{4/3}\xi_0{}^{5/2} \quad (5.25)$$

Thus, it seems to the author that the present method of the model flow is useful to obtain the pressure distribution and the head drag coefficient, but the reliable relation among L, t and ξ_0 under the choking state cannot be obtained by this method.

We shall proceed to apply this method to the flow past a thin symmetric profile with curved walls and a flat base.

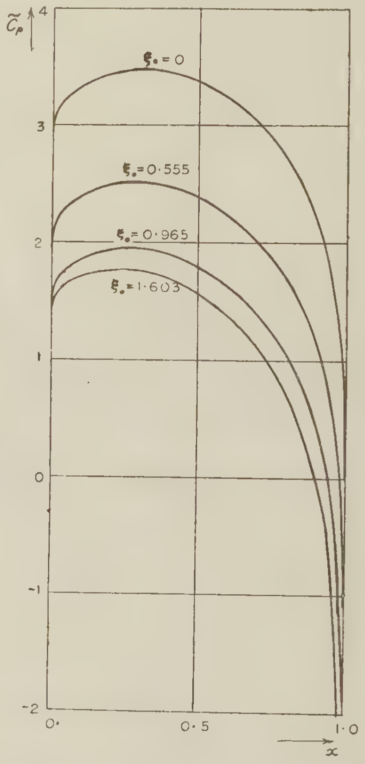

Fig. 9. The distributions of $\tilde{C}_p$ on the surface of a profile $y=\pm tx^2$ in an unbounded fluid.

(II) Profile $y=\pm tx^2$

(A) In an unbounded fluid

By the use of Eq. (3.15), we obtain

$$\eta=\frac{2t}{\pi}\left[x\log\left|\frac{v+1}{v-1}\right|\right.$$
$$\left.-e^{k_1}\sqrt{(1-x)(1-xe^{-2k_1})}\log\left(1-\frac{2e^{-k_1}}{1+e^{-k_1}}\right)\right], \quad (5.26)$$

where v is given by Eq. (3.16). For several values of ξ_0 the distributions of $\tilde{C}_p$ and C_p^* over the surface of the profile are calculated and they are shown in Figs. 9 and 10.

For small values of ξ_0, $\tilde{C}_p{}^*$ is expanded in power series in ξ_0 as

$$\tilde{C}_p{}^* = \tilde{C}_{p_0} + 2R(x)\xi_0{}^3 + \cdots \tag{5.27}$$

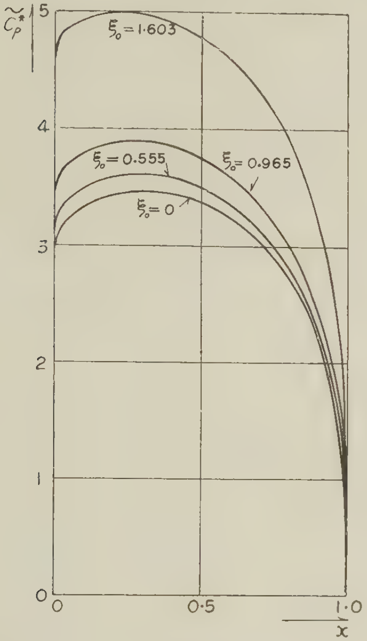

Fig. 10. The distributions of $\tilde{C}_p{}^*$ on the surface of a profile $y = \pm tx^2$ in an unbounded fluid.

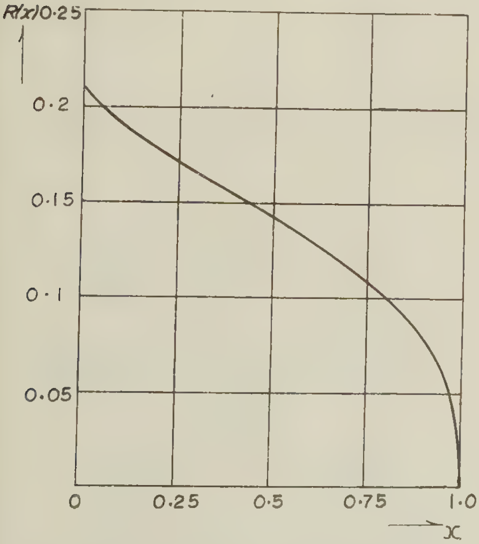

Fig. 11. The perturbation function $R(x)$.

with

$$\tilde{C}_{p_0} = \left(\frac{18}{\pi^2}\right)^{1/3}\left[2x \log\left|\frac{1+\sqrt{1-x}}{1-\sqrt{1-x}}\right| + 4\sqrt{1-x}\right]^{2/3}. \tag{5.28}$$

and

$$R(x) = \frac{(18)^{1/3}}{36}\pi^{4/3}(1-x)^{1/2} \times\left[2x \log\left|\frac{1+\sqrt{1-x}}{1-\sqrt{1-x}}\right| + 4\sqrt{1-x}\right]^{-1/3}. \tag{5.29}$$

The value of $R(x)$ is shown in Fig. 11.

Integrating Eq. (5.11) graphically, the reduced head drag coefficient $\tilde{C}_d$ is obtained and is shown in Fig. 12.

(B) In the choked wind tunnel

In this case Eq. (4.5) becomes

$$\eta = \frac{4tv}{\pi}\int_1^\infty \left\{1 + \frac{h}{\pi}\log(1-[1-e^{-\pi/h}]u^{-2})\right\}\frac{du}{u^2-v^2}, \tag{5.30}$$

where v is given by Eq. (4.6). When the width L of tunnel is very large, the value of h may also be large. Then, the integral of Eq. (5.30) may be evaluated in the form of series in (π/h). Thus we can obtain the distribution of $\tilde{C}_p{}^*$ in the following form:

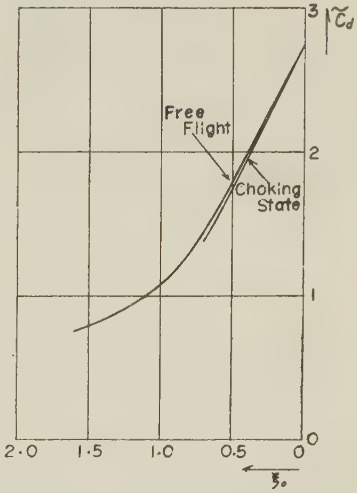

Fig. 12. The variation with the transonic parameter ξ_0 of the reduced head drag coefficient $\tilde{C}_d$ of a profile $y = \pm tx^2$ in an unbounded fluid and in a choked wind tunnel.

$$\tilde{C}_p{}^* = \tilde{C}_{p_0} + R(x)\xi_0{}^3 + \cdots, \tag{5.31}$$

with

$$\xi_0 = (4/\pi)^{2/3}(\pi/h)^{1/2} + \cdots, \tag{5.32}$$

where $\tilde{C}_{p_0}$ hnd $R(x)$ are given by Eqs. (5.28) and (5.29).

The values of $\tilde{C}_p$ and $\tilde{C}_p{}^*$ calculated for several values of the transonic parameter ξ_0 are shown in Figs. 13 and 14 respectively.

The variation of the reduced head drag coefficient $\tilde{C}_d$ is also shown in Fig. 12 in comparison with the case in an unbounded fluid.

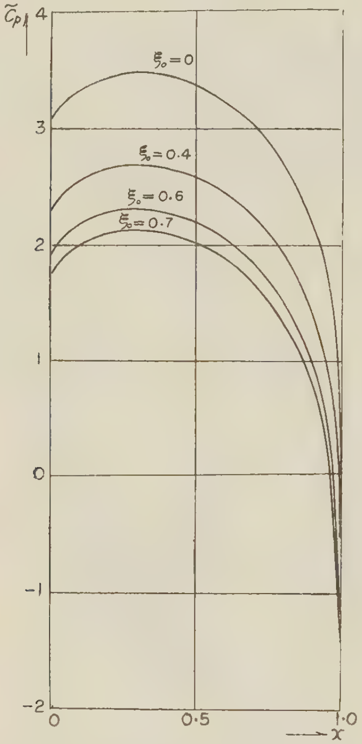

Fig. 13. The distributions of $\tilde{C}_p$ on the surface of a profile $y=\pm tx^2$ in a choked wind tunnel.

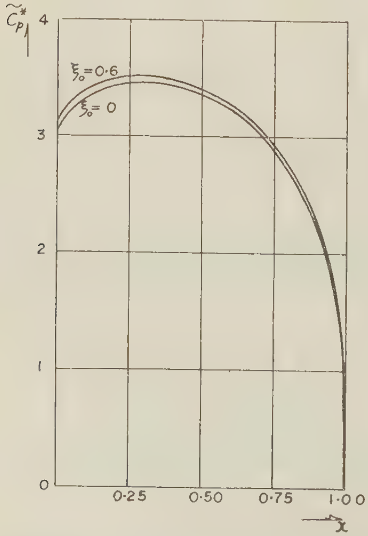

Fig. 14. The distributions of $\tilde{C}_p$* on the surface of a profile $y=\pm tx^2$ in a choked wind tunnel.

(III) Profile: $y=\pm tx^4$

Now we shall calculate the reduced pressure coefficient a Mach number 1.

Substituting $e^{-k_1}=0$, $H(x)=x^4$ into Eq. (3.15), and performing the integral we obtain

$$\eta=\frac{4t}{\pi}\left[\left\{1-\frac{3}{v^2}+\frac{3}{v^4}-\frac{1}{v^6}\right\}\log\left|\frac{v+1}{v-1}\right|\right]$$
$$+\frac{4tv}{\pi}\left[\frac{11}{5}\left(\frac{1}{v^2}\right)-\frac{8}{3}\left(\frac{1}{v^4}\right)+\frac{1}{v^6}\right], \tag{5.33}$$

where

$$v=1/\sqrt{1-x}\,. \tag{5.34}$$

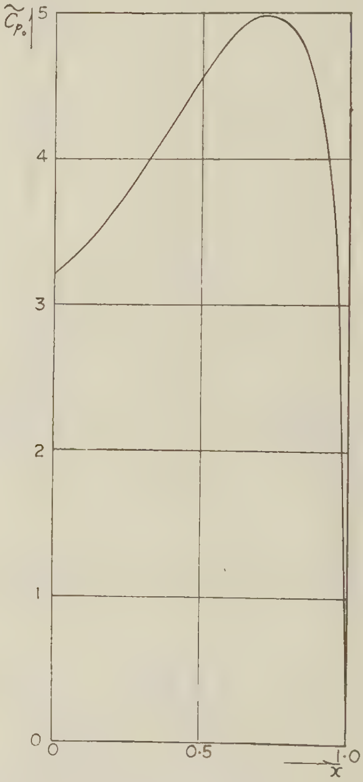

Fig. 15. The distribution of $\tilde{C}_p$ on the surface of a profile $y=\pm tx^4$ at sonic speed.

Table II.

Profile	$\tilde{C}_{d0}$
$y=tx$	1.837
$y=tx^2$	2.749
$y=tx^4$	4.103

Combining Eq. (5.33) with Eq. (2.10), we obtain the reduced pressure coefficient $\tilde{C}_p$ and it is shown in Fig. 15.

Finally the values of the reduced head drag coefficient $\tilde{C}_{a_0}$ of the profiles considered above at Mach number 1 compared in Table II.

§ 6. Conclusion

It has been ascertained that the simple method of the model flow gives a fairly good approximation for the pressure distribution over the surface of a finite wedge placed in an unbounded fluid as well as in a choked wind tunnel at sonic and high subsonic speeds. This simple method was applied to the flows past some profiles with curved surface and sharp shoulders, and several numerical informations were obtained.

Inspecting Figs. 5–10 and 13–14, it is found that the value of $\tilde{C}_p{}^*$ increases as ξ_0 increases, while the value of $\tilde{C}_p$ decreases. Owing to this fact, the value of $\tilde{C}_d{}^*$ also increases as ξ_0 increases, while the value of $\tilde{C}_d$ decreases. (cf. Fig. 12) This model flow method cannot be applied to the flow past a body placed in a sonic free jet, which was studied by Marschner$^{5)}$, because in this case the right-hand side of Eq. (2.11) becomes infinite, and no incompressible flow can be transformed to the compressible sonic free jet of finite width.

In conclusion, the author would like to express his heartiest gratitude to Professor I. Imai for his kind suggestion and valuable discussions during the course of the present investigations.

On the Compressible Flow over a Slender Body of Revolution with a Flat Base Placed in an Unbounded Fluid and in a Choked Wind Tunnel

By Ken-ichi KUSUKAWA

Department of Physics, Faculty of Science, Tokyo Metropolitan University

(Received May 11, 1957)

The flows past a slender body of revolution with a sharp shoulder placed in an unbounded compressible fluid and along the axis of a choked circular wind tunnel have been studied by the method of the correspondence between the axisymmetric and the two-dimensional flows, which was derived by the present author³⁾. The corresponding two-dimensional flow, which is necessary for evaluating the axisymmetric flow, is given by the model flow method in the previous paper⁴⁾. By comparing the pressure coefficient on the surface of a cone at sonic speed calculated by this method with Yoshihara's result²⁾ obtained by the relaxation method, the accuracy of this method has been ascertained. Then we have applied this method to the several flows past a body of revolution of finite length with a curved surface.

§ 1. Introduction

The flow past a body of revolution with a sharp shoulder at high subsonic and sonic speeds cannot be dealt with by the so-called linearized theory, because a Prandtl-Meyer expansion occurs at the shoulder, and the flow has a typical transonic character. In this case it is necessary to consider the fundamental equation of the transonic approximation originally due to von Kármán¹⁾.

While the fundamental equation of the two-dimensional flow can be reduced to a linear equation by the hodograph transformation, that of the axisymmetric flow remains nonlinear in the hodograph space as well as in the physical space. Owing to this reason it is very difficult to obtain the solution of the transonic equation of the axisymmetric flow subject to the given boundary conditions. Yoshihara²⁾ obtained the flow past a slender cone-cylinder at Mach number 1 by the relaxation method. Except this, no solution has been given for the axisymmetric transonic equation subject to given boundary conditions as far as the author is aware. In the previous paper³⁾, the present writer treated this transonic eqpation with some approximation, and found the relation between the axisymmetric flow and a corresponding two-dimensional transonic flow. In that paper, starting from the flow past a finite wedge at Mach number 1, the author obtained the flow past a paraboloid of revolution at Mach number 1.

If the flow past an two-dimensional symmetric obstacle with sharp shoulders in an unbounded fluid (in a choked wind tunnel) is known, we can obtain the flow past a corresponding axisymmetric body in the unbounded fluid (in a choked circular wind tunnel).

In another paper⁴⁾, the present writer utilized the flow separating from the surface of the body at the shoulder as a model flow of the two-dimensional transonic flow with a Prandtl-Meyer expansion at the shoulder, and obtained the pressure distribution and the head drag coefficient by the simplified W.K.B. method⁵⁾ with fairly high accuracy. As examples the flows past a finite wedge, and some symmetric profiles were studied, and the pressure distributions over the surface of these bodies were obtained. In this paper, starting from these two-dimensional flows, we shall find the solutions for the flow past a finite cone and a finite body of revolution with a curved surface.

§ 2. Correspondence between the Axisymmetric and the Two-dimensional Flows

For convenience a brief account will be given of the method of correspondence between the axisymmetric and the two-dimensional transonic flows³⁾.

We shall consider the flow past a slender body of revolution placed along the axis of a circular wind tunnel and that past a two-dimensional symmetric obstacle placed along the centre line between the two parallel plane walls at zero incidence.

The two-dimensional symmetric obstacle with sharp shoulders is represented by

$$\eta=\pm\tau H(\xi) \qquad 0\leqq\xi\leqq 1, \tag{2.1}$$

where τ denotes the half thickness ratio, and the chord length is taken to be unity. If the width $2L_1$ of tunnel can be expressed as a function λ_1 of the transonic parameter K_1 such that

$$L_1\tau^{1/3}\Gamma_1{}^{1/3}=\lambda_1(K_1)\,, \tag{2.2}$$

the pressure coefficient on the surface C_{p_1} is given in the following form:

$$C_{p_1}\Gamma^{1/3}\tau^{-2/3}=F(\xi,\,K_1)-2K_1\,, \tag{2.3}$$

where

$$C_{p_1}=(p-p_\infty)\,/\,\tfrac{1}{2}\rho_\infty U_1{}^2 \tag{2.4}$$

$$K_1=(1-M_1)(\tau\Gamma_1)^{-2/3},\quad \Gamma_1=(\gamma_1+1)/2\,, \tag{2.5}$$

and γ_1 denotes the ratio of specific heats, p the surface pressure, and p_∞, ρ_∞ and M_1 denote the pressure, density and the Mach number at infinity upstream.

If we find the pressure distribution (2.3) or the functional form $F(\xi,\,K_1)$ for a given value of K_1, we can obtain the pressure distribution over the surface of an axisymmetric body placed along the axis of a circular wind tunnel of radius L, the meridian curve of which is represented by

$$y=tH^{1/2}(x)\,,\qquad 0\leqq x\leqq 1\,, \tag{2.6}$$

where t denotes the half-thickness ratio.

We shall define the pressure coefficient C_p and the transonic parameter K in the axisymmetrical case respectively by

$$C_p=(p-p_\infty)\,/\,\tfrac{1}{2}\rho_\infty U^2 \tag{2.7}$$

and

$$K=(1-M)t^{-2}\Gamma^{-1},\quad \Gamma=(\gamma+1)/2, \tag{2.8}$$

where U and M denote the uniform velocity and the Mach number at infinity upstream, and γ denotes the ratio of specific heats in the axisymmetric case.

If the radius L of the wind tunnel can be expressed as a function λ of the transonic parameter K such that

$$Lt\Gamma^{1/2}=\lambda(K)\,, \tag{2.9}$$

the pressure coefficient C_p on the surface of the body of revolution is represented by

$$\begin{aligned}C_pt^{-2}=\tfrac{3}{4}F(x,\,K)\,H^{-1/3}(x)-\tfrac{3}{2}H''(x)\{1-H^{2/3}(x)\}&\\+2H''(x)\log\{2(27\Gamma)^{-1/4}\,t^{-1}\}-2K\,,&\end{aligned} \tag{2.10}$$

where

$$K=(3/4)K_1\,, \tag{2.11}$$

and

$$\lambda(K)=4(3)^{-3/2}\,\lambda_1{}^{3/2}(K_1)\,. \tag{2.12}$$

In the extreme case where $1/L$ vanishes, we can obtain the correspondence between the flows past the two-dimensional and the axisymmetric bodies placed in an unbounded fluid. In the case of the flow in a choked wind tunnel, Eqs. (2.2) and (2.9) determine the relations among the width (radius) of tunnel, the thickness ratio of the body and the transonic parameter under the choking state of the two-dimensional and the circular wind tunnels respectively.

The head drag coefficient C_d of a body of revolution is obtained by

$$\begin{aligned}C_d\,t^{-2}=&\int_0^1\left\{\frac{3}{4}F(x,\,K)H^{-1/3}+\frac{3}{2}\,H''H^{2/3}\right\}H'\,dx\\&-\left[\log\{(27)^{1/4}/2\}+\frac{3}{4}\right]\{H'(1)^2-H'(0)^2\}\\&+\{\log(1/\Gamma^{1/4}\,t)\}\{H'(1)^2-H'(0)^2\}-2K\,.\end{aligned} \tag{2.13}$$

Eq. (2.13) should be compared with Miles's result[6):

$$\begin{aligned}C_d\,t^{-2}=&\left(\frac{H'(1)^2}{4}\right)\left[\log\left\{\frac{1.786\left[\int_0^1 H\,dx\right]^3}{H'(1)}\right\}+\frac{7}{2}\right]\\&+\{\log(1/\Gamma^{1/4}\,t)\}H'(1)^2-2K\,.\end{aligned} \tag{2.14}$$

Eq. (2.14) was deduced by matching the linearized theory with the asymptotic solution of Guderley and Yoshihara along the sonic line, and it is worthy to note that Eq. (2.14) cannot be probably applied to a body with a blunt nose.

Under certain circumstances we may use the pressure coefficients $C_{p_1}{}^*$ and $C_p{}^*$ with respect to the sonic point instead of C_{p_1} and C_p respectively, which are defined as

$$C_{p_1}{}^*=(p-p^*)/\tfrac{1}{2}\rho^*U_1{}^{*2}\,, \tag{2.15}$$

$$C_p{}^*=(p-p^*)/\tfrac{1}{2}\rho^*U^{*2}\,, \tag{2.16}$$

where the asterisk refers to the quantities at the sonic point.

Remembering Eqs. (2.4), (2.5), (2.7) and (2.8), we obtain the following relations within the accuracy of the approximation considered here:

$$C_{p_1}\Gamma_1^{1/3}\tau^{-2/3}=C_{p_1}{}^*\Gamma_1^{1/3}\tau^{-2/3}-2K_1\,, \tag{2.17}$$

$$C_p t^{-2} = C_p{}^* t^{-2}-2K\,. \tag{2.18}$$

Comparing Eqs. (2.17) and (2.18) with Eqs. (2.3) and (2.10) respectively, we obtain the following relations:

$$C_{p_1}{}^*\Gamma_1^{1/3}\tau^{-2/3}=F(\xi,\,K_1), \tag{2.19}$$

$$C_p{}^*t^{-2}=\tfrac{3}{4}F(x,\,K)H^{-1/3}(x)-\tfrac{3}{2}H''(x)\{1-H^{2/3}(x)\}$$
$$+2H''(x)\log\{2(27\Gamma)^{-1/4}t^{-1}\}. \tag{2.20}$$

In Reference [4], we introduced the reduced pressure coefficient $\tilde{C}_{p_1}{}^*$ and the transonic parameter ξ_0 in the two-dimensional case, which were respectively defined as

$$\tilde{C}_{p_1}{}^*=C_{p_1}{}^*(1+\gamma_1)^{1/3}\tau^{-2/3}\,, \tag{2.21}$$

$$\xi_0=(1-M_1^2)\tau^{-2/3}(1+\gamma_1)^{-2/3}\,. \tag{2.22}$$

Comparing Eqs. (2.21) and (2.22) with Eqs. (2.19) and (2.5) respectively, we obtain

$$\tilde{C}_{p_1}{}^*=2^{1/3}F(\xi,\,K_1)\,, \tag{2.23}$$

$$\xi_0 = 2^{1/3}K_1\,. \tag{2.24}$$

In the paper [4], the several examples of the transonic flow past a two-dimensional symmetric body of unit length placed in an unbounded fluid and in a choked wind tunnel were studied. Starting from the distribution of $\tilde{C}_{p_1}{}^*$, and utilizing Eqs. (2.10), (2.11), (2.23) and (2.24), we can obtain the pressure distribution over the surface of a corresponding body of revolution. We shall study the several examples in the following section.

§ 3. Examples

(A) *Paraboloid of Revolution*

As the meridian curve of a paraboloid revolution of unit length is represented by

$$y=tx^{1/2}\,, \qquad 0\leqq x\leqq 1\,, \tag{3.1}$$

the corresponding two-dimensional profile is a finite wedge. The pressure distributions on the surface of a finite wedge placed in an unbounded fluid for $\xi_0=0$, 0.5 and 1.0 are shown in Fig. 6 of the reference [4]. Starting from these distributions, we can calculate the pressure distributions on the surface of the paraboloid of revolution of unit length placed in an unbounded fluid. The second and the third terms in the right hand side of Eqs. (2.10) and (2.20) vanish, as the second derivative of $H(x)=x$ vanishes. Thus $C_p t^{-2}$ or $C_p{}^* t^{-2}$ can be represented as a function of x and the transonic parameter K. The surface distributions of $C_p t^{-2}$ and $C_p{}^* t^{-2}$ for $K=0$, 0.298 and 0.595 are shown in Figs. 1 and 2 respectively. It is found that the value of $C_p{}^* t^{-2}$ increases with increasing value of K, while the value of $C_p t^{-2}$ decreases.

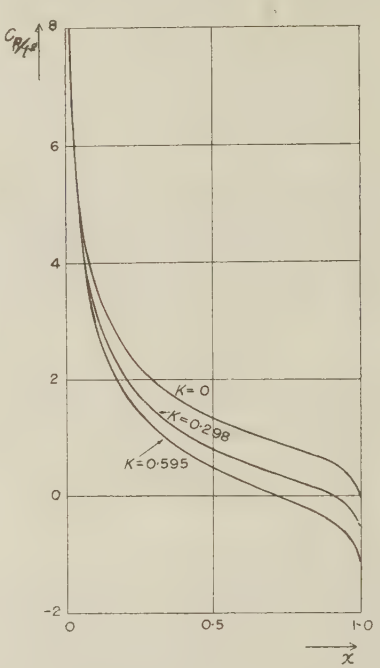

Fig. 1. The distributions of C_p/t^2 over the surface of a paraboloid of revolution in an unbounded fluid.

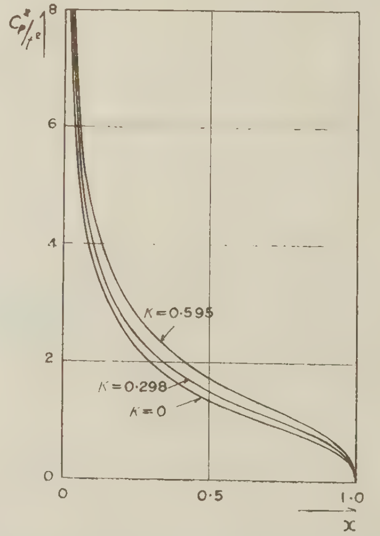

Fig. 2. The distributions of $C_p{}^*/t^2$ over the surface of a paraboloid of revolution in an unbounded fluid.

If we desire to study the flow past the

paraboloid of revolution placed along the axis of a choked circular wind tunnel, we must start from the flow past the wedge placed along the centre line between the two parallel plane walls under the choking state. By the use of the pressure distributions for the two-dimensional case (cf. Fig. 8 of Reference [4]), the distributions of $C_p t^{-2}$ and $C_p^* t^{-2}$ on the surface of the paraboloid of revolution in the choked wind tunnel are obtained, and they are shown in Figs. 3 and 4 respectively.

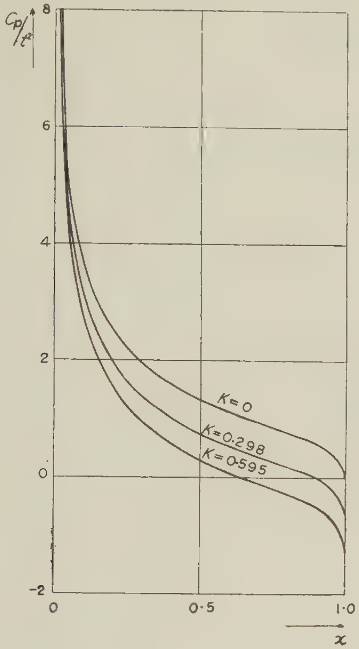

Fig. 3. The distributions of C_p/t^2 over the surface of a paraboloid of revolution of unit length in a choked wind tunnel.

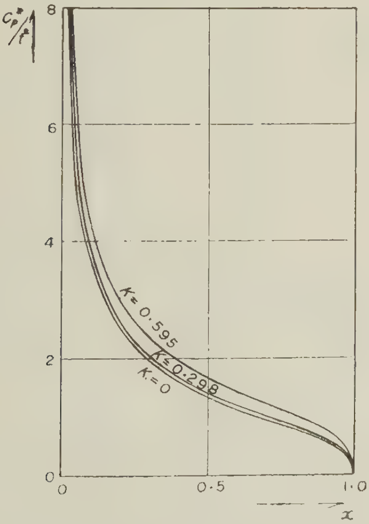

Fig. 4. The distributions of C_p^*/t^2 over the surface of a paraboloid of revolution of unit length in a choked wind tunnel.

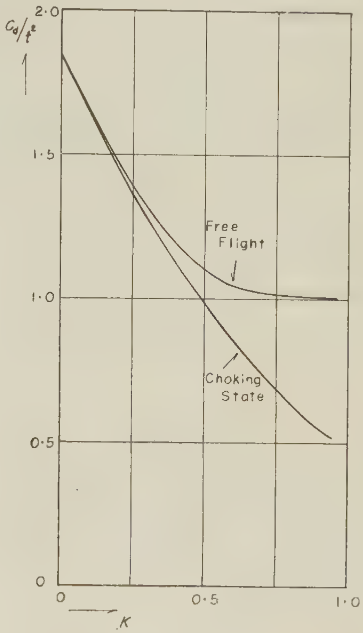

Fig. 5. The variation with the transonic parameter K of the head drag coefficient of a paraboloid of revolution.

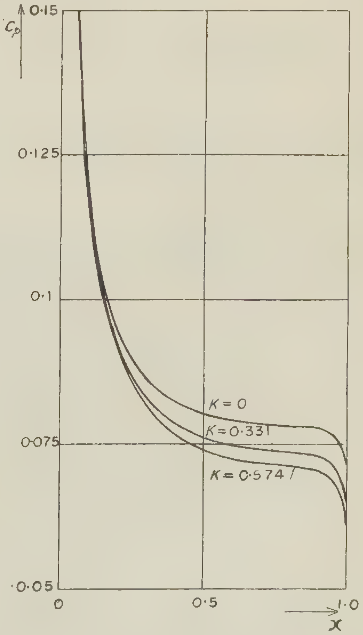

Fig. 6. The distributions of C_p over the surface of a cone of the half vertex angle 5° in an unbounded fluid.

The drag coefficient C_d is evaluated by integrating the curve in Figs. 1 and 3 graphically, and is shown in Fig. 5. In this case we cannot utilize Miles's equation (2.14) because the nose of the paraboloid is blunt.

In a previous paper [3], it has been shown that as for the choking Mach number the model flow method cannot give a good approximation, though we can obtain the pressure distribution with good accuracy by the method. Marschner[7] gave the choking Mach number of the wedge in the wind tunnel by the perturbation method applied to the Guderley's solution[8]. For the small value of the transonic parameter ξ_0, his result can be transformed into the following form[4]:

$$L_1^{-1}(\gamma_1+1)^{-1/3}\tau^{-1/3}=1.235\times 0.586\times(2/3)^{4/3}\xi_0^{5/2}, \tag{3.2}$$

where $2L_1$ denotes the width of tunnel. Comparing Eq. (3.2) with Eq. (2.2), and remembering Eqs. (2.9), (2.11), (2.12) and (2.24), we find the choking relation for the flow past a paraboloid of revolution placed along the axis of a circular wind tunnel such that:

$$\begin{aligned}&(Lt\sqrt{\Gamma})^{-1}\\ &=\frac{3\sqrt{3}}{4}\Big\{1.235\times 0.586\times(2/3)^{4/3}\\ &\qquad\times 2^{5/6}\times(4/3)^{5/2}\Big\}^{3/2}K^{15/4}.\end{aligned} \tag{3.3}$$

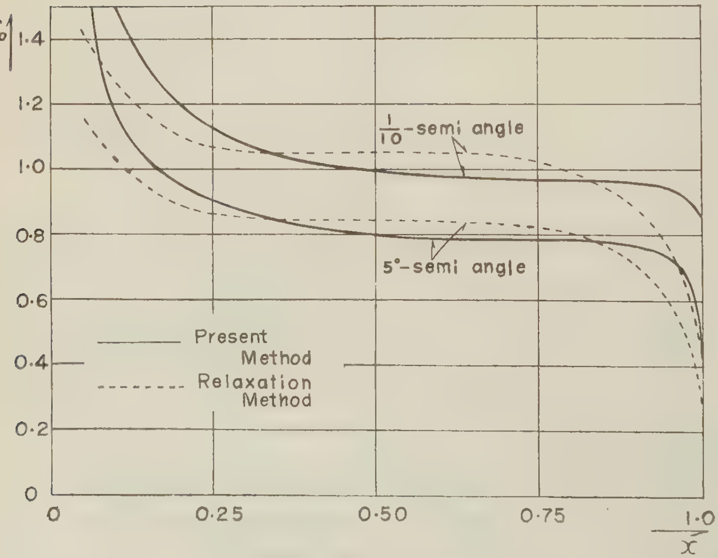

Fig. 7. The pressure distributions over the surface of a finite cone at sonic speed.

(B) *Cone*

The meridian curve of a cone of unit length is represented by

$$y=tx \qquad 0\leq x\leq 1\,. \tag{3.4}$$

The corresponding two-dimensional profile is represented by

$$\eta=\pm\tau\xi^2\,, \qquad 0\leq\xi\leq 1\,. \tag{3.5}$$

The pressure distributions on the surface of this two-dimensional profile placed in an unbounded fluid are shown in Fig. 10 of Reference [4].

Starting from these distributions we calculate the pressure distributions on the surface of a cone of the half vertex angle 5° (or $t=\tan 5°=0.08716$) for several values of K. The results are shown in Fig. 6.

Yoshihara[2] obtained the pressure distributions over the surface of a cone of the half vertex angle 5° and 1/10 radian at sonic speed by the relaxation method. Our results are compared with those of Yoshihara in Fig. 7.

The coincidence seems to be fairly good except the vicinities of the shoulder and the nose. As was shown in the paper [3], the correspondence between the pressure distributions over the surfaces of a two-dimensional and of an axisymmetric bodies was derived on the assumptions that the fluid velocity is almost sonic and that there exists the general transonic similarity law of the axisymmetric flow originally due to Oswatitsch and Berndt.[9] Then the departure of the present result from Yoshihara's exact solution may be anticipated because the fluid velocity vanishes at the nose and because the general similarity law does not completely consistent with the Prandtl-Meyer expansion at the shoulder. The variation of the head drag coefficient of the cone with the transonic parameter K is shown in Fig. 8.

When the cone is placed in the circular wind tunnel, and the flow is choked, we must start from the flow past the correponding two-dimensional profile placed along the centre line between the two parallel plane walls under the choking state. The surface distributions of $C_{p_1}{}^*$ for this two-dimensional flow are shown in Fig. 14 of the reference [4]. Starting from these distributions, we calculate the distributions of C_p on the surface of the cone in the choked circular wind tunnel, and they are shown in Fig. 9.

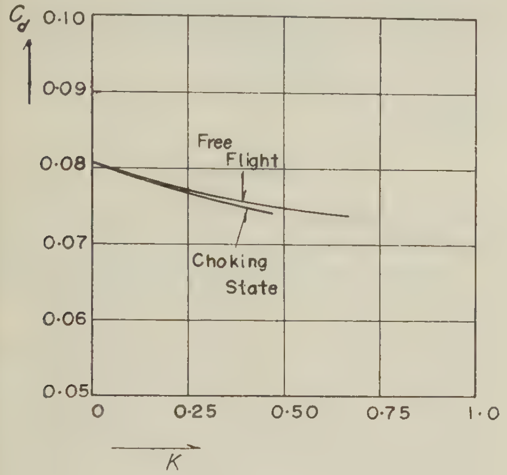

Fig. 8. The variation with the transonic parameter K of the head drag coefficient of a cone of the half vertex angle 5°.

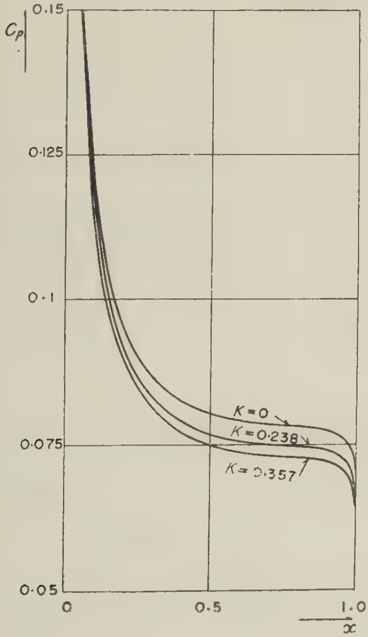

Fig. 9. The distributions of C_p over the surface of a cone of the half vertex angle 5° in a choked wind tunnel.

From Figs. 6 and 9, it is found that C_p decreases with increasing value of K. Evaluating $C_p{}^*$ defined by Eq. (2.16) for these values of K, the $C_p{}^*$-distribution slightly increases with ikcreasing value of K. But the differences are so small that these $C_p{}^*$-curves are almost the same curve as C_{p_0}-curve for $K=0$ in Figs. 6 and 9. The head drag coefficient of the cone placed in the choked wind tunnel is obtained by graphical integration, and is also shown in Fig. 8.

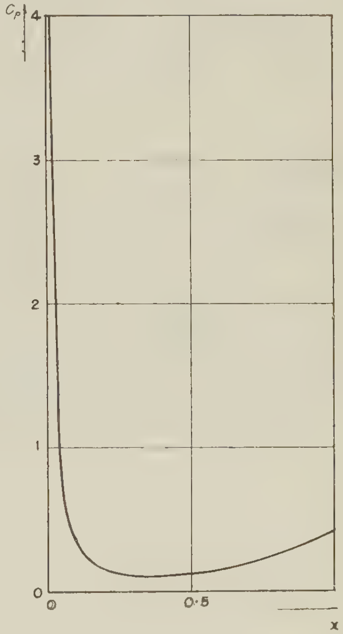

Fig. 10. The pressure distribution over the surface of a body of revolution $y=0.0872x^2$ at sonic speed.

(C) *Profile*: $y=tx^2$, *for* $0\leq x\leq 1$

The corresponding two-dimensional body is represented by

$$\eta=\pm\tau\xi^4\,,\qquad 0\leq\xi\leq1\,. \tag{3.6}$$

The pressure distribution on the surface of the two-dimensional body at sonic speed is shown in Fig. 15 of Reference [4]. Starting from this distribution, we calculate the pressure distribuiton on the surface of the body of revolution of the same thickness as the cone of the half vertex angle 5°. Since the velocity at the shoulder is sonic and the meridian curve has a cusp at the nose of the body, the pressure coefficient should vanish and take a finite value at the shoulder and the nose respectively. The result shown in Fig. 10

does not satisfy these conditions because the assumption in the present method does not hold at the shoulder and near the nose. (cf. (b) case of cone).

The head drag coefficient of the body is given in Table I together with those of other profiles at sonic speed.

Table I. The head drag coefficient of several bodies of revolution of half thickness ratio $t=0.08716$ at sonic speed for $\gamma=1.4$.

Profile	Present	Yoshihara	Miles
$y=t\sqrt{x}$ (paraboloid)	0.014	—	—
$y=tx$ (cone)	0.080	0.076	0.073
$y=tx^2$	0.281	—	0.226

§ 4. Conclusion

Combining the correspondent relations between the axisymmetric and the two-dimensional flows with the simple model flow method, we have obtained the pressure distributions on the surface of several bodies of revolution with sharp shoulder in an unbounded fluid and in a choked circular wind tunnel. In the case of wedge, we compared the present result with the exact solution derived by the relaxation method. Considering that the flow assumed in the present method is very simple, the result may be regarded as satisfactory.

In conclusion, the author would like to express his heartiest gratitude to Professor I. Imai for his kind suggestion and valuable discussions during the course of the present investigations.

Dynamic Programming and the Variational Solution of the Thomas-Fermi Equation

By Richard BELLMAN

The RAND Corporation Santa Monica, California

(Received April 24, 1957)

1. *Introduction.* In a recent paper, Ikebe and Kato, [8], considered the problem of the numerical integration of the nonlinear equation

$$u''-u^{3/2}x^{-1/2}=0\ ,\quad u(0)=1\ ,\quad u(\infty)=0 \qquad (1)$$

which arises in connection with the Thomas-Fermi statistical model of a free neutral atom. Equations of this type arose a number of years before in connection with astrophysical questions, Emden, [4], Fowler, [5], [6], [7], Bellman, [3], Sansone, [9].

In their paper, Ikebe and Kato treat the problem of determining $u'(0)$ by means of the associated variational problem: Minimize

$$J(u)=\int_0^\infty\left(u'^2+\frac{4}{5}u^{5/2}x^{-1/2}\right)dx \qquad (2)$$

over all functions u for which the integral exists and which satisfy the constraints $u(0)=1$, $u(\infty)=0$.

In this note we wish to indicate a new approach to problems of this type based upon the functional equation technique of the theory of dynamic programming, [1], [2]. Detailed computational results will be presented subsequently.

2. *Functional Equations.* Define the new functional

$$J(u)=\int_a^\infty(u'^2+u^m x^{-n})dx\ ,\quad u(a)=c\ ,\quad u(\infty)=0\ , \qquad (1)$$

where $a>0$, $-\infty<c<\infty$. Define the function $f(a, c)=\operatorname*{Min}_u J(u)$. Then as in [1] and [2], we have the nonlinear partial differential equation.

$$\frac{\partial f}{\partial a}=\frac{1}{4}\left(\frac{\partial f}{\partial c}\right)^2-c^m a^{-n}\ . \qquad (2)$$

As pointed out by a referee, this is the Hamilton-Jacobi equation associated with the variational problem.

Making the transformations, $x=ay$, $w(y)=u(ay)a^{-k}$, we see that

$$f(a, c)=a^{(2+m-2n)/(2-m)}f(1, c/a^{(2-n)/(2-m)})\ . \qquad (3)$$

Thus $f(a,c)=a^{(2+m-2n)/(2-m)}\phi(c/a^{(2-n)/(2-m)})$, where $\phi(x)=f(1, x)$.

Substituting in (2), we obtain the ordinary differential equation

$$\left(\frac{2+m-2n}{2-m}\right)\phi(x)-\left(\frac{2-n}{2-m}\right)x\phi'(x)=\frac{\phi'(x)^2}{4}-x^m \qquad (4)$$

Since $\phi(x)=f(1, x)$, we see that $\phi(0)=0$.

The original second order differential equation with a two-point boundary value problem has been replaced by the above first order equation. The numerical integration, however, requires some care since the equation is singular at $x=0$. We have

$$f(0, 1)=\lim_{x\to\infty}x^{2n-m-2/2-n}\phi(x)\ . \qquad (5)$$

The equation $u''-(m+1/2)e^{\lambda x}u^m=0$ gives rise to the problem of minimizing $J(u)=\int_a^\infty(u'^2+e^{\lambda x}u^m du)$, over all functions u satisfying the constraints $u(a)=c$, $u(\infty)=0$. It may be treated in a similar fashion.

Effect of Iron Group Ions on the Dielectric Properties of $BaTiO_3$ Ceramics

By Tunetaro SAKUDO

Electrotechnical Laboratory, Nagatacho, Tokyo

(Received June 5, 1957)

In the investigation of $BaTiO_3$ single crystal grown by the method of Remeika, it was observed that the Curie point of the crystals was lowered very remarkably when a small amount of Fe_2O_3 was introduced[1].

To examine the effect in the case of other iron group ions, ceramic samples containing several atomic percent of the ions were prepared. The change in the Curie point with the content of the ions is shown in Fig. 1, determined by the measurement of ε-T curve (permittivity vs. temperature) at 70 Kc.

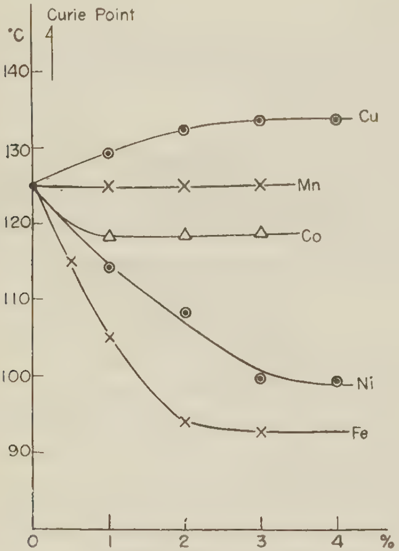

Fig. 1.

In the cases of Fe and Ni ions, the Curie point drops linearly up to 2～3 atomic percent content, whereas it remains almost constant while the content is further increased. For Mn and Co ions, only small change in the Curie point is observed, almost independent of the added amount.

These tendencies can be explained as the results of different solubility-limit of the ions in the $BaTiO_3$ lattice. These solubility-limit seem to be unaffected by sintering conditions, i.e. firing temperature, sintering atmosphere and cooling rate. In the case of Cu ion, however, the Curie point rises unexpectedly with the content of the ions. Fig. 2. shows the change in the Curie point with added Cu ion up to 30 atomic percent, with indicated composition of starting materials. Fig. 3 shows the examples of ε-T curves in these cases. As can be seen from the figure, the peak value of ε decreases with increasing amount of added ions. The dielectric measurement becomes very hard for Cu amount of more than 40 percent, as the d.c. conductivity of the samples increases with the added amount.

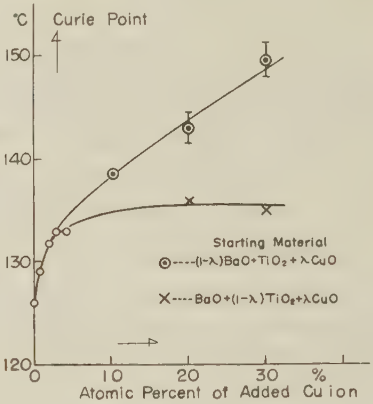

Fig. 2.

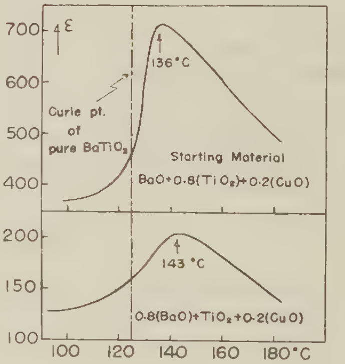

Fig. 3.

In the X-ray diffraction pattern of the samples containing Cu ion of the concentration of 10～50 percent, there were observed other lines than those corresponding to perovskite structure. Extra lines resemble the diffraction pattern of the samples made by sintering BaO and CuO, but not yet identified. The latter samples show ordinary paraelectric properties.

This effect might be attributed to some apparent phenomena arising from d.c. donductivity and dielectric loss.

But the change in the Curie point was ascertained to be frequency independent by measurement of the ε-T curves of the above samples again at 6 Mc.

Studies are going on to find the mechanism of the effect.

This work was supported by the Scientific Research Expenditure of the Ministry of Education.

Paramagnetic Susceptibility of $CoCl_2 \cdot 6H_2O$ between 290°K–1.52°K

By Taiichiro HASEDA and Eizo KANDA
The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai, Japan

(Received June 14, 1957)

We have measured the paramagnetic molar susceptibility, χ_m, of $CoCl_2 \cdot 6H_2O$ in the temperature range between 290°K and 1.52°K by the usual a.c. bridge method. The results are shown in Figs. 1 and 2. The broad hump located at about 3.0°K in Fig. 2 may be considered as due to antiferromagnetic transition. However, this transition temperature is higher than that expected from the usual picture that each Co^{+2} ion is surrounded by six water molecules octahedrally.

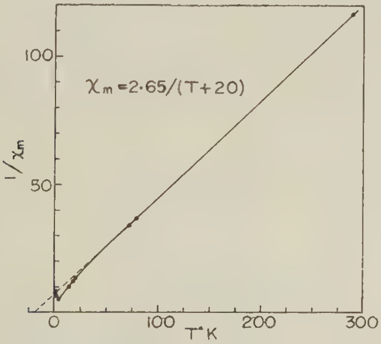

Fig. 1. Inverse molar susceptibility, $1/\chi_m$ of $CoCl_2 \cdot 6H_2O$ in the temperature range below the room temperature.

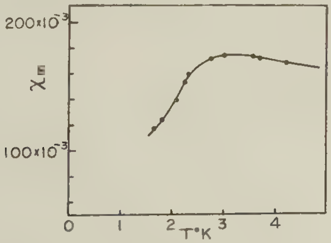

Fig. 2. Molar susceptibility, χ_m, of $CoCl_2 \cdot 6H_2O$ near the liquid helium temperature.

Some of the hydrated halides of iron group metals which have two or four water molecules were studied down to the liquid helium temperature[1]. Among these, for instance, $CuCl_2 \cdot 2H_2O$ shows antiferromagnetic transition at 4.31°K. It is well known that, in $CuCl_2 \cdot 2H_2O$, each Cu^{+2} ion is surrounded by two water molecules and two chlorine atoms. Along the a axis, two Cu^{+2} ions are adjacent to each other, locating one chlorine atom between them. In general, in most of the hydrated halides so far investigated, magnetic ions are separated from each other at least along one direction by only *one* diamagnetic atom.

In halides which have more than six hydrated water molecules, metallic ions are surrounded, in general, by six water molecules octahedrally, as in alums or Tutton salts. In these cases, magnetic ions are separated by at least *two* of the diamagnetic atoms or molecules. Then it may be expected that the magnetic transition temperatures of these salts are lower than those of the former salts. In alums or Tutton salts, the octahedron formed by the surrounding six water molecules are separated further by sulphate ions or monovalent anions. It may be considered, in these cases, that exchange or superexchange interaction between magnetic ions passes over *several* atoms or molecules, so that any magnetic transition, say, antiferromagnetic one occurs below 1°K as is actually the case.

On the other hand, in anhydrous halides and sulphates, distance between magnetic ions is considerably short. For instance, in $CoCl_2$ which has the layer structure, ($CdCl_2$ structure) magnetic ions interact each other directly in a layer and through two chlorine atoms between layers. In such halides and sulphates the antiferromagnetic transition or some anomalous behaviour has been observed at rather high temperatures such as the liquid hydrogen and liquid nitrogen temperatures.

Thus, it may be inferred, from the above stated consideration that in $CoCl_2 \cdot 6H_2O$ one or two chlorine atoms will take positions of octahedral coordination in the place of water molecules and these octahedrons are adjacent to each other without inserting any atom or molecule.

The determination of crystal structure of $CoCl_2 \cdot 6H_2O$ by J. Mizuno, K. Ukei and T. Sugawara in our Institute[2] is now in progress. The most probable structure inferred at present from their results is such that each Co^{+2} ion is surrounded by four water molecules forming a square and by two chlorine atoms on an axis normal to the square. This picture is quite consistent with the magnetic behaviour observed.

H. J. Gerritzen failed to detect paramagnetic resonance in this salt at liquid hydrogen temperatures[3] Antiferromagnetic resonance measurement made, using 9800 Mc, by M. Date in our Institute has also yielded negative result[4].

The sample used was that from Kanto Chem. Co. Japan and analysed to be exactly $CoCl_2 \cdot 6H_2O$.

Convex Molecules in Non-Uniform Gases,— Supplement

By Taro KIHARA and Akiji ŌUCHI

Department of Physics, Faculty of Science, University of Tokyo

(Received July 3, 1957)

In "Geometrical Theory of Convex Molecules in Non-Uniform Gases" by T. Kihara (J. Phys. Soc. Japan **12** (1957) 564) a geometrical theorem on convex bodies was applied to transport phenomena in gases, molecules being represented by rigid convex bodies without attraction. Collisions between heavy convex molecules and light spherical molecules were treated; shape and size of molecules of nitrogen, carbon dioxide, carbon tetrachloride, sulfur hexafluoride, and benzene were determined from the coefficients of diffusion in hydrogen. This note is a supplement, in which results for several other molecules are added. Tables Ia through IVa and Fig. 2a are continuations of the corresponding tables and Fig. 2.

Table Ia. Interatomic distance.

Molecule		Bond	Distance in A
Carbon disulfide	CS_2	C–F	1.54

Table IIa. The cores of molecules.

Mole-cules	Cores	V_0 (A^3)	S_0 (A^2)	M_0 (A)
CS_2	thin rod joining 2S's	0	0	9.68
CH_4	tetrahedron joining 4H's	0.67	5.52	10.23
C_2H_4	rectangle joining mid-points of C–H	0	3.48	8.95
$C_{10}H_8$	octagon joining mid-points of C–H	0	44.74	25.75
$C_{14}H_{10}$	octagon joining mid-points of C–H	0	70.13	33.32

Table IIIa. Coefficients of diffusion D at 0°C, 1 atm. and the effective cross sections Q in Eq. (13).

Gases	D (cm^2/sec)	Q (A^2)	$S_A+S_B+\frac{1}{2\pi}M_AM_B$ (A^2)
H_2-CS_2	0.369	204	
H_2-CH_4	0.625	126	
H_2-C_2H_4	0.486	158	
CO_2-CS_2	0.063	316	292
CS_2-Air	0.0892	258	253
CO_2-CH_4	0.153	201	196
$C_{10}H_8$-Air	0.0513	502	
$C_{14}H_{10}$-Air	0.0421	423	

The values of D are also taken from *International Critical Tables* vol. V (McGraw-Hill, New York, 1929).

Table IVa, Constants of rigid convex-body model of molecules determined from coefficients of diffusion at 0°C.

Molecules	a (A)	S (A^2)	A (A)
CS_2	2.06	92.9	35.5
CH_4	1.11	43.8	24.2
C_2H_4	1.59	63.8	28.9
$C_{10}H_8$	2.08	206	51.8
$C_{14}H_{10}$	2.06	260	59.1

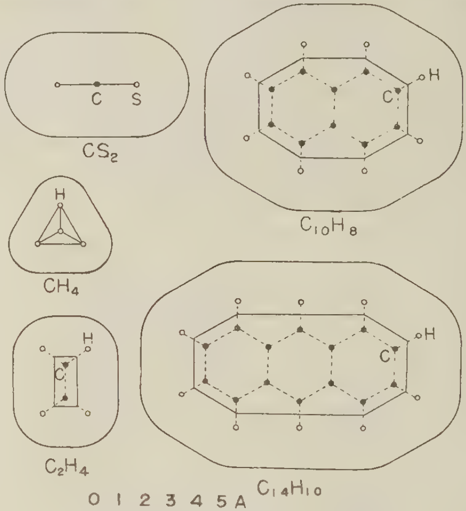

Fig. 2a. Shape and size of molecules according to the rigid convex-body model determined from diffusion coefficients at 0°C.

Carbon disulfide CS_2 can be treated just as carbon dioxide. Diffusion of naphthalene $C_{10}H_8$ and anthracene $C_{14}H_{10}$ in air can be approximately treated as a collision phenomenon between a light spherical molecule and a heavy convex molecule with a large moment of inertia. As regards the radius of the sphere representing an "air molecule" we have $b=1.73$ A, which is effective for diffusion at 0°C. Diffusion of methane CH_4 and ethylene C_2H_4 in hydrogen can be treated within the accuracy of the "geometrical approximation" mentioned in the main article.

Erratum: in Eq. (4) change $\boldsymbol{r}\cdot(\cdots)$ to $\boldsymbol{u}\cdot(\cdots)$.

Proposal for a Solid State Radio-Frequency Maser

By Junkichi Itoh
Department of Physics, Osaka University

(Received July 4, 1957)

Bloembergen[1] has proposed a solid state maser in microwave frequency range by the use of double resonance among fine structure levels of paramagnetic ion in crystal, and this method has been applied by Scovil, Feher, and Seidel[2] to a gadolinium salt with great success.

By a similar double resonance method, it seems possible to construct a radio-frequency solid state maser, using Zeeman levels of pure quadrupole spectrum.

Consider nuclei with spin 3/2 in a single crystal and assume that there exists large axially symmetric nuclear quadrupole interaction for these nuclei. When this single crystal is inserted in a magnetic field, H_0, two pure quadrupole levels, $\pm 3/2$ and $\pm 1/2$, split into four levels as shown in Fig. 1[3].

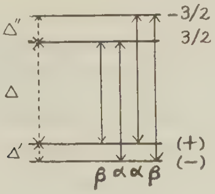

Fig. 1.

Two levels split from $\pm 1/2$ level are mixed states which will be denoted as (+) and (−) levels, respectively. By the assumption of large e^2qQ, energy differences $\varDelta'$ and $\varDelta''$ indicated in the figure are very much smaller than $\varDelta$. By some thermal motions in the crystal, spin-lattice relaxation processes take place, and assuming that main contribution comes from electric quadrupole interaction, the probabilities of thermal transitions between these levels are denoted as α and β, respectively, as shown in the figure.

When a sufficiently strong r.f. field is applied on the crystal, with the frequency equal to $(\varDelta+\varDelta'')/h$, the states $-3/2$ and (+) will saturate and the population difference between these two levels will disappear. At the same time, the population difference between (+) and (−) levels. $N_- - N_+$, becomes

$$N_- - N_+ \fallingdotseq (n/4)(\varDelta/kT)(\alpha+\beta)/(2\alpha+\beta) \tag*{(1)*}$$

where n is total number of nuclei in the crystal, and T is the temperature of the crystal. Therefore, $N_- - N_+$ which is proportional to $\varDelta'/kT$ when there is no r.f. field becomes to be proportional to $\varDelta/kT$ when the transition between $-3/2$ and (+) levels saturates. Since $\varDelta \gg \varDelta'$, the population difference increases enormously by this procedure.

When a sufficiently strong r.f. field with the frequency $(\varDelta+\varDelta')/h$ is applied on the crystal, the population difference, $N_- - N_+$ becomes negative, with the absolute magnitude equal to that given by (1)**. In this case, emission spectrum by the transition between (+) and (−) levels will be expected. When another weak r.f. field with the frequency $\varDelta'/h$, which lies generally in r.f. frequency range for the value of the static field of few thousand oersteds, is applied with the amplitude $2H_2$, the power of induced emission by this radiation field, P, can be calculated easily to be

$$P=(1/2)(\varDelta/kT)\varDelta' n\gamma^2 H_2{}^2 T_2(\alpha+\beta)/(2\alpha+\beta) \tag{2}$$

where T_2 is the spin-spin relaxation time and γ is the gyromagnetic ratio, and this r.f. field is assumed to have a direction to give maximum transition probability. In the case where $\gamma=10^4\,\mathrm{sec}^{-1}\,\mathrm{gauss}^{-1}$, $T_2=10^{-4}\,\mathrm{sec}$, $H_2=3\times10^{-2}$ oersted, $H_0=10^4$ oersted, $n=0.1$ mole, and $\alpha \ll \beta$***, P becomes to be about $3(\varDelta/kT)\cdot 10^{-3}$ watt, or, if $\varDelta/kT \sim 10^{-2}$, the power obtainable will be about 30 microwatts.

When $Q(\text{loaded})^{-1} > P/\omega \times (\text{storage energy}) > Q(\text{unloaded})^{-1}$, cw amplification will be possible, and when $P/\omega \times (\text{storage energy}) > Q(\text{loaded})^{-1}$, self-sustained oscillation will be realized. With the same values of γ, T_2 and H_0 given above, and assuming $Q(\text{loaded})=100$ and the volume occupied by a nucleus $=6\times10^{-23}$ cc, the condition for self-sustained oscillation is $(e^2qQ/kT) > 0.01$, or, if we take $T=1$°K, e^2qQ/h should be larger than 460 Mc/sec.

Thus, in favorable cases, it will be possible to construct an r.f. maser by this principle, though it might be less important in actual applications as compared with microwave maser.

---

* When a strong r.f. field with the frequency $\varDelta/h$ is applied, a similar expression for $N_- - N_+$ is obtained in which α and β are mutually interchanged.

** When a strong r.f. field with the frequency $(\varDelta+\varDelta'+\varDelta'')/h$ is applied, $N_+ - N_-$ becomes equal to $N_- - N_+$ of the case with the frequency $\varDelta/h$.

*** This condition is not always necessary. For arbitrary values of α and β, the power obtainable differes only within a factor of two.

Free Bonds on the Clean Surfaces of Germanium Single Crystals

By Akio KOBAYASHI and Shinji KAWAJI
The Research Institute for Catalysis, Hokkaido University, Sapporo, Japan

(Received June 22, 1957)

There is good evidence that two types of surface states, fast and slow states, exist on germanium surfaces[1)2)]. According to the latest investigations of several workers, the density of fast states is about 10^{11}/cm^2 ev. If the fast states are Tamm levels, their density should be about 10^{15}/cm^2. Field effect experiments on germanium surface cleaned by ion bombardment were carried out by Handler and others[3)] lately. But they could not observe the minimum of conductance by field effect, therefore, their estimation might include some ambiguity in the density of fast states. We have observed field effect patterns of clean germanium surface and their change with introduction of oxygen. In all cases we could observe the minimum of conductance so that we have obtained the density of the fast states.

The sample used was an etched slice of 40 ohmcm p-type germanium single crystal, $0.5 \times 2.5 \times 15$ mm^3, which was mounted on the sample holder shown in Fig. 1. Field effect was measured using a 50 cps voltages from peak to peak 4×10^5 volts/cm applied to a field probe. The circuit used was similar to Montgomery and Brown's. After the sample stood in hydrogen gas at pressure about 5 cmHg at 500°C for 24 hours in order to reduce the germanium surface, the system was evacuated to 10^{-8} mmHg. The sample was then heated upto about 800°C for ten minutes by passing an ac current through itself and, then allowed to cool to room temperature at the free radiation rate. After measurements for this clean surface were carried out, oxygen gas was introduced into the vacuum system. The measured field-effect patterns for clean and oxidized surfaces are shown in Fig. 2.

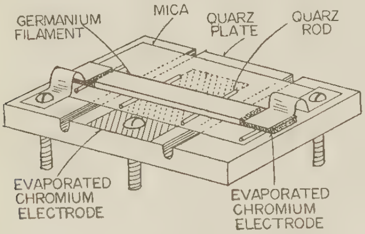

Fig. 1. The sample holder.

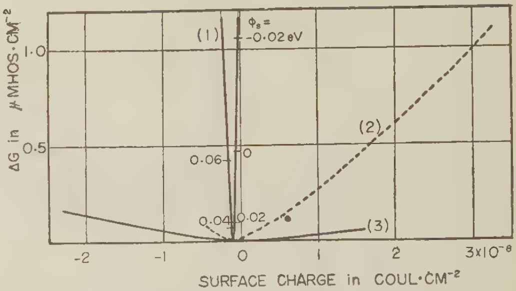

Fig. 2. Curve (1): theoretical conductance changes. ϕ_s is the position of the Fermi level at the surface measured with respect to the Fermi level in intrinsic material. Curve (2): conductance changes for clean surface and, Curve (3): that for oxidized surface.

In this figure the minimum points of experimental patterns are shifted at the same point of theoretical one.

From this figure the density of fast states is estimated at 1.7×10^{13}/cm^2 ev for clean surface and at 2.4×10^{12}/cm^2 ev for oxidized surface. The surface potential, defined as the difference of the electrostatic potential at the surface from its bulk value, decreased by 0.03 volts with the introduction of oxygen. The decrease in the density of fast states with introduction of oxygen shows that the fast states are dangling bonds at the surface of the germanium proper. But the observed density of fast states is still much lower than expected as Tamm states. This discrepancy may be attributed to the contamination of the surface by residual gases during experiments.

Angular Distributions of the Si^{28} (d, p) Si^{29} Reaction

Shigeo TAKEMOTO, Tsunekichi DAZAI and Shinji SUGANOMATA

Department of Physics, Faculty of Science,
Tohoku University, Sendai, Japan

(Received July 3, 1957)

The angular distributions of five proton groups from the Si^{28} (d, p) Si^{29} reaction have been measured in energy range 0.77- to 1.30-Mev. In our energy region complicated compound nucleus effect was observed.

§ 1. Introduction

Holt and Marsham[1)] investigated the Si^{28} (d, p) Si^{29} reaction at 8-Mev deuteron energy. Their results showed pronounced stripping effect in the angular distribution of various proton groups. Recently, the experiments of Cox and Williamson[2)] have shown many resonance structures in the Si^{28} (d, p) Si^{29} excitation curve at 50° to the beam direction, but no such structures at 0°. We have studied whether stripping effect is present or not in our low energy region (0.77- to 1.30-Mev).

§ 2. Experimental Procedure

In order to measure the angular distribution, a multiple plate camera was used. Nuclear emulsion plates used to detect protons were the Sakura 100 μ nuclear plates.* Their properties are believed not to differ appreciably from those of the Ilford C2 emulsions. Aluminium foils, inserted in front of them, were 70 to 100 microns thick. Apparatus and procedure were described in detail in the previous report[3)].

The homogeneous deuteron beam from the Tohoku Van de Graaff generator was used to bombard a thin silicon target. The deuteron energy spread was about 1% and the calibration of the energy scale was made at the known $Li^7(p, \gamma)Be^8$ 441-kev resonance using a diatomic beam.

A thin silicon target, few tenths of a micron thick, was prepared by vacuum evaporation of natural metallic silicon onto a silver backing, about 1 mg/cm² thick. As the target thickness and the beam current were not measured precisely, the absolute cross sections could not be obtained.

§ 3. Results and Discussions

A typical range spectrum of Si^{28} (d, p) Si^{29} protons is shown in Fig. 1. A number of proton groups is clearly resolved, and assignment to known levels in Si^{29} was carried out with the aid of the range-energy relation of the Sakura nuclear emulsion and known reaction Q-values.[4)] Groups P_0, P_1, P_2, P_3 and P_4 correspond to the ground state, 1st. (1.28-Mev), 2nd. (2.03-Mev), 3rd. (2.43-Mev). and 4th. (3.07-Mev) excited state in Si^{29}, respectively. C group is protons from C^{12} (d, p) C^{13}

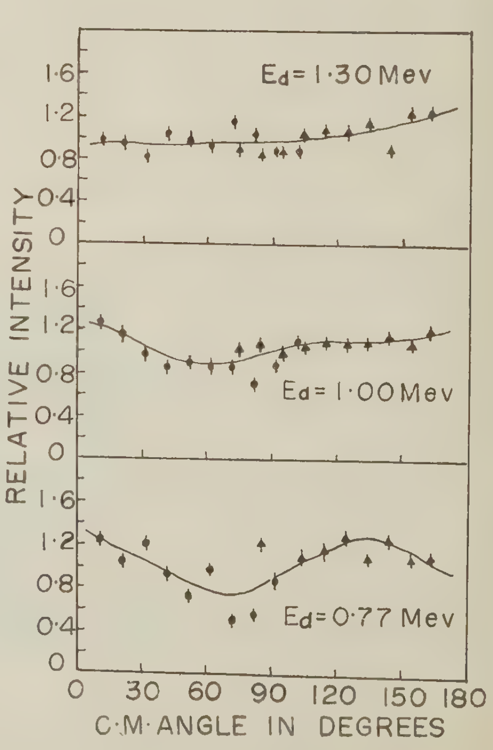

Fig. 5. Angular distributions of the P_3 group.

(Q=2.72 Mev) for carbon contamination deposited during the target preparation process and the running time. Although groups X_1 and X_2 is not undoubtedly assigned to any excited state in Si^{29}, one of them may be due to C^{13} (d, p) C^{14} (Q=5.94 Mev) and the other due to other contamination. Relative intensities of five assigned groups at $\theta_{lab}=90°$ are given in Table I, together with those reported by Van Patter and Buechner[5)].

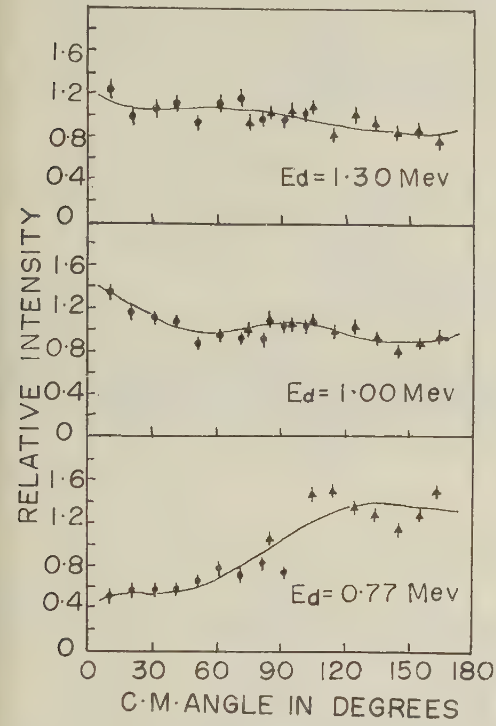

Fig. 6. Angular distributions of the P_4 group.

The angular distributions for each group are shown in Figs. 2, 3, 4, 5 and 6, for deuteron energies at 0.77-, 1.00- and 1.30-Mev. Distributions of all groups vary appreciably with deuteron energy, and the strong stripping effect in forward direction, which was revealed in the work of Holt and Marsham[1)] at $E_d=8$ Mev, is not observed in the present investigation at low bombarding energies. However, the distribution for P_3 is isotropic even at 8-Mev, and present results for that group is also nearly isotropic (Fig. 5). Cox and Williamson[2)] stated that, in energy region 1.3- to 3.0-Mev, although interference effects between stripping and compound nucleus formation process is present in the Si^{28} (d, p) Si^{29} excitation curve for P_0 group at $\theta_p=50°$, such effects in not seen at all at 0°. In our work excitation curves were not measured, but strong resonance effect is surely present not only for P_0, as seen from rapid variations of distribution patterns with deuteron energy.

All angular distributions were expanded

Cluster Variation Method of Cooperative Phenomena and its Generalization II. Quantum Statistics

By Tohru MORITA

Physics Department, Tokyo Institute of Technology

(Received June 12, 1957)

The formulation of the cluster variation method of approximation for cooperative phenomena is generalized to the cases where the quantum statistics is to be taken into account. In this generalization, the nature of approximation becomes more obscure, but the quantum counterparts of the various approximations introduced in classical statistics are easily found.

The method in its lowest approximation—the point approximation—is applied to the lattice model of liquid helium proposed by Matsubara and Matsuda and found to lead to the same results as they obtained under the consideration of the analogy to an anisotropic spin system.

The formulation proposed by the present author in I[1] is translated word for word to the quantum statistical case. The equations in this paper are numbered with the same numbers as the corresponding classical equations in I[*].

The system to be considered in this pape is one which is characterized by the followin three conditions: 1) The configuration of th system is described by the configurations o L fixed points in it. 2) The possible configurations x_i for i-th point (i=1, 2,..., L) ar denoted by $\alpha_i, \beta_i, \ldots, \nu_i$. 3) The Hamiltonia of the system $\boldsymbol{H}$ is given by

---

[*] No quantum counterparts of classical equations (8) and (9′) in I, were found; so equations with these numbers will not appear in this paper.

$$\boldsymbol{H}=\sum_{i=1} H_i^{(1)}+\frac{1}{2}\sum_{\substack{i=1\\(i\neq j)}}^{L}\sum_{j=1}^{L} H_{ij}^{(2)}$$

$$+\frac{1}{3!}\sum_i\sum_j\sum_k H_{ijk}^{(3)}+\dots \tag{1}$$

which is explicitly expressed as

$$\boldsymbol{H}(x_1,\dots,x_L;\,x_1',\dots,x_L')=\sum_{i=1}^{L} H_i^{(1)}(x_i;\,x_i')$$

$$+\frac{1}{2}\sum_i\sum_j H_{ij}^{(2)}(x_i,\,x_j;\,x_i',\,x_j')$$

$$+\frac{1}{3!}\sum_i\sum_j\sum_k H_{ijk}^{(3)}(x_i,\,x_j,x_k;\,x_i',\,x_j',\,x_k')$$

$$+\dots \tag{1'}$$

in the representation where the configurations of the L points are diagonal*.

The problem in this paper is to calculate the free energy of the system abovementioned. The free energy is given by the minimum value of

$$F\equiv\mathrm{Tr}\,[\rho^{(L)}\cdot\boldsymbol{H}+kT\,\rho^{(L)}\cdot\ln\rho^{(L)}] \tag{2}$$

under the variation of the density matrix $\rho^{(L)}$ (elements of which are $\rho^{(L)}(x_1,\dots,x_L;\,x_1',\dots x_L')$), the variation being restricted by the normalization condition

$$\mathrm{Tr}\rho^{(L)}=\sum_{x_1=\alpha_1}^{\nu_1}\dots\sum_{x_L=\alpha_L}^{\nu_L}\rho^{(L)}(x_1,\dots,x_L;\,x_1,\dots,x_L)=1. \tag{3}$$

Likewise as in I, we introduce 2^L-1 clusters, a "cluster" meaning any set of points selected from the L fixed points. Then, we introduce two kinds of matrices and two kinds of functions connected with a cluster $(i_1,\dots,i_n)$: the reduced density matrix $\rho_{i_1,\dots,i_n}^{(n)}$ defined by

$$\rho_{i_1,\dots,i_n}^{(n)}(x_{i_1},\dots,x_{i_n};\,x_{i_1}',\dots,x_{i_n}')$$

$$=\sum_{x_1''=\alpha_1}^{\nu_1}\dots\sum_{x_L''=\alpha_L}^{\nu_L}\;\sum_{x_1'''=\alpha_1}^{\nu_1}\dots\sum_{x_L'''=\alpha_L}^{\nu_L}\;\prod_{s=1}^{n}\delta_{x_{i_s},\,x_{i_s}''}\;\delta_{x_{i_s}',\,x_{i_s}'''}\prod_{\substack{i=1\\(i\neq i_1,\dots,\,i_s)}}^{L}\delta_{x_i'',\,x_i'''}\;\rho^{(L)}(x_1'',\dots,x_L'';\,x_1''',\dots x_L'''), \tag{4}$$

the correlation matrix $g_{i_1,\dots,i_n}^{(n)}$ by

$$\rho_{ij}^{(2)}(x_i,\,x_j;\,x_i',\,x_j')=\rho_i^{(1)}(x_i;\,x_i')\rho_j^{(1)}(x_j;\,x_j')g_{ij}^{(2)}(x_i,\,x_j;\,x_i',\,x_j') \tag{5''}$$

$$\rho_{ijk}^{(3)}(x_i,\,x_j,\,x_k;\,x_i',\,x_j',\,x_k')=\rho_i^{(1)}(x_i;\,x_i')\,\rho_j^{(1)}(x_j;\,x_j')\,\rho_k^{(1)}(x_k;\,x_k')\,g_{ij}^{(2)}(x_i,\,x_j;\,x_i',\,x_j')$$

$$\times g_{jk}^{(2)}(x_j,\,x_k;\,x_j',\,x_k')\,g_{ik}^{(2)}(x_k,\,x_i;\,x_k',\,x_i')\,g_{ijk}^{(3)}(x_i,\,x_j,\,x_k;\,x_i',\,x_j',\,x_k') \tag{5'''}$$

. . . .

$$\rho_{1,\dots,L}^{(L)}(x_1,\dots,x_L;\,x_1',\dots x_L')=\prod_{i=1}^{L}\rho_i^{(1)}(x_i;\,x_i')\prod_{i>j}g_{ij}^{(2)}(x_i,\,x_j;\,x_i',\,x_j')$$

$$\times\prod g_{ijk}^{(3)}(x_i,\,x_j,\,x_k;\,x_i',\,x_j',\,x_k')\dots g_{1,\dots,L}^{(L)}(x_1,\dots,x_L;\,x_1',\dots,x_L'), \tag{5^L}$$

the function $G^{(n)}(i_1,\dots,i_n)$ defined by

$$\ln G^{(n)}(i_1,\dots,i_n)=-\mathrm{Tr}\,[\rho_{i_1,\dots,i_n}^{(n)}\ln\rho_{i_1,\dots,i_n}^{(n)}], \tag{6}$$

and the correlation function $F^{(n)}(i_1,\dots,i_n)$ by

$$G^{(2)}(i,\,j)=G^{(1)}(i)G^{(1)}(j)F^{(2)}(i,\,j) \tag{7''}$$

$$G^{(3)}(i,\,j,\,k)=G^{(1)}(i)G^{(1)}(j)G^{(1)}(k)F^{(2)}(i,\,j)F^{(2)}(j,\,k)F^{(2)}(k,\,i)F^{(3)}(i,\,j,\,k) \tag{7'''}$$

. . . .

$$G^{(L)}(1,\dots,L)=\prod_{i=1}^{L}G^{(1)}(i)\prod_{i>j}F^{(2)}(i,\,j)\prod F^{(3)}(i,\,j,\,k)\dots F^{(L)}(1,\dots,L). \tag{7^L}$$

By means of these functions, we rewrite Eq. (2) as

$$F=\sum_{i=1}^{L}\mathrm{Tr}\,[\rho_i^{(1)}\cdot H_i^{(1)}]+\frac{1}{2}\sum_{\substack{i=1\\(i\neq j)}}^{L}\sum_{j=1}^{L}\mathrm{Tr}\,[\rho_{ij}^{(2)}\cdot H_{ij}^{(2)}]+\frac{1}{3!}\sum_i\sum_j\sum_k\mathrm{Tr}\,[\rho_{ijk}^{(3)}\cdot H_{ijk}^{(3)}]+\dots$$

$$+kT\,[\sum_{i=1}^{L}\ln G^{(1)}(i)+\sum_{i>j}\ln F^{(2)}(i,\,j)+\sum\ln F^{(3)}(i,\,j,\,k)+\dots+\ln F^{(L)}(1,\dots,L)]. \tag{9}$$

The cluster variation method of approximation is as follows: We divide 2^L-1 clusters into two groups, “preserved clusters” and “not-preserved clusters”. We rewrite the right-hand side of Eq. (9) and express the first row in terms of the preserved $\rho^{(n)*}$ and the not-preserved $g^{(n)}$ with no preserved $g^{(n)}$ or not-preserved $\rho^{(n)}$ and the second row in terms of the preserved $G^{(n)}$ and the not-preserved $F^{(n)}$ with no preserved $F^{(n)}$ or not-preserved $G^{(n)}$. In the expression for F thus obtained, we equate $F^{(n)}$ and $g^{(n)}$ to 1, and substitute from (6) into preserved $G^{(n)}$. Then the function F is obtained in terms of the preserved $\rho^{(n)}$'s. Now we let this approximate expression for F take the minimum value with respect to the preserved $\rho^{(n)}$'s. In doing so we have to notice that there exist the recurrence relations

---

* In the following, this representation will be always used to express any matrix in explicit form.

$$\rho^{(s-1)}_{i_1,\ldots,i_{s-1}}(x_{i_1},\ldots,x_{i_{s-1}};x'_{i_1},\ldots,x'_{i_{s-1}})$$
$$=\sum_{x_{i_s}=\alpha_{i_s}}^{\nu_{i_s}}\cdots\sum_{x_{i_n}=\alpha_{i_n}}^{\nu_{i_n}}\rho^{(n)}_{i_1,\ldots,i_n}(x_{i_1},\ldots,x_{i_{s-1}},x_{i_s},\ldots,x_{i_n};x'_{i_1},\ldots,x'_{i_{s-1}},x_{i_s},\ldots,x_{i_n}) \qquad (10)$$

between two preserved $\rho^{(s-1)}$ and $\rho^{(n)}$ and the normalization conditions

$$\mathrm{Tr}\,\rho^{(n)}_{i_1,\ldots,i_n}=\sum_{x_{i_1}=\alpha_{i_1}}^{\nu_{i_1}}\cdots\sum_{x_{i_n}=\alpha_{i_n}}^{\nu_{i_n}}\rho^{(n)}_{i_1,\ldots,i_n}(x_{i_1},\ldots,x_{i_n};x_{i_1},\ldots,x_{i_n})=1 \qquad (11)$$

for the preserved $\rho^{(n)}$'s. The minimum value obtained can be considered to be an approximate value to the exact free energy.

Which clusters are to be preserved must be decided from physical considerations. The approximation will generally be improved as larger and more clusters are preserved. The lowest approximation of the method is “the point approximation”, where L clusters of one point are preserved. This corresponds to the Bragg-Williams approximation in classical statistics. To the Bethe-Fowler approximation corresponds “the point pair approximation”, where $L(L-1)/2$ clusters of pair of points are preserved. And so on.

Application to a Lattice Model of Liquid Helium

In the following, the method in the point approximation is applied to the lattice model of liquid helium proposed by Matsubara and Matsuda[2)].

The system they took up as the model for liquid helium is characterized by that: 1) The configuration of the system is described by the configurations of L fixed points, which constitute a simple cubic lattice with lattice constant d in the coordinate space of the system. 2) The possible configurations of any point are “a particle is present at the point—present” and “no particle is at the point—absent”. 3) The Hamiltonian of the system is

$$\boldsymbol{H}=\frac{\hbar^2}{2md^2}\sum_{\langle ij\rangle}(a_i^*-a_j^*)(a_i-a_j)$$
$$-v_0\sum_{\langle ij\rangle}a_i^*a_ia_j^*a_j \qquad (\mathrm{A1})^*$$

where the summations are taken over nearest neighbor lattice site pairs, and a_i^* and a_i are

$$a_i^*=\begin{array}{c|cc} & \text{p. at i} & \text{a. at i}\\ \hline \text{p. at i} & 0 & 1\\ \text{a. at i} & 0 & 0\end{array},$$
$$a_i=\begin{array}{c|cc} & \text{p. at i} & \text{a. at i}\\ \hline \text{p. at i} & 0 & 0\\ \text{a. at i} & 1 & 0\end{array} \qquad (\mathrm{A2})$$

in the representation where the configurations of the L points are diagonal; either of a_i^* and a_i and either of a_j^* and a_j being commutative when $i\neq j$.

We apply the point approximation to this system, then the function F is to be written in terms of $\rho_i^{(1)}$. In the fluid, the point reduced density matrices $\rho_i^{(1)}$'s are equal for all of the lattice points, i's, which we write as

$$\rho^{(1)}=\begin{array}{c|cc} & \mathrm{p} & \mathrm{a}\\ \hline \mathrm{p} & \rho & \xi\\ \mathrm{a} & \xi & 1-\rho\end{array}, \qquad (\mathrm{A3})$$

where $\rho=N/L$, N being the number of particles in the system, and ξ is the parameter which is determined by minimizing F. (This ξ is found to be identified to ξ introduced in the theory of Matsubara and Matsuda.) To find the entropy term in F, we need the eigenvalues of $\rho^{(1)}$ which are

---

* The terminology, preserved $\rho^{(n)}$, not-preserved $g^{(n)}$, etc., follows that introduced in I.

* $\hbar^2/m$ and v_0 are constants characteristic to the system under consideration.

$$\frac{1}{2}(1\pm\sqrt{(1-2\rho)^2+4\xi^2})\ . \tag{A4}$$

In the point approximation,

$$\begin{aligned}\frac{F}{LkT}=&\frac{6\hbar^2}{4md^2kT}(2\rho-2\xi^2)-\frac{\rho^2}{2kT}\cdot 6v_0\\&+\frac{1}{2}(1+\sqrt{(1-2\rho)^2+4\xi^2})\\&\times\ln\frac{1}{2}(1+\sqrt{(1-2\rho)^2+4\xi^2})\\&+\frac{1}{2}(1-\sqrt{(1-2\rho)^2+4\xi^2})\\&\times\ln\frac{1}{2}(1-\sqrt{(1-2\rho)^2+4\xi^2})\ .\end{aligned}\tag{A5}$$

The condition determining ξ is $0=\partial/\partial\xi^2\cdot F/LkT$ which reduces to

$$\begin{aligned}\frac{3\hbar^2}{md^2kT}=&\frac{1}{\sqrt{(1-2\rho)^2+4\xi^2}}\\&\times\Big[\ln\frac{1}{2}(1+\sqrt{(1-2\rho)^2+4\xi^2})\\&-\ln\frac{1}{2}(1-\sqrt{(1-2\rho)^2+4\xi^2})\Big]\end{aligned}\tag{A6}$$

which can be rewritten as

$$\begin{aligned}\tanh&\left[\frac{T_0}{T}\sqrt{(1-2\rho)^2+4\xi^2}\right]\\&=\sqrt{(1-2\rho)^2+4\xi^2}\end{aligned}\tag{A6$'$}$$

where $kT_0=3\hbar^2/2md^2$. The last is the equation (28) with (30) and (18) in Matsubara and Matsuda's paper. When T is large, this equation has no solution, where the minimum of F corresponds to $\xi^2=0$. The transition line, T_c—ρ_c, between these regions is given by

$$\tanh\left[\frac{T_0}{T_c}|1-2\rho_c|\right]=|1-2\rho_c|\ . \tag{A7}$$

The free energy of the system is given by Eq. (A 5), when ξ^2 is determined by Eq. (A 6) at lower temperature than T_c and equated to zero at higher temperature. The thermodynamical quantities will be obtained from this free energy.

The identity of the results of this calculation to those of Matsubara and Matsuda, is convinced by confirming from their results that their

$$f_L+\rho\mu=\left(f-\frac{1}{N\beta}\ln C\right)+\rho\mu \tag{A8}$$

is coincident to our free energy, F/L from Eq. (A 5) with (A 6) or $\xi^2=0$ (cf. Eq. (16) of ref. 2).

The author wishes to express his cordial thanks to Prof. A. Harasima and Dr. K. Hiroike for the former's continual guidance and the latter's suggestive discussions and also for their kind inspection of the manuscript.

The Input Power Limit of the Cylindrical Rotating Anode of a X-ray Tube

By Tsutomu ISHIMURA, Toshio SHIRAIWA and Masao SAWADA

Department of Physics, Faculty of Science, Osaka University

(Received March 18, 1957)

The permissible maximum input power of the cylindrical anode of a continuous operating X-ray tube was calculated. Calculation was done for the cyclic dynamical steady state which was realized after sufficiently long continuous operation. This thermal problem was treated by DuMond as a one-dimensional problem in which heat flow was normal to the surface of the target. In our case a focus of an electron beam was a line focus and the width was small compared with the thickness of the target and the problem was treated as a two-dimensional problem containing transversal thermal flow.

§ 1. Introduction

The temperature of a rotating anode or a mobile focal spot on stationary target of an X-ray tube was calculated by many authors, who treated mainly the problem in which the input power was applied for a very brief time. In the case of a continuously operated mobile focal spot, a rough estimation has been done by Oosterkamp[1] and a exact theoretical analysis by the dynamically steady cyclic thermal state has been made by DuMond.[2] He treated this thermal problem as a one-dimensional problem. His assumption was that the flow of heat was straight back normally from the target surface to the inner surface cooled by water without any lateral spreading of the heat. This is the approximation in the case of the larger dimensions of a focal spot compared with the thickness of the target. For a small focal spot compared with the thickness of the target, the deviation from his calculation increases. In the case of a rotating anode X-ray tube which planned in our laboratory, the thickness of the target was the order of 1 mm and the width of a focal line was the order of 1/10 mm, so that we had to consider the transversal flow of heat. This paper is the result of our calculation for a rotating cylindrical target, in which DuMond's treatment is extended into the two-dimensional problem.

§ 2. Statement of Thermal Problem

The target has a cylindrical form of the constant thickness, d, and it is rotated around the axis of the cylinder of which radius, k, is large compared with the thickness. The inner surface of the target is cooled by water and the temperature on the inner surface is assumed as constant T_0 (Fig. 1). A focus of an electron beam on the target is a line shape focus along the generatrix of the cylinder. The length of the focal line is sufficiently large compared with the width, b, and we can treat the thermal problem as a two-dimensional problem, in which we consider the longitudinal flow normal to the surface and the transversal flow normal to the generatrix.

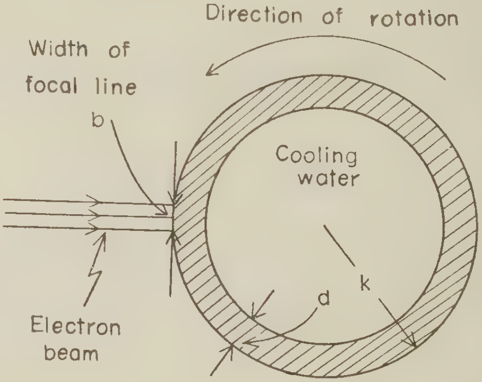

Fig. 1. Diagram of a target.

Instead of the rotating anode and the stationary electron beam, we suppose that the anode is fixed and the focal line moves on the surface of the anode. As the thickness of the target is sufficiently small compared with to the radius, we can assume that the surface of the target is a plane normal to the electron beam. We shall further assume that the input power per unit area, value, w, is uniform over the focal area, that is, the small area of the target surface will receive heat at the surface rate, w, for τ_1 seconds and will be left for τ_2 seconds. τ_1 and τ_2 is (Fig. 2)

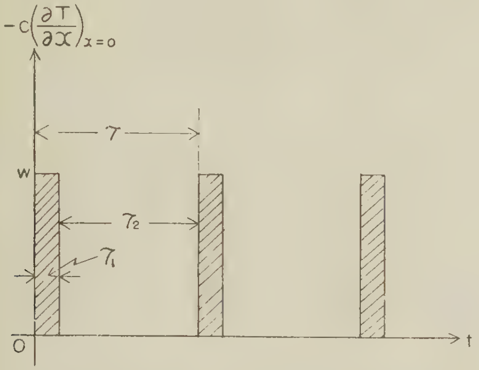

Fig. 2. Illustrating heat input on an element of the target surface as a function of time.

$$\tau_1=\frac{1}{n}\times\frac{b}{2\pi k},\quad \tau_2=\tau-\tau_1,\quad \tau=\frac{1}{n},$$

where n is the number of rotations of the target per second. In the present paper the same nomenclature used by DuMond are adopted for the convenience of reference. (Table I)

Table I. Nomenclature.

ρ	mass density of target material
c	heat conductivity of target material
σ	heat capacity of target material per unit mass
w	watts input per unit area in the focal area
d	thickness of target from face to cooling water
b	width of the focal line
k	radius of target
n	the number of rotations per second of target
τ	period of a rotation
τ_1	heating time in a rotation
r	τ_1/τ
v	velocity of a point on target surface

§ 3. Thermal Equation and Solution

Thermal equation: We take the x-axis along the normal of the surface of the target and y-axis along the normal of the generatrix on the surface of the target that indicated in Fig. 3.

The equation of the thermal flow is

$$\frac{\partial^2 T}{\partial x^2}+\frac{\partial^2 T}{\partial y^2}=\frac{\rho\sigma}{c}\frac{\partial T}{\partial t} \tag{1}$$

where ρ is the density, c is the heat conductivity and σ is the heat capacity per unit mass of the target material.

We shall confine the problem to the stationary state in which the temperature is a periodic function of τ. This dynamically steady cyclic thermal state will be established after a sufficiently long time in the continuous operation. An input beam moves along the y-axis with the constant speed, v, where $v=2\pi kn$ and we can put

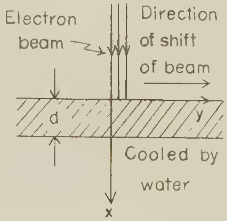

Fig. 3. A part of the target is represented by shaded area and instead of a rotating target and stationary electron beam we assume the focal area moves on the stationary target surface.

$$T(x,\,y,\,t)=T(x,\,o,\,t-y/v).$$

Let

$$t-\frac{y}{v}=u\,,$$

then equation (1) becomes

$$\frac{\partial^2 T}{\partial x^2}+\frac{1}{v^2}\frac{\partial^2 T}{\partial u^2}=\frac{\rho\sigma}{c}\frac{\partial T}{\partial u} \tag{2}$$

Boundary condition: For boundary conditions we obtain

$$T=T_0 \qquad \text{at} \qquad x=d \tag{3}$$

$$-c\left(\frac{\partial T}{\partial x}\right)_{x=0}=\begin{cases} w \text{ for interval } \tau_1 \\ 0 \text{ for interval } \tau_2 \end{cases} \text{at } x=0. \tag{4}$$

Solution of the equation: The particular solutions of eq. (2) are

$$T=T_c-gx$$
$$\left.\begin{aligned} T&=e^{-\alpha x}\sin(2\pi nu-\beta x)\\ T&=e^{-\alpha x}\cos(2\pi nu-\beta x)\end{aligned}\right\}$$
$$\text{or } T=e^{-(\alpha+i\beta)}\,xe^{i2\pi nu}$$

where

$$\alpha=a\alpha',\quad \beta=a\beta',\quad a=\pm(\pi n\rho\sigma/c)^{1/2},$$

$$\alpha'=\left\{\sqrt{1+\frac{4\pi^2c^2n^2}{v^4\rho^2\sigma^2}}+\frac{2\pi cn}{v^2\rho\sigma}\right\}^{1/2},$$

$$\beta'=\left\{\sqrt{1+\frac{4\pi^2c^2n^2}{v^4\rho^2\sigma^2}}-\frac{2\pi cn}{v^2\rho\sigma}\right\}^{1/2}.$$

The most general solution for the state of steady thermal oscillation is the sum of the particular solutions multiplied by constant coefficients, then

$$\begin{aligned} T = T_c - gx &+ \sum_{s=1}^{\infty} A_s \exp(-\alpha_s x)\sin(2\pi n_s u - \beta_s x) \\ &+ \sum_{s=1}^{\infty} B_s \exp(-\alpha_s x)\cos(2\pi n_s u - \beta_s x) \\ &+ \sum_{s=1}^{\infty} C_s \exp(\alpha_s x)\sin(2\pi n_s u + \beta_s x) \\ &+ \sum_{s=1}^{\infty} D_s \exp(\alpha_s x)\cos(2\pi n_s u + \beta_s x). \end{aligned} \tag{5}$$

In this solution s takes only integer values from 1 to infinity and expressed as $n_s = ns$ from periodicity.

Our problem consists in evaluating A_s, B_s, C_s, D_s and g so as to fit the expression (5) to the boundary conditions (3) and (4). From condition (4) we obtain

$$g = wr/c\ , \tag{6}$$

$$\alpha_s' A_s - \beta_s' B_s - \alpha_s' C_s + \beta_s' D_s = \frac{w}{\pi c s a_s}\{1 - \cos(2\pi s r)\}\ , \tag{7}$$

$$\beta_s' A_s + \alpha_s' B_s - \beta_s' C_s - \alpha_s' D_s = \frac{w}{\pi c s a_s}\sin(2\pi s r)\ , \tag{8}$$

and from condition (3)

$$T_c = T_0 + \frac{wr}{c}d\ , \tag{9}$$

$$\begin{aligned} A_s \exp.(-\alpha_s d)\cos\beta_s d &+ B_s \exp(-\alpha_s d)\sin\beta_s d \\ &+ C_s \exp(\alpha_s d)\cos\beta_s d \\ &- D_s \exp(\alpha_s d)\sin\beta_s d = 0\ , \end{aligned} \tag{10}$$

$$\begin{aligned} -A_s \exp(-\alpha_s d)\sin\beta_s d &+ B_s \exp(-\alpha_s d)\cos\beta_s d \\ &+ C_s \exp(\alpha_s d)\sin\beta_s d \\ &+ D_s \exp(\alpha_s d)\cos\beta_s d = 0\ . \end{aligned} \tag{11}$$

From eq. (7) and (8)

$$A_s - C_s = \frac{w}{2\pi c s a_s} \times \left\{ \frac{2\alpha_s'}{\alpha_s'^2 + \beta_s'^2}(1 - \cos 2\pi s r) + \frac{2\beta_s'}{\alpha_s'^2 + \beta_s'^2}\sin 2\pi s r \right\} \equiv P_s'\ , \tag{12}$$

$$D_s - B_s = \frac{w}{2\pi c s a_s} \times \left\{ \frac{2\beta_s'}{\alpha_s'^2 + \beta_s'^2}(1 - \cos 2\pi s r) - \frac{2\alpha_s'}{\alpha_s'^2 + \beta_s'^2}\sin 2\pi s r \right\} \equiv Q_s'\ , \tag{13}$$

and from eq. (10), (11), (12) and (13), we obtain

$$A_s + C_s = \frac{P_s' \sinh\alpha_s d \cosh\alpha_s d + Q_s' \sin\beta_s d \cos\beta_s d}{\cos^2\beta_s d + \sinh^2\alpha_s d}\ , \tag{14}$$

$$D_s + B_s = \frac{P_s' \sin\beta_s d \cos\beta_s d - Q_s' \sinh\alpha_s d \cosh\alpha_s d}{\cos^2\beta_s d + \sinh^2\alpha_s d}\ , \tag{15}$$

where

$$\begin{aligned} &\alpha_s = a_s\alpha_s', \quad \beta_s = a_s\beta_s', \quad a_s = (\pi\rho\sigma/c)^{1/2}(sn)^{1/2}, \\ &\alpha_s' = \left\{ \sqrt{1 + \frac{4\pi^2 c^2 n^2 s^2}{v^4\rho^2\sigma^2}} + \frac{2\pi c n s}{v^2\rho\sigma} \right\}^{1/2} \\ &\beta_s' = \left\{ \sqrt{1 + \frac{4\pi^2 c^2 n^2 s^2}{v^4\rho^2\sigma^2}} - \frac{2\pi c n s}{v^2\rho\sigma} \right\}^{1/2} \end{aligned} \tag{16}$$

The calculation of the temperature at every point and every time from above solution is very complicated, then we choose the point of the surface at $x=0$ and at the time of the end of a heating period, that is at $u = \tau_1$, of which temperature T_m is considered nearly the maximum temperature of the target. T_m is expressed as follows

$$\begin{aligned} T_m &= T_c + \sum_{s=1}^{\infty}(A_s + C_s)\sin 2\pi s r + \sum_{s=1}^{\infty}(D_s + B_s)\cos 2\pi s r \\ &= T_0 + \frac{wr}{c}d + \frac{w}{2\pi c}\sum_{s=1}^{\infty}\frac{1}{s a_s}\,\frac{p_s' \sinh\alpha_s d \cosh\alpha_s d - q_s' \sin\beta_s d \cos\beta_s d}{\cos^2\beta_s d + \sinh^2\alpha_s d}\ , \end{aligned} \tag{17}$$

where

$$\begin{aligned} p_s' &= \left[\frac{2\alpha_s'}{\alpha_s'^2 + \beta_s'^2}(1 - \cos 2\pi s r) + \frac{2\beta_s'}{\alpha_s'^2 + \beta_s'^2}\sin 2\pi s r \right]\sin 2\pi s r \\ &\quad - \left[\frac{2\beta_s'}{\alpha_s'^2 + \beta_s'^2}(1 - \cos 2\pi s r) - \frac{2\alpha_s'}{\alpha_s'^2 + \beta_s'^2}\sin 2\pi s r \right]\cos 2\pi s r \\ &= \frac{2\alpha_s'}{\alpha_s'^2 + \beta_s'^2}\sin 2\pi s r + \frac{2\beta_s'}{\alpha_s'^2 + \beta_s'^2}(1 - \cos 2\pi s r)\ , \end{aligned}$$

$$q_s'=-\left[\frac{2\beta_s'}{\alpha_s'^2+\beta_s'^2}(1-\cos 2\pi sr)-\frac{2\alpha_s'}{\alpha_s'^2+\beta_s'^2}\sin 2\pi sr\right]\sin 2\pi sr$$

$$-\left[\frac{2\alpha_s'}{\alpha_s'^2+\beta_s'^2}(1-\cos 2\pi sr)+\frac{2\beta_s'}{\alpha_s'^2+\beta_s'^2}\sin 2\pi sr\right]\cos 2\pi sr$$

$$=\frac{2\alpha_s'}{\alpha_s'^2+\beta_s'^2}(1-\cos 2\pi sr)-\frac{2\beta_s'}{\alpha_s'^2+\beta_s'^2}\sin 2\pi sr\ .$$

We put

$$\theta=d(\pi\rho\sigma/c)^{1/2}n^{1/2}\ ,\qquad \theta_s=\theta\cdot s^{1/2}$$

$$a_s d=\theta_s=\frac{\theta_s'}{2}\ ,\qquad \alpha_s d=\alpha_s'\theta_s=\varphi_s=\frac{\varphi_s'}{2}\ ,\qquad \beta_s d=\beta_s'\theta_s=\psi_s=\frac{\psi_s'}{2}\ ,$$

then we get

$$T_m=T_0+\frac{wr}{c}d+\frac{wd}{\pi c}\sum_{s=1}^{\infty}\frac{1}{s\theta_s'}\frac{p_s'\sinh\varphi_s'-q_s'\sin\psi_s'}{\cosh\varphi_s'+\cos\psi_s'}\ . \tag{18}$$

Now let

$$X=\sum_{s=1}^{\infty}\frac{1}{s\theta_s'}\frac{p_s'\sinh\varphi_s'-q'_s\sin\psi_s'}{\cosh\varphi_s'+\cos\psi_s'}$$

$$=\sum_{s=1}^{\infty}\frac{F_-}{s\theta_s'}-\sum_{s=1}^{\infty}\frac{F_-}{s\theta_s'}\cos 2\pi sr+\sum_{s=1}^{\infty}\frac{F_+}{s\theta_s'}\sin 2\pi sr\ , \tag{19}$$

where

$$F_+=\frac{m_1\sinh\varphi_s'+m_2\sin\psi_s'}{\cosh\varphi_s'+\cos\psi_s'}\ ,$$

$$F_-=\frac{m_2\sinh\varphi_s'-m_1\sin\psi_s'}{\cosh\varphi_s'+\cos\psi_s'}\ , \tag{20}$$

$$m_1=\frac{2\alpha_s'}{\alpha_s'^2+\beta_s'^2}\quad\text{and}\quad m_2=\frac{2\beta_s'}{\alpha_s'^2+\beta_s'^2}$$

we obtain

$$T_m=T_0+\frac{wr}{c}d+\frac{wd}{\pi c}X \tag{21}$$

If the number of rotations, n, is infinite, that is, the input energy is distributed uniformly over the target surface,

$$T_m=T_0+\frac{w}{c}rd$$

so wdX/c is the temperature increase due to the finite shape of the focus or finite number of rotations.

Now, we proceed to the calculation of X-function (19). For this purpose we explain the properties of functions which are included in X-function.

α_s', β_s', m_1, and m_2 functions: These are functions of s and we put

$$\xi_s=\frac{2\pi cn}{v^2\rho\sigma}s=\frac{1}{2\pi nk^2}\frac{c}{\rho\sigma}s\ , \tag{22}$$

then

$$\alpha_s'=\sqrt{\sqrt{1+\xi_s^2}+\xi_s}\ ,\qquad \beta_s'=\sqrt{\sqrt{1+\xi_s^2}-\xi_s}\ ,$$

$$m_1=\frac{\sqrt{\sqrt{1+\xi_s^2}+\xi_s}}{\sqrt{1+\xi_s^2}}\quad\text{and}\quad m_2=\frac{\sqrt{\sqrt{1+\xi_s^2}-\xi_s}}{\sqrt{1+\xi_s^2}}\ .$$

When ξ_s tends to 0, α_s', β_s', m_1, and m_2 converge to 1. More precisely when $\xi_s\leq 0.002$, α_s', β_s', m_1, and m_2 are between $1-0.01$ and $1+0.01$. When ξ_s tends to $+\infty$, α_s' diverges to $+\infty$, and β_s', m_1 and m_2 converge to 0. Especially for m_1 and m_2, we obtain following expression,

$$m_1=\frac{1}{\sqrt{\xi_s}}\sqrt{\frac{\sqrt{1+1/\xi_s^2}+1}{1+1/\xi_s^2}}$$

$$\to\sqrt{\frac{2}{\xi_s}}\qquad(\text{for }\xi_s\to+\infty)\ ,$$

and if $\xi_s>5$, the error which is caused by substituting $\sqrt{2/\xi_s}$ for m_1 is smaller than 0.01. And

$$m_2=\frac{1}{\sqrt{\xi_s}}\sqrt{\frac{\sqrt{1+1/\xi_s^2}-1}{1+1/\xi_s^2}}$$

$$\to\frac{1}{\sqrt{2\xi_s^3}}\qquad(\text{for }\xi_s\to+\infty)$$

and if $\xi_s>3.5$, the error which is caused by substituting $1/\sqrt{2\xi_s^3}$ for m_2 is smaller than 0.01. These approximation formulae are utilized to calculate F-functions. The graphical forms of α_s', β_s', m_1 and m_2 functions are given in Fig. 4.

F-functions (20): For convenience, we put $\mu=8\pi^2d^2k^2\rho^2\sigma^2/c^2$, for example, in the case of a copper anode, whose radius 5 cm, the thickness 0.3 cm and number of rotations is 20 sec^{-1}, the value of μ is 7.1×10^4. As $\xi_s=\theta_s'^2/\mu$, if $\mu \gtrsim 10^4$, the value of α_s', β_s', m_1 and m_2 are approximately 1 within errors of 1% for the value $\xi_s \leq 0.02$. In this region,

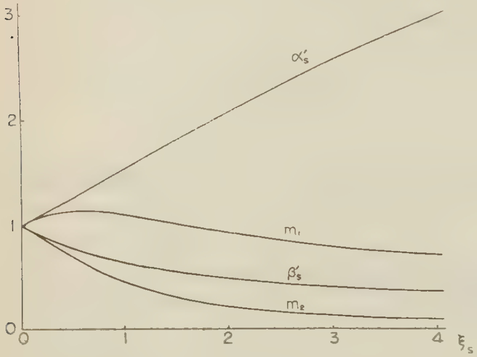

Fig. 4. Illustrating the behavior of functions α_s', β_s', m_1 and m_2 as functions of ξ_s.

$$F_+(\theta_s')=\frac{\sinh\theta_s'+\sin\theta_s'}{\cosh\theta_s'+\cos\theta_s'},$$

$$F_-(\theta_s')=\frac{\sinh\theta_s'-\sin\theta_s'}{\cosh\theta_s'+\cos\theta_s'},$$

and these are coincident with DuMond's formulae. Furthermore, when $\theta_s'>2\pi$, each function is approximated with 1, because in this region hyperbolic functions are larger than circular functions and two hyperbolic functions are almost equal.

In the case of $\xi_s>0.02$, they have following expressions,

$$F_+=m_1(\xi_s) \qquad \text{and} \qquad F_-=m_2(\xi_s)$$

and from the properties of m_1 and m_2, each F_+ and F_- has two appoximation formulae corresponding to the two regions of ξ_s, i.e. $0.02<\xi_s\leq5$ and $\xi_s>5$.

Conclusively, we obtain four expressions of F-functions corresponding to the four regions of ξ_s for $\mu \gtrsim 10000$.

(i) $$F_+^{(1)}(\theta_s')=\frac{\sinh\theta_s'+\sin\theta_s'}{\cosh\theta_s'+\cos\theta_s'},$$

$$F_-^{(1)}(\theta_s')=\frac{\sinh\theta_s'-\sin\theta_s'}{\cosh\theta_s'+\cos\theta_s'},$$

$$\left(\text{for } \theta_s'^2\leq4\pi^2 \text{ or } s\leq\frac{\pi^2}{\theta^2}\right) \tag{23}$$

(ii) $$F_+^{(2)}=F_-^{(2)}=1,$$

$$\left(\text{for } 4\pi^2<\theta_s'^2\leq0.02\,\mu \text{ or } \frac{\pi^2}{\theta^2}<s\leq\frac{0.005}{\theta^2}\,\mu\right) \tag{24}$$

(iii) $$F_+^{(3)}=\frac{\sqrt{\sqrt{1+\xi_s^2}+\xi_s}}{\sqrt{1+\xi_s^2}},$$

$$F_-^{(3)}=\frac{\sqrt{\sqrt{1+\xi_s^2}-\xi_s}}{\sqrt{1+\xi_s^2}},$$

$$\left(\text{for } 0.02<\xi_s\leq5 \text{ or } \frac{0.005}{\theta^2}\,\mu<s\leq\frac{5}{4\theta^2}\,\mu\right) \tag{25}$$

(iv) $$F_+^{(4)}=\sqrt{\frac{2}{\xi_s}},$$

$$F_-^{(4)}=\frac{1}{\sqrt{2\xi_s^3}}.$$

$$\left(\text{for } \xi_s>5 \text{ or } s>\frac{5}{4\theta^2}\,\mu\right) \tag{26}$$

We calculated numerically the functions $F_+^{(1)}$, $F_-^{(1)}$, $F_+^{(3)}$ and $F_-^{(3)}$ and the graphical forms of F-functions are given in fig. 5 (a), (b) and (c).

X-function: When the condition $\mu \geq 10000$ is fulfiled, X-function can be expressed with

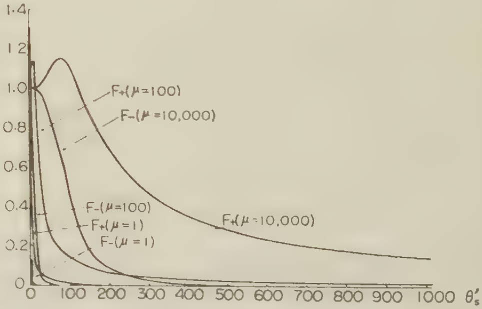

Fig. 5 (*a*). Illustrating the behavior of functions F_+ and F_- for several μ values and range of θ_s' from 0 to 1000.

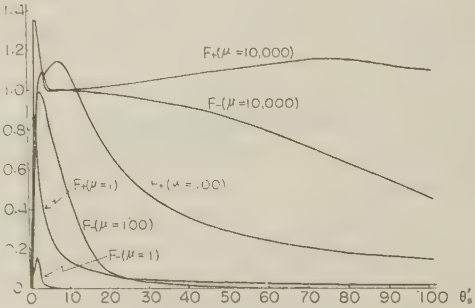

Fig. 5 (*b*). Illustrating the behavior of functions F_+ and F_- for several μ values and range of θ_s' from 0 to 100.

the next form from the properties of F-functions,

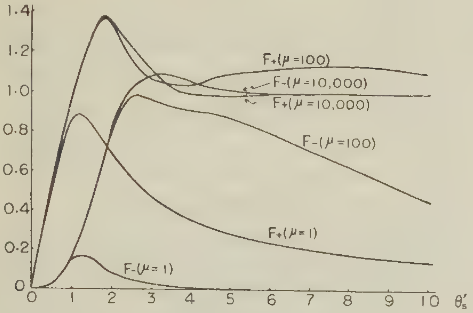

Fig. 5 (*c*). Illustrating the behavior of functions F_+ and F_- for several μ values and range of θ'_s from 0 to 10.

$$
\begin{aligned}
X=&\left\{\Sigma\frac{F_+{}^{(1)}}{s\theta_s'}\sin 2\pi sr+\Sigma\frac{F_-{}^{(1)}}{s\theta_s'}(1-\cos 2\pi sr)\right\}\\
&+\left\{\Sigma\frac{F_+{}^{(2)}}{s\theta_s'}\sin 2\pi sr+\Sigma\frac{F_-{}^{(2)}}{s\theta_s'}(1-\cos 2\pi sr)\right\}\\
&+\left\{\Sigma\frac{F_+{}^{(3)}}{s\theta_s'}\sin 2\pi sr+\Sigma\frac{F_-{}^{(3)}}{s\theta_s'}(1-\cos 2\pi sr)\right\}\\
&+\left\{\Sigma\frac{F_+{}^{(4)}}{s\theta_s'}\sin 2\pi sr+\Sigma\frac{F_-{}^{(4)}}{s\theta_s'}(1-\cos 2\pi sr)\right\}.
\end{aligned}
\tag{27}
$$

From this expression, when $r \ll 1$, $\sin 2\pi sr$ and 1–$\cos 2\pi sr$ in the first blacket are so small that the influence of the other terms are comparatively large and X cannot be approximated by the sum of finite terms of the beginning of the series. So we adopt the next method where $r \ll 1$ is assumed, that is, following calculations are allowable under the condition $r=1/1000$ or small.

Except the region where $s \leq \pi^2\theta^2$, F-functions change very slowly with the change of s, and $\sin 2\pi sr$ and 1–$\cos 2\pi sr$ also change very slowly. Regarding $1/s\theta_s'$ it changes rapidly with the change of s in the region of small s, but in the case where s reaches at 50, the change is only a few percent for a unit change of s. So, in the region of $s > 50$, we can substitute an integral for the summation. In the region of $s < 50$, each term is numerically calculated and summed. Usually the latter region include the first, the second and some of the third bracket in the expression (27). The integrals in the former region, usually including the fourth and some of the third bracket are calculated as follows.

For the third term,

$$
\begin{aligned}
&\Sigma\frac{F_+{}^{(3)}}{s\theta_s'}\sin 2\pi sr+\Sigma\frac{F_-{}^{(3)}}{s\theta_s'}(1-\cos 2\pi sr)\\
&=\frac{1}{\sqrt{\mu}}\int_a^5\frac{1}{\xi_s\sqrt{\xi_s}}\left\{F_+{}^{(3)}(\xi_s)\sin 2\pi\frac{\mu r}{4\theta^2}\xi_s\right.\\
&\qquad\left.+F_-{}^{(3)}(\xi_s)\left(1-\cos 2\pi\frac{\mu r}{4\theta^2}\xi_s\right)\right\}d\xi_s\,,
\end{aligned}
\tag{28}
$$

where a is the value of ξ_s corresponding to the value of $s=51$. For the fourth term

$$
\begin{aligned}
&\Sigma\frac{F_+{}^{(4)}}{s\theta_s'}\sin 2\pi sr+\Sigma\frac{F_-{}^{(4)}}{s\theta_s'}(1-\cos 2\pi sr)\\
&=\sqrt{\frac{2}{\mu}}\int_5^\infty\frac{1}{\xi_s{}^2}\sin 2\pi\frac{\mu r}{4\theta^2}\xi_s\cdot d\xi_s\\
&\qquad+\frac{1}{\sqrt{2\mu}}\int_5^\infty\frac{1}{\xi_s{}^3}\left(1-\cos 2\pi\frac{\mu r}{4\theta^2}\xi_s\right)d\xi_s
\end{aligned}
\tag{29}
$$

Above method of calculation is restricted only in the region where $\mu \gtrsim 10000$ and $r \leq 1/1000$.

§ 4. Application to Actual Problems

In § 3 we have given the method of calculation of X-function. In this paragraph we describe a few examples of calculations, which are limited to the tube which has a copper anode and dimensions given in Table II.

Table II. Dimensions of the target and other conditions ofa X-ray tube to which calculation was applied.

No.	k(cm)	d(cm)	n(sec⁻)	b(cm)	r
1	2	0.3	20	0.013	1/1000
2	5	0.3	20	0.031	1/1000

Table III. Numerical values of parameters.

No.	θ	θ^2	$\sqrt{\mu}$	μ	π^2/θ^2	$4\theta^2/\mu(\times 10^3)$	$4\theta^2$
1	2.38	5.66	106.6	11370	1.75	1.99	22.6
2	2.38	5.66	266.6	71062	1.75	0.318	22.6

From these numerical values, we calculated necessary parameters which are given in Table III. From these values the summations from $s=1$ to $s=50$ are 0.01795 and 0.01831, each of which corresponds to example 1 and 2. The integrals corresponding (28) are difficult to calculate because of frequently oscillating terms of $\sin 2\pi\mu r\xi_s/4\theta^2$ and $1-\cos 2\pi\mu r\xi_s/4\theta^2$, but the upper limits of these integrals are easily calculated from the following formulae,

$$
\begin{aligned}
&\int_a^5\frac{1}{\xi_s\sqrt{\xi_s}}F_+{}^{(3)}(\xi_s)\sin 2\pi\frac{\mu r}{4\theta^2}\xi_s\cdot d\xi_s\\
&\qquad<\int_a^5\frac{1}{\xi_s\sqrt{\xi_s}}F_+{}^{(3)}(\xi_s)\cdot d\xi_s\,,
\end{aligned}
$$

$$\int_a^5 \frac{1}{\xi_s\sqrt{\xi_s}} F_-^{(3)}(\xi_s)\left(1-\cos 2\pi\frac{\mu r}{4\theta^2}\xi_s\right)d\xi_s$$

$$<2\int_a^5 \frac{1}{\xi_s\sqrt{\xi_s}} F_-^{(3)}(\xi_s)d\xi_s\,, \tag{30}$$

and right hand integrals are evaluated by Simpson's method. Calculating these values, we obtained the upper limits of values of (28), 0.0144 and 0.0251 for example 1 and 2. Similarly for the upper limit of (29) we obtained next formulae,

$$\int_5^\infty \frac{1}{\xi_s^2}\sin 2\pi\frac{\mu r}{4\theta^2}\xi_s\cdot d\xi_s < \int_5^\infty \frac{1}{\xi_s^2}d\xi_s = \frac{1}{5}\,,$$

$$\int_5^\infty \frac{1}{\xi_s^3}\left(1-\cos 2\pi\frac{\mu r}{4\theta^2}\xi_s\right)\cdot d\xi_s$$

$$<2\int_5^\infty \frac{1}{\xi_s^3}d\xi_s = \frac{1}{25}\,, \tag{31}$$

and obtained values 0.00279 and 0.00111 respectively for example 1 and 2.

From above numerical values we obtained following X values

for example 1, $X<0.03514$, $X/\pi<0.01119$ and $r+X/\pi<0.01219$,

for example 2, $X<0.04452$, $X/\pi<0.01417$ and $r+X/\pi<0.01517$.

If the anode is stationary and the transversal thermal flow is negligible the temperature T_m is expressed by

$$T_m = T_0 + \frac{w}{c}d$$

and from eq. (21) it is shown that the value of $r+X/\pi$ gives the efficiency of heat divergency due to the rotation and the transversal flow. For example 1 the ratio of temperature rise is smaller than 1.2%, and for example 2 the ratio is smaller than 1.5%, or the permissible input power per unit area is more than 82 times of the stationary anode with the large focus for example 1, and for example 2 it is more than 66 times.

The heat conductivity of copper is 0.8 cal. cm.$^{-1}$ sec.$^{-1}$ deg.$^{-1}$ or 3.4 joule cm.$^{-1}$ sec.$^{-1}$ deg.$^{-1}$ at 1000°C and the value below 1000°C is larger than this value, and the melting point of copper is 1083°C. For the conditions T_m=melting point and $T_0=100$°C the boiling point of water, we obtain

$$w = \frac{(T_m-T_0)c}{(r+X/\pi)d} = \frac{3.34\times10^3}{(r+X/\pi)d}\ \text{watts/cm}^2\,.$$

The values for both examples are

$w=9.13\times10^5$ watts/cm² for example 1,

and

$w=7.33\times10^5$ watts/cm² for example 2.

Each permissible input power per unit length of the focal line is calculated as follows,

$W=1.19\times10^4$ watts/cm for example 1,

and $W=2.30\times10^4$ watts/cm for example 2.

§ 5. Conclusion and Discussion

In paragraphs from 2 to 4 we have described the method of calculation and have given a few examples of numerical calculation. These calculations are unfortunately so complicated that we cannot give a general formula of the input limit as a function of r, n, μ, etc. Furthermore when more accurate estimation is wanted, we must remark such questions that the point of maximum temperature is closely near to the end of the heating period, the temperature of the internal surface cooled by water is the same of the cooling water and the input power distributes uniformly upon the focal area.

If the number of rotations increases the temperature approaches asymptotically to the T_0+wrd/c which corresponds infinite number of rotations, for instance in DuMonds calculation, $r=2/10$, the permissible input power at 20 r.p.s. is 57% of that for infinite number of rotations and the effect of further increasing the number of rotations is very small. But in our case $r\leq 1/1000$ the power limit is sufficiently small compared with the case of infinite rotations and input power can be increased by increasing the number of rotations.

Regarding the comparison with the one-dimensional procedure, the third and the fourth terms of formula (27) is different, as the functions F are different for both procedures, and for $r\ll 1$ i.e. for small width of the focal line, the difference of both procedures are prominent, because the first and the second terms of formula (27) are very small and the other terms have significant influence to X.

Determination of Dislocation Densities Through Nuclear Resonance Studies

By Eizo OTSUKA and Hazimu KAWAMURA

Institute of Polytechnics, Osaka City University, Osaka

(Received May 14, 1957)

Studies of quadrupolar effects of mixed alkali halide on nuclear resonance previously reported for Na in NaCl–NaBr have been extended to Br in KBr–NaBr. Amplification factor for eQq is thus derived and making use of this factor densities of dislocation are determined for a series of plastically deformed crystals of KBr. Although the effects of the screw and edge dislocations are additive for the broadening of the spectral line, their contributions to the net shift of the center of gravity of the line are in the opposite directions for $H_0//[100]$. Hence the two kinds of dislocation are separable in density through the measurement of the breadth and asymmetry of the spectral line. Extrapolation to zero strain shows that for an undeformed crystal screw and edge dislocations are nearly balanced in number and their total density lies around $4\times10^8\,\mathrm{cm}^{-2}$. Linear Compression more favors the production of screw dislocations than that of edge dislocations and the density of each type dislocation increases quite linearly with strain up to fourty percent deformation. For the heaviest deformed sample the total dislocation density achieved was about $3\times10^9\,\mathrm{cm}^{-2}$.

§ 1. Introduction

Recently the authors investigated the quadrupolar effect on the nuclear magnetic resonance line of sodium in the mixed alkali halide crystal NaCl–NaBr¹⁾, which arises from the electric field gradients due to the local strains produced by halogen ion substitution, and succeeded in giving a similar analysis to that made by Bloembergen and Rowland for the case of alloys²⁾. Differing from the negative ions in KBr and KI, the sodium nuclei in pure NaCl retain in its absorption line not only the central line component corresponding to $m=1/2\rightarrow m=-1/2$ transition, but also the satellite components arising from $m=3/2\rightarrow m=1/2$ and $m=-1/2\rightarrow m=-3/2$ transitions, and these are little affected by the internal crystalline defects such as dislocation or vacancies, indicating that the eQq at the sodium site is relatively small in a pure specimen. On the other hand, once a small amount of NaBr is dissolved into the NaCl crystal, intensity of the satellites promptly diminishes and even the central line undergoes the second order broadening upon heavier doping of NaBr. This latter effect, i.e., the second order broadening of the central line, is observable only when the minority halogen comes next to the sodium nucleus and hence has a remarkable directional asymmetry characteristic depending upon the relative directions of the crystalline axes and the applied magnetic field, offering a striking contrast to the case of powdered alloys.

The work on a metallic ion in alkali halide required a sister work on a halogen ion of a mixed crystal, having a common negative but different positive ions. Two convenient candidates lying at hand are KBr–NaBr and KI–NaI, in which the bromine and iodine nuclei are to be checked on account of their finite nuclear electric quadrupole moments. However, such trial on these elements ought to be accompanied by much difficulty not seen in the NaCl–NaBr case. Apart from the technical difficulty in growing a mixed alkali halide crystal bearing different alkalis, we have to be encountered with the fact that because of the large eQq at the sites of bromine and iodine nuclei, even in pure KBr and KI the satellite components of these resonance lines have been almost perfectly smeared out, and the central lines only can be observed³⁾. Hence if we further introduce NaBr or NaI into them and make mixed crystals, there arises a possibility that even a little bit addition of such minority component might cause a fatal second order broadening so that no signal could be picked out from the noise level. This is the barrier, though not insurmountable, in the mixed crystal experiment for bromine and iodine. Nevertheless, the large *eQq*, which produces the cause of difficulty on one hand, brings a convenient means to study the internal defects in pure crystals on the other, chiefly the effect of dislocations. Effects of this sort could not be easily seen in pure NaCl, but now in pure KBr or KI, situation is quite different and dislocation effect is an object of easy detection. In fact, Watkins[3] has brought it to light that quadrupolar interaction with these dislocations is responsible for the disappearance of the satellites and further that increased dislocation density upon cold working could even bring about the second order broadening of the central line itself; in other words, the nuclear magnetic resonance signals of these elements are very sensitive to the presence of dislocations. Unfortunately, however, no sufficient information is available as to the quantitative nature of the quadrupolar interaction with dislocations. Total density of dislocations and the way in which they are divided into edge- and screw-type ones are not clear at present. Moreover, the amplification factor for *eQq* due to the ion core distortion is out of our knowledge and this makes the problem entangled all the more. For the first time Watkins led experimentally the value ten for the amplification factor, β in his notation. Although his way of derivation is quite consistent, yet he puts a little too much confidence upon Seitz's estimation of dislocation density, that the determination of the amplification factor had to be rather subordinate. The value ten seems to be a little too small in the light of today's konwledge, since now Kranendonk[4] predicts much larger value from his point charge model, and even for free polar molecules, such calculations as made by Sternheimer et al.[5] suggest larger values for these heavy elements. One way of determining this amplification factor, we shall henceforth denote it by λ, is to investigate the resonance signal of mixed crystals. The dividend paid for performing a difficult mixed crystal experiment is that λ can be determined through an experiment independent of dislocation analysis. This consideration drove us to grow KBr–NaBr mixtures. In the following paragraphs the quadrupolar interaction due to the introduction of minority alkali is described as well as the dislocation studies pursued at the same time, using a number of plastically deformed crystals. Their analyses are intimately connected with each other. For the specimens containing iodine, similar experiments will be reported in a later paper.

§ 2. Experimental Techniques

The measuring equipments are essentially the same as those described in the previous paper. However, the object in this time is bromine which contains two isotopes of nearly equal abundance in nature. Moreover, the disappearance of the satellites further reduces the signal strength to one-fifth of that for sodium even at pure KBr. With a mixed crystal, the signal observed will still be much weaker. Thus the sensitivity required for the measuring equipment becomes very high. A handiest way to get a larger signal to noise ratio is to raise the resonance observation frequency. This must be accompanied by a higher applied magnetic field strength. Unfortunately, however, the small capacity of our electromagnet could not control its too fast a heating-up under a heavier current supply with all cooling water velocity. Hence we rather kept the magnetic field strength around 3,600 oersted just as in the previous work, but altered the magnetic field modulation frequency from 30 to 320 cps. By this we meant to reduce the flicker noise in order to get a higher signal to noise ratio. In absence of any established theory of flicker noise, we are not sure to what an extent this method is effective. However, it seems to be true that the higher the frequency, the less the flicker noise. In fact, thanks to this raised modulation frequency, the noise level has been much reduced and we could throughout operate the phase-sensitive amplifier with a time constant of about one second for chart-recording. This shorter time constant responds quickly the incoming true signal, yet much more insensitive to the unfavorable noise signal than in the case of 30 cps modulation. One disadvantage in using a high frequency modulation is the need of a compensator as a preventive against the pick-up from the modulation coil system to r-f. This was achieved by winding a pair of Helmholtz coils, some fifty turns in total, on the outer surface of the cylindrical shielding copper wall around the r-f coil.

Every specimen used in the present work has been grown in our laboratory from the melt within a platinum crucible by the Kyropoulos method. When dealing with NaCl-NaBr mixture, even growing an extremum of 50–50 crystal was a relatively easy task. This time, however, we were met with an extremely slow rate of growing for a crystal containing only a few percent minority. And the actually dissolved amount of the minority within a grown crystal could not be the same as that added while the reagents had been still in powder form, but would somewhat be less in quantity on account of the segregation effect during crystallization. Real quantities of the minority were later determined at the Department of Chemistry of Osaka University with a Beckman flame spectrometer, by analyzing the alkali flame intensities. In Table I is shown the actually dissolved amounts of the minority, together with its added amounts before crystal-growth. The maximum degree of doping is 1.87 percent. In view of the fast decay of the signal, any heavier doping than this would not be a sensible one. The pure KBr specimen as the intensity standard was selected in respect of its perfect singleness and growing and annealing conditions. Its size was cylindrical in form with 1.2 cm in diameter and 2 cm in height, and just fit the r-f coil. The standard was changed three times in the course of experiment, and it was confirmed that all the characteristics of the resonance line were common to each one; neither asymmetry of the line nor intensity change being noticeable. It must be noted in passing, however, that for a crystal bearing a slight trace of small angle boundaries and even a crystal quenched in mineral oil from a temperature just below the melting point showed no remarkable reduction in its signal strength. At least, there was not the faintest indication of a second order broadening so long as the crystal was pure and undeformed, and hence we had not to get too nervous in selecting the standard.

Table I. The relative concentrations of the minority in the specimens used.

Sample	Added amount	Actually dissolved
1	0.01	0.0061
2	0.03	0.0147
3	0.05	0.0187

In performing plastic deformation, two different methods were conducted. In the first place, the specimens were cleaved in rectangular shapes and linearly compressed between the plates of an oil compressor capable of producing the weights ranging from zero to one ton over the plates. As buffer, a pair of tin foils were placed on the upper and lower surfaces of the specimen. The creep rate for plastic flow was accelerated by irradiating the metallic plates with an infrared lamp, thus somewhat elevating the temperature of the crystal indirectly. In this way we were able to get a series of deformed crystals, ranging from 4.7 percent to 40.9 percent in the produced strains.

Another way of plastic deformation was first to cut a cleaved crystal into several thin slices and each of them be put within a hollow cylindrical brass tube with its inner radius of curvature 1.4 cm. Then, while warming up the tube with a burner, one presses the slice with a thick cylindrical iron rod placed on it. In this manner many arc-shaped slices having the equal radius of curvature 1.4 cm were produced. The aim of this device was to get many edge-type dislocations having a uniform direction. The effect of the deformation process of this type will be discussed in later sections.

All the measurements were carried out at room temperature.

§ 3. Experimental Results and Their Analyses

3.1) Doped Crystals

The intensity measurements were made both for Br^{79} and for Br^{81}. Since both of these nuclei in pure KBr give only 0.4 times the total absorption signal, we are bound to ascribe any change observed in a doped crystal to the second order broadening. In Fig. 1 are plotted the changes in maximum meter deflections against the relative concentration of the minority. One can see how quickly the line broadens on a little bit addition of the minority. Since the quadrupole moment of Br^{79} is $0.335 \times 10^{-24}\,\text{cm}^{-2}$ and that of Br^{81} is $0.280 \times 10^{-24}\,\text{cm}^{-2}$, the effect is more striking for the former. In Fig. 2 are shown the integrated absorption curves for Br^{81}. For doped crystals, the lines have an asymmetry characteristic of having a somewhat longer tail on the higher magnetic field side. This asymmetry is a little more noticeable at derivative curves, and has little dependence on the direction of the magnetic field, in contrast with NaCl–NaBr mixtures. That is to say, in the latter case the second order broadening occurs for only so heavy a doping that the probability of the minority halogen coming next to sodium becomes appreciable, and therefore, the number of halogen sites around the sodium nucleus responsible for the effect is limited to six. Under this situation, a simple analysis shows that for $[100]//H_0$ the line should have a tail on the lower magnetic field side, while for $[110]//H_0$ tails should appear on the both sides. In the case of KBr, however, the second order broadening comes into existence even if the location of the sodium ion is pretty far. Hence the radius vectors connecting the bromine nucleus and the sodium responsible for the broadening have a considerable angular spread with respect to the direction of the applied magnetic field for a given r. According to the second order perturbation theory, the energy difference corresponding to $m=1/2 \rightarrow m=-1/2$ transition perturbed by a quadrupolar interaction with an axially symmetric electric field gradient is given by

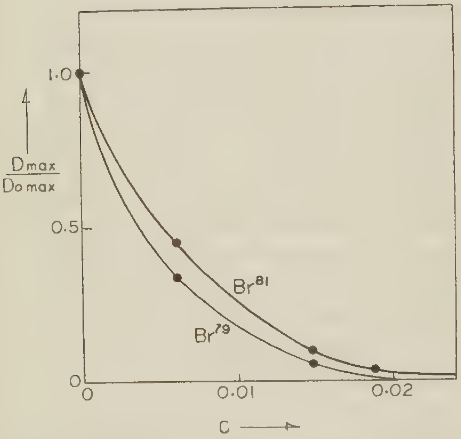

Fig. 1. Normalized signal strengths of both Br^{79} and Br^{81} in $(1-c)$KBr-cNaBr plotted against the relative concentration c of the minority.

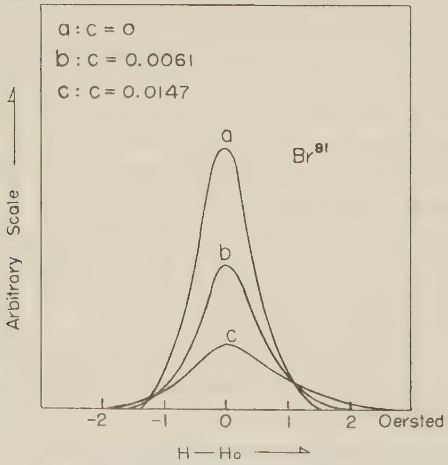

Fig. 2. Integrated absorption curves for Br^{81} in a series of mixed crystals $(1-c)$KBr-cNaBr.

$$\Delta E_{1/2\rightarrow -1/2}=h\nu_0+\frac{9}{64}\frac{2I+3}{4I^2(2I-1)}\frac{e^4Q^2q^2}{h\nu_0}\times(1-9\cos^2\theta)(1-\cos^2\theta)\ . \qquad (1)$$

Or writing the deviation from the Zeeman frequency as $\Delta\nu$

$$h\Delta\nu=A(1-9\cos^2\theta)(1-\cos^2\theta)\ , \qquad (2)$$

where

$$A=\frac{9}{64}\frac{2I+3}{4I^2(2I-1)}\frac{e^4Q^2q^2}{h\nu_0}\ . \qquad (3)$$

The minority ion placed at a distance r from the nucleus concerned will produce a field gradient:

$$eq=6\lambda e(a_i-a_0)/ar^3\ , \qquad (4)$$

where a_i and a_0 are the ionic radii of the minority and majority alkalis, respectively, a the lattice constant of KBr and λ the amplification factor including the Sternheimer correction. Putting this into (3), and (3) into (2), we get the shift of the Zeeman frequency due to the ionic substitution with a given radial distance r from the nucleus concerned. Since θ, the angle between the direction of the magnetic field and the axis of the electric field gradient, varies as the minority ion moves on the sphere of radius r around the nucleus, the frequency shift will take a series of values corresponding to the possible locations of the minority ion on this spherical surface. If there correspond many such possible orientations for a given r, we shall have a broad frequency spectrum having two peaks whose separation is given by

$$\Delta\nu_Q=\frac{25}{9}\frac{A}{h}$$

$$=\frac{225}{16}\frac{2I+3}{4I^2(2I-1)}\frac{e^4Q^2}{h\nu_0 r^6}\left(\frac{a_i-a_0}{a}\right)^2\lambda^2\ . \qquad (5)$$

This gives the order of the second order quadrupolar broadening due to the minority ion on the sphere of the radius r. We shall then be able to assume that, if the minority ion comes within a certain critical sphere, the line is so much shifted that it contributes almost nothing to the peak intensity. This assumption can easily be accepted, since $\Delta\nu_Q$ given by (5) varies in the inverse sixth power of r.

Thus the peak intensity of the integrated absorption curve will be proportional to the probability that the minority ion does not come within this critical sphere. If there are n sites for the positive ion and the mean concentration of the minority ion is c, this probability is given by

$$I_c/I_0=(1-c)^n\ , \qquad (6)$$

where I_0 is the peak intensity for pure KBr. Since $c<0.02$, we may safely put

$$\ln(I_c/I_0)=-nc\ , \qquad (7)$$

and the semilogarithmic plot will give the value of n. In Fig. 3 are shown the plots of this kind. The intensity measurements were carried out both for $[100]//H_0$ and $[110]//H_0$ and the averages of the two are given there, though no significant difference in slope for the two directions occurs. The heaviest doped sample gives no point for Br^{79} and even for Br^{81} the point is written with a white circle, indicating that the determination is not so certain. The remaining three points for each isotope, however, assure the linearity. The values of n calculated from these slopes are 105 and 92 for Br^{79} and Br^{81}, respectively. The latter corresponds to the number of alkalis just as far as the fifth ones, while the former lies between the fifth and sixth. The distance from a bromine to its fifth alkali neighbor is $\sqrt{11}a$ and to sixth $\sqrt{13}a$, where a is the lattice constant as before and 3.29 A for KBr. Then, we may be justified by equating the critical radius r_i to $\sim\sqrt{11}a$ for Br^{81} and $\sim\sqrt{12}a$ for Br^{79}. Using this critical radius, we can deduce the amplification factor by equating (5) to a definite broadening of reasonable magnitude, say the dipolar width for each nucleus. Theoretical values for dipolar broadening obtained by applying the Van Vleck's formula[6)] are $\Delta\nu_{79}=0.73$ kcps and $\Delta\nu_{81}=0.79$ kcps with $H_0//[100]$. On the other hand, experimental values are 1.07 kcps and 1.20 kcps for each. These discrepancies may partly arise from the invalidity of the Van Vleck's formula for a resonance line split and partly from the inhomogeneity broadening due to the finite dimension of the specimen as well as the slight saturation broadening; yet the second order broadening by virtue of the inner defects such as dislocations or impurities should be ruled out, since no asymmetry feature, characteristic of the second order broadening, does not turn up. The assumption that a broadening of this order occurs as the minority comes at the distance of the critical radius may be justified by the fact that the observed wings of the doped crystals extend over the range nearly of this width. The minorities nearer to the bromine would contribute the wings too far to be observed. Thus we may find the value of λ by equating the left-hand side of (5) tentatively to the theoretical dipolar widths, at the same time putting the critical radii determined above, for Br^{79} and Br^{81}. In this way the amplification factor is determined separately for each isotope as

$$\lambda=35 \text{ for } Br^{79}\ ,$$
$$\lambda=39 \text{ for } Br^{81}\ .$$

Considering the not so strictly sharp a nature of the way of derivation for these values, we had better put $\lambda\sim40$ for both isotopes.

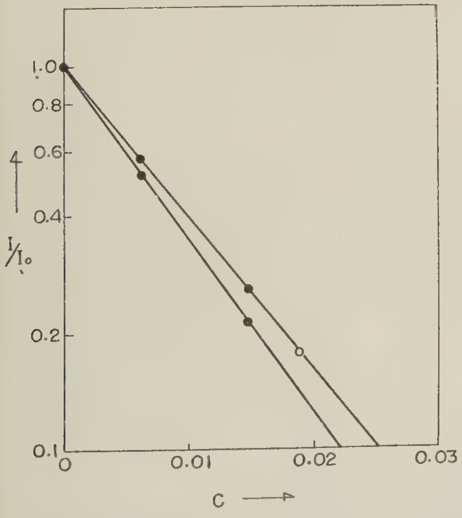

Fig. 3. Semilogarithmic plot of the relative peak intensities of both Br^{79} and Br^{31} resonance lines against the relative concentration c of the minority.

3.2) Linearly Compressed Crystals

In Fig. 4, the relative signal strengths $D_{\max}/D_{0\max}$ are plotted against the degree of strain for a number of deformed crystals. Since only the data of Br^{79} were used for dislocation analysis, those of Br^{81} are not shown in the figure, but suffice it to note that the effect of plastic deformation is again greater for Br^{79} than for Br^{81}. In the same figure is given a similar plot for $\sqrt{D_{\max}/D_{0\max}}$ which is very nearly equal to the ratio of the peak intensities I/I_0. The measurement was made thoroughly with $[100]//H_0$. The cross in the figure is the value of I/I_0 obtained by Watkins using a higher magnetic field of 6380 gauss[3]. In Fig. 5, a couple of absorption curves for deformed crystals are shown for illustration. Every absorption curve has a common feature of having a longer tail on the higher magnetic field side. Apparently this is quite analogous to the case of polycrystalline alloys under the second order broadening; however, the inner situation is rather different, since the strains which are responsible for the effect would not be caused by point defects such as impurities or vacancies, but mostly by dislocations which bear a line character. This will be checked a little more quantitatively in the next section. For the present, we shall implicitly assume that dislocations play a dominant role and proceed along this line.

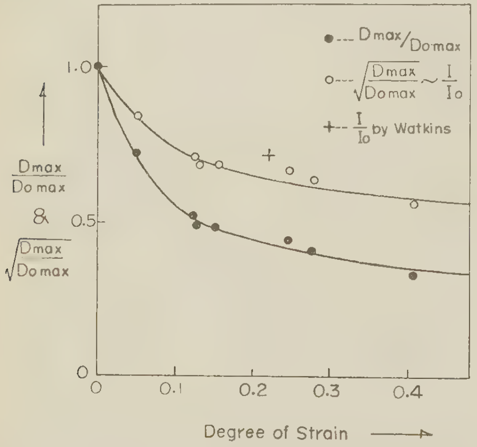

Fig. 4. Normalized signal strengths for Br^{79} in pure KBr and their square roots which are very nearly equal to the relative peak intensities plotted against the degree of strain. The cross indicates I/I_0 previously reported by Watkins.

It is expected that the result of linear compression will be that the produced dislocations are such that edge- and screw-types being mixed-up. So we have to consider two types of field gradients: one is that due to edge-type dislocations and the other due to screw-type ones. In alkali halides, a slip occurs always on a (110) sheet, the Burgers vector being parallel to the [110] direction with magnitude $|\boldsymbol{b}|=\sqrt{2}a$. The screw dislocation line lies along the slip direction and accordingly parallel to the [110] direction, while the edge dislocation line is perpendicular to this, lying along the [100] direction. The stress field of the former is cylindrically symmetric and described solely with the shear stress $\sigma_{\theta z}$ in the cylindrical coordinates. On the other hand, the latter is more complicated and three components of the stress tensor appear; namely, σ_{xx}, σ_{yy} and σ_{xy}. However, the compliance constants are $s_{11}=3.0$, $s_{12}=-0.43$ and $s_{44}=20.00$ for KBr[7] and hence the largest component is shear. Thus, for an approximate treatment we may be justified by neglecting all other components than shear in dealing with edge dislocation. This has been done also by Watkins. Justification for this approximation will be all right also for KI, for which $s_{11}=3.9$, $s_{12}=-0.53$ and $s_{44}=23.8$[7].

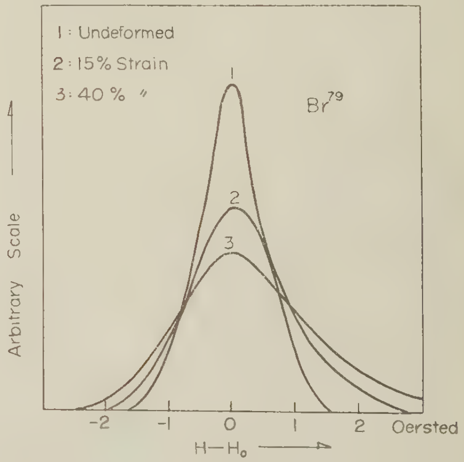

Fig. 5. Absorption curves of Br^{79} for a series of deformed pure KBr crystals.

Moreover, we shall approximate that the field gradients produced by the squeeze corresponding to a dislocation is axially symmetric around the squeeze direction and hence described by the following familiar expressions[8]:

$$\left.\begin{aligned}(\nabla E)_0&=\frac{1}{4}\,eq(3\cos^2\theta-1)\,,\\(\nabla E)_{\pm1}&=\pm\frac{1}{4}6^{1/2}eq\sin\theta\cos\theta e^{\pm i\varphi}\,,\\(\nabla E)_{\pm2}&=\frac{1}{8}6^{1/2}eq\sin^2\theta e^{\pm2i\varphi}\,.\end{aligned}\right\}\quad(8)$$

Now with H_0 being parallel to [100] and considering only the electric field due to the six nearest neighbors, Watkins shows for a squeeze in an arbitrary direction

$$(\nabla E)_0=3\eta\frac{e}{a^3}(3\cos^2\theta-1)\,,\qquad(9)$$

where η is the fractional compression, or strain. Comparing this with the first expression of (8) we see that we are dealing with an axially symmetric field with $eq=12\eta\frac{e}{a^3}$. Any squeeze in an arbitrary direction should be accompanied by another one with opposite sign in the perpendicular direction to it; in other words, the strain is composed by tension and compression. Hence we must add two terms of ∇E components having two θ's corresponding to tension and compression, in order to calculate the frequency shift due to the quadrupolar interaction. Detailed accounts of such calculations will be given in the appendix and suffice it to say here that θ varies only for a screw dislocation and hence averaging process is unnecessary for edge dislocations in order to get the first and second moments of the frequency deviation.

If there are screw and edge dislocations with the densities of c_S and c_E, the first moment, or the center of gravity of the absorption curve, becomes

$$\langle\nu-\nu_0\rangle=-\frac{36}{\pi^2}\lambda^2\frac{e^4Q^2}{h^2a^6\nu_0}\times\left(\frac{363}{4096}\pi a^2c_S\ln\frac{1}{9\pi a^2c_S}-\frac{49}{1016}\pi a^2c_E\ln\frac{1}{9\pi a^2c_E}\right).\qquad(10)$$

It is worthwhile to note here that the directions of the shift are opposite to each other for screw and edge dislocations. This enables us to separate the effects of the two type dislocations as shown later. For the time being, however, we might as well tentatively put $c_S=c_E$, since this assumption is not unreasonable so long as an order of magnitude discussion is concerned. Then we are able to deduce the dislocation density by experimentally determining the first moment for a deformed crystal which shows a second order broadening. The observed first moments and the corresponding dislocation densities are given in the Table II for four representative deformed crystals. The large probable error for the heaviest deformed crystal is caused by the small sample size and too much broadened tails at the far wings. For the crystals not shown here, errors are even greater than this on account of their smallness in size and hence not used for a quantitative analysis.

Table II. The observed first moments together with their corresponding dislocation densities for representative deformed crystals with the assumption $c_S=c_E$.

Degree of Strain	$-\langle\nu-\nu_0\rangle$ in cps.	c in cm^{-2}
4.7%	104 ± 6	$(8.0\pm0.5)\times10^8$
15.4%	239 ± 11	(19.7 ± 0.9) 〃
27.5%	361 ± 4	(31.2 ± 0.4) 〃
40.9%	496 ± 59	(44.0 ± 5.2) 〃

As mentioned above, the assumption that $c_S=c_E$ will not cause a serious error so long as the order of magnitude estimation is concerned. However, this may not be true in reality, and we are tempted to find a way by which the ratio c_S/c_E can be determined. This is qualitatively achieved through second moment analysis. For the quadrupolar second moment the effects of screw and edge dislocations are additive, and the expression becomes

$$\langle\delta\nu^2\rangle=\frac{729}{128}\left(\frac{e^4Q^2}{h^2a^6\nu_0}\right)^2\frac{\lambda^4}{\pi^3}\left(\frac{a}{r_i}\right)^2\times\left(\frac{81011}{16384}c_Sa^2+\frac{2401}{2304}c_Ea^2\right).\qquad(11)$$

Here r_i is the inner cut-off radius in the course of integration. This quantity is so defined that the signal from the nuclei nearer to the dislocation line than r_i escapes observation on account of the fatal frequency shift. The corresponding frequency spread will be expressed in terms of r_i as

$$\Delta\nu_{Q,\,\mathrm{disl}}=\frac{75}{8\pi^2}\frac{e^4Q^2}{h^2a^6\nu_0}\left(\frac{a}{r_i}\right)^2\lambda^2\,.\qquad(12)$$

Insertion of (12) into (11) will eliminate r_i. Writing $\sqrt{\langle\delta\nu^2\rangle}=\delta\nu_Q$ and $\Delta\nu_{Q,\,\mathrm{disl}}/\delta\nu_Q=\alpha$, we have

$$\delta\nu_Q=0.193\alpha\frac{e^4Q^2}{h^2a^6\nu_0}\lambda^2\left(\frac{81011}{16384}c_Sa^2+\frac{2401}{2304}c_Ea^2\right).\qquad(13)$$

The parameter α in this equation can be determined experimentally and its order of magnitude can be inferred to be 3~10 as seen just from the line shapes illustrated in Fig. 5. Combining (10) and (13), we can construct a set of simultaneous equations for c_S and c_E. $\delta\nu_Q$ is determined by subtracting the dipolar second moment, or half the line width of the undeformed crystal, thus picking up the broadening having purely quadrupolar nature. Before solving the simultaneous equations, we might as well again tentatively put $c_S=c_E$ in (13). In Table III, $\delta\nu_Q$'s and the corresponding dislocation densities times α thus derived are shown.

Table III. The quadrupolar broadenings together with the corresponding dislocation densities times α.

Degree of Strain	$\delta\nu_Q$ in cps.	αc in cm^{-2}
4.7%	165.0 ± 19.1	$(6.0\pm0.7)\times10^9$
15.4%	366.5 ± 40.3	(13.4 ± 1.5) 〃
27.5%	485.5 ± 41.1	(17.8 ± 1.5) 〃
40.9%	637.5 ± 76.1	(23.3 ± 2.8) 〃

Comparing Table II and Table III, the parameter α can be determined. This parameter, however, can also be found otherwise by directly measuring $\Delta\nu_{Q,\,\mathrm{disl}}$ for each absorption curve. Since $\Delta\nu_{Q,\,\mathrm{disl}}$ is by definition the separation of the frequencies where the signal intensity just escapes observation, it can be determined experimentally, although the determination itself cannot be said so definite. At any rate, two sets of α values are derived in this manner and in Table IV are listed these two kinds of α for each deformed crystal. Their coincidence is fairly good, so that one may expect the solution to lie near at hand around $c_S=c_E$. This situation facilitates the actual solution of the simultaneous equations. That is, the logarithmic factors in the first moment expression may safely be put equal and expressed by κ. Thus the final expressions for c_S and c_E are written as

Table IV. The parameter $\Delta\nu_{Q,\mathrm{disl}}/\delta\nu_Q=\alpha$ with two different ways of derivation, one with the assumption $c_S=c_E$, the other just through direct observation.

Degree of Strain	$\alpha_{c_S=c_E}$	α_{exp}
4.7%	7.55	8.5
15.4%	6.80	8.3
27.5%	5.70	7.6
40.9%	5.27	7.0

$$\left.\begin{aligned}c_S&=\left[-0.580\frac{\langle\nu-\nu_0\rangle}{\kappa}+1.60\frac{\delta\nu_Q}{\alpha}\right]\times10^7\,\mathrm{cm}^{-2},\\ c_E&=\left[2.76\frac{\langle\nu-\nu_0\rangle}{\kappa}+2.94\frac{\delta\nu_Q}{\alpha}\right]\times10^7\,\mathrm{cm}^{-2}.\end{aligned}\right\}\tag{14}$$

Thus combining the shift $\langle\nu-\nu_0\rangle$ and broadening $\delta\nu_Q$, we are able to separate c_S and c_E, where the experimentally determined values are to be used for α. The obtained c values are plotted in Fig. 6 for each stage of deformation. It is seen that each kind of dislocation increases quite linearly with degree of strain, and the screw dislocation outnumbers the edge dislocation in the deformed crystals. Extrapolation to the zero strain shows that for an undeformed crystal, the densities of the screw and edge dislocation are nearly balanced in number and the total density lies around $4\times10^8\,\mathrm{cm}^{-2}$.

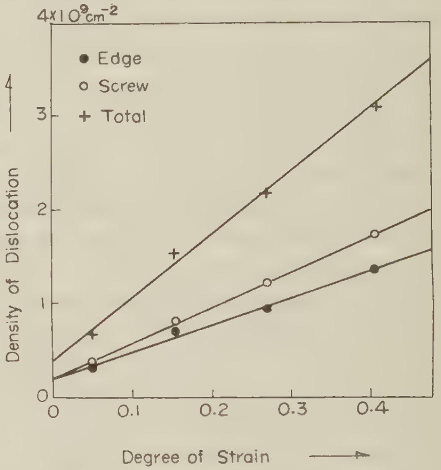

Fig. 6. Edge, screw and their total dislocation densities plotted against the degree of strain.

3.3) Circularly Bent Crystals

In contrast with the linearly compressed crystals, in which we could observe remarkable second order broadenings, neither broadening nor asymmetry characteristic was found for the circularly bent crystals. Of this negative result we shall discuss in the next section.

§4. Discussions

It is already accepted as an established fact that even with a pure and undeformed

KBr, the resonance lines of both Br^{79} and Br^{81} are perfectly split, the satellites being so widely spread out under the noise level. It is believed that this first order broadening is caused not by point defects such as impurities or vacancies but by dislocations. Indeed if we try to have the satellites spread over a range of 10 kcps by adding an impurity of the same valence, say Na, to the perfect KBr crystal, a simple first order perturbation calculation will show that a lower limit of impurity concentration needed for that spread of satellites is $\sim 10^{19}\,\mathrm{cm}^{-3}$. In usual reagents such a high impurity concentration is not allowed. Also an impurity of different valence ordinarily does not exceed $10^{16}\,\mathrm{cm}^{-3}$ in concentration. Accordingly, apart from an artificially added one, a quadrupolar effect due to impurity can be said entirely negligible.

Then how about the vacancies? The eQq due to a vacancy is similar to that due to a divalent ion, and may be assumed by not more than an order of magnitude greater than that due to Na. Their concentration, however, scarcely exceeds 10^{17} per unit volume even for $T=1{,}000°\mathrm{K}$, if calculated from the thermal equilibrium condition $n=N\exp(-W/2kT)$, putting $N=10^{22}\,\mathrm{cm}^{-3}$ and $\frac{1}{2}W=0.96$ ev. for KBr; hence for a crystal quenched at very high temperature, we might as well ascribe the satellite reduction only in part to these vacancies. Yet it is far from the second order broadening, and as stated in § **2**, the signal intensity for a quenched crystal showed no observable change compared with a good one.

Now for the plastic deformation: Although the quadrupolar effect is highly sensitive to a linear compression, practically no effect is observable for a circularly bent crystal. The aim of this bending technique was to get a certain regularity of the field gradient by producing many edge-type dislocations pointing the same direction. If this had been done for a sufficient degree, we should have been able to observe an asymmetry characteristic of the absorption curve dependent on the magnetic field direction. The possibility of a directional effect for asymmetry characteristic will be discussed in more detail in a later paper, and for the present we discuss simply the reason why this trial ended in a negative result for KBr. A simple theory⁹⁾ predicts that when we bend a thin slice of the crystal, the order of magnitude density of the dislocations produced by bending will be given by

$$c=1/rb\,, \tag{15}$$

where b is the magnitude of the Burgers vector and r the radius of curvature. By putting $r=1.4\,\mathrm{cm}$ and $b=4.65\times10^{-8}\,\mathrm{cm}$, we obtain $c\sim2\times10^{7}\,\mathrm{cm}^{-2}$. On the other hand, from the analysis for the linear compression we see that a density of more than $10^{8}\,\mathrm{cm}^{-2}$ is needed to cause an observable second order broadening. This may be the possible reason for the negative result. The value of c obtained from (15), however, is not necessarily the maximum density attainable through this technique. For example, by repeating the bending back and forth several times, we might be able to get more than 10^{8} unidirectional edge dislocations per unit area. This repitition of bending indeed was put on trial, but with no avail. An observable effect might be expected for an element with larger eQq. Potassium iodide is one with such a possibility. An experiment on this object is now under preparation.

It is not so certain why linear compression does introduce much more dislocations than bending. However, some clue might be obtained if one considers the fact that the most important increases of dislocations occur when those belonging to different slip systems intersect each other. In the case of bending the specimen surfaces are free over most of their area and the strain may be brought about by only one slip system in any one region. In linear compression, on the contrary, there is constraint from the pressure plates over a large part of the surface area, which will usually compel intersecting slip systems to operate. The conclusion that liner compression introduces much more dislocations is therefore quite an acceptable one, but the situation is rather complicated for one to have been able to predict this with certainty.

It is of interest to compare the two kinds of frequency spread (5) and (12). Since λ is common to both the formulae, the critical radii responsible for broadening comparable with dipolar one are connected by the relation

$$\frac{\sqrt{2}}{\pi}\,\frac{a}{r_d}=\frac{a^3}{r_i^3}\,\frac{a_i-a_0}{a}\,, \tag{16}$$

where r_d is the critical radius for the dislocation. For Br^{79} we may put $r_i \sim \sqrt{12}a$, and get $r_d/a \sim 200$. If the dislocation density c exceeds $(\pi r_d^2)^{-1} \sim 7\times10^9\,\mathrm{cm}^{-2}$, each nucleus undergoes a broadening at least comparable with the dipolar broadening; in other words, the central line itself will practically be smeared out. However, even for the fourty percent deformed crystal the signa does not vanish, thus proving that its dislocation density has not yet exceeded this limit. In fact, we see from Fig. 5 that c still lies around $3\times10^9\,\mathrm{cm}^{-2}$ for this crystal and hence well below the above-mentioned limit.

The undeformed crystal has a perfectly symmetrical absorption curve and thus for this sample $c \ll 7\times10^9\,\mathrm{cm}^{-2}$. Or, a little more strictly, we may safely assume that for this crystal less than ten percent of the total nuclei are closer to the dislocation line than r_d. Thus $c < 7\times10^8\,\mathrm{cm}^{-2}$ would be a pretty reasonable value as an upper limit of dislocation density for an undeformed crystal.

On the other hand, the lower limit of the dislocation density for an undeformed crystal can be deduced from the requirement that the satellites be smeared out by the strains due to dislocations. The first order perturbation calculation gives for the frequency shift due to a dislocation as

$$h\Delta\nu = (2m-1)(3\cos^2\theta-1)\frac{3e^2Q\lambda}{8I(2I-1)}\,\frac{12}{\sqrt{2}\,\pi}\cdot\frac{1}{a^2r}\,. \tag{17}$$

If we replace $3\cos^2\theta-1$ by 3, we get a measure of the spreading range of the satellites for a given r. The signal would become unobservable for sufficient spread, say 10 kcps, and the value of r corresponding to this spread gives the above-mentioned lower limit for the dislocation density. Calculation shows that this limit is $5\times10^7\,\mathrm{cm}^{-2}$. The allowable range for the dislocation density for an undeformed crystal therefore becomes

$$5\times10^7 < c < 7\times10^8\,\mathrm{cm}^{-2}\,. \tag{18}$$

The extrapolation made in Fig. 6 drops just within the range prescribed by this condition and $c = 4\times10^8\,\mathrm{cm}^{-2}$ would be a reasonable result consistent with all these analyses.

§ 5. Conclusion

The absence of the knowledge of the correction factor λ in the quadrupolar interaction has often been an obstacle for the study of lattice imperfections. Through an experiment of mixed crystals we have found this value to be ~ 40 for bromine in KBr. Using this value thus derived, we have been able to determine the dislocation density for plastically deformed crystals and thence further estimate the density for an undeformed crystal. It is concluded that the dislocation density for a usual pure and undeformed potassium bromide lies in the stage of $10^8\,\mathrm{cm}^{-2}$, the edge and screw dislocations being nearly balanced in quantity. The linear compression, however, more favors the production of screw dislocations rather than that of edge dislocations and for the heaviest deformed crystal, 40.9 percent strain, the total dislocation density achieved is $3\times10^9\,\mathrm{cm}^{-2}$. Up to this high stage of plastic deformation, the dislocation density seems to increase quite linearly with strain.

§ 6. Acknowledgement

We should like to express our profoundest gratitude to Prof. F. C. Frank for his deep interest shown to our work and also for many valuable discussions. We are also very much indebted to Mr. T. Honda for his technical assistance during the course of experiment. Discussions with Mr. M. Tomura and Mr. H. Okura on dislocation topics were most welcome.

Appendix

The frequency shift due to the second order quadrupolar interaction for nuclei with $I=3/2$ is given by

$$\nu-\nu_0 = -\frac{e^2Q^2}{h^2\nu_0}\left\{|\nabla E_{-1}|^2 - \frac{1}{2}|\nabla E_{+2}|^2\right\}. \tag{A1}$$

where ∇E_{-1} and ∇E_{+2} are those in (8) in the text. In order to calculate the field gradients due to dislocations, we must refer to the stress equations of a dislocation.

1) Screw Dislocation

In rectangular coördinates, the stress has only two nonvanishing components:

$$\left.\begin{aligned} \sigma_{xz} &= -\frac{Gb}{2\pi}\frac{y}{x^2+y^2}\,, \\ \sigma_{yz} &= \frac{Gb}{2\pi}\frac{x}{x^2+y^2}\,, \end{aligned}\right\} \tag{A2}$$

where G is the shear modulus and the direction of the screw dislocation line is taken as the z-axis, which is parallel to [110]. The plane perpendicular to this is shown in Fig. 7. In cylindrical coördinates, the stress tensor yields only one nonvanishing component:

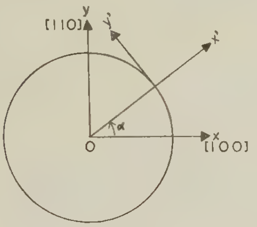

Fig. 7. A diagram indicating the cylindrical symmetry of a screw dislocation, with yz plane being the slip plane and Oz the dislocation line which is parallel to a [110] type direction.

$$\sigma_{\theta z}=\frac{Gb}{2\pi r}\,. \tag{A3}$$

Thus the stress field is in the form of cylindrical symmetry. By deriving the direction cosines of both the magnetic field direction and the axis of the field gradient with respect to the x, y and z axes of the dislocation, we can find the angle θ appearing in (8). Since the magnetic field has been applied throughly along the [100] direction, its direction cosines are either $(\pm1, 0, 0)$ or $(0, \pm1/\sqrt{2}, \pm1/\sqrt{2})$. In other words, there are two kinds of equivalent (110) sheets on which a slip occurs with regard to the magnetic field direction. We shall next introduce a new coördinate system $(x'y'z')$, which is rotating on the surface of a cylinder of radius r coaxial with the dislocation as shown in Fig. 7. The z' axis is fixed and identical with the z axis of the dislocation. Then the axes of the field gradients lie in the $y'z'$ plane and along the lines $y'=\pm z'$; one is for compression and the other for tension, whose magnitudes being given by

$$\left.\begin{aligned}(eq)_1&=+12\lambda\frac{e}{a^3}\frac{\sigma_{\theta z}}{G}\,,\\(eq)_2&=-12\lambda\frac{e}{a^3}\frac{\sigma_{\theta z}}{G}\,.\end{aligned}\right\} \tag{A4}$$

Now that their direction cosines with respect to the rotating coördinates are $(0, \pm1/\sqrt{2}, \pm1/\sqrt{2})$, those with respect to the axes of the fixed coördinate system can now be expressed in terms of the rotation angle α of the $(x'y'z')$ system and thus written as $(-1/\sqrt{2}\sin\alpha,\ 1/\sqrt{2}\cos\alpha,\ \pm1/\sqrt{2})$.

Hence the angle θ between the direction of the magnetic field and the axis of the field gradient is found to be either

$$\left.\begin{aligned}&\text{a)}\qquad \cos\theta=\pm\frac{1}{\sqrt{2}}\sin\alpha\,,\\&\text{or}\\&\text{b)}\qquad \cos\theta=\frac{1}{2}\cos\alpha\pm\frac{1}{2}\,.\end{aligned}\right\} \tag{A5}$$

This set of cosine values should properly be associated with corresponding tension and compression. Introducing (A5) into (A1) and averaging over the angle α and radial distance r, we get the contribution of screw dislocations to (A1). It becomes

$$\begin{aligned}\langle\nu-\nu_0\rangle_{\text{Screw}}&=-\frac{363}{4096}\cdot\frac{72}{\pi^2}\lambda^2\left(\frac{e^2Q}{ha^3}\right)^2\frac{1}{\nu_0}\int_{3a}^{(\pi c_S')^{-1/2}}\frac{1}{r^2}r\,dr\Big/\int_0^{(\pi c_S')^{-1/2}}r\,dr\\&=-\frac{363}{4096}\cdot\frac{72}{\pi^2}\lambda^2\left(\frac{e^2Q}{hd^3}\right)^2\frac{1}{\nu_0}(\pi a^2c_S')\ln\frac{1}{9\pi a^2c_S'}\,,\end{aligned} \tag{A6}$$

where c_S' is half the screw dislocation density, or the density on an equivalent set of the two of the (110) sheets with regard to the magnetic field direction. The lower limit of the radial integration has been rather arbitrarily chosen $3a$ as by other authors, within which one may expect that Hooke's law would fail to be valid. This arbitrariness will be allowed if one considers the logarithmic nature of the result.

2) Edge Dislocation

As stated in the text, we shall only consider the shear component in dealing with an edge dislocation. This greatly simplifies the problem and all we have to do is to consider the two squeezes which always lie along [100] type directions (See Fig. 8). Hence $\cos\theta$ in this case is either 0 or 1, and there is no need of averaging process. There are again two kinds of equivalent (110) sheets on which a slip occurs: one for which $(eq)_1$ satisfies $\cos\theta=1$ and $(eq)_2$ $\cos\theta=0$, the other for which both $(eq)_1$ and $(eq)_2$ satisfy $\cos\theta=0$. For $\cos\theta=1$, there is no frequency shift corresponding to

(A1). For $\cos\theta=0$, we have

$$|\nabla E_{-1}|^2-\frac{1}{2}|\nabla E_{+2}|^2=-\frac{3}{64}e^2q^2\,, \tag{A7}$$

with

$$\left.\begin{aligned}(eq)_1&=+12\lambda\frac{e}{a^3}\frac{\sigma_{xy}}{G}\,,\\ \text{and}\quad (eq)_2&=-12\lambda\frac{e}{a^3}\frac{\sigma_{xy}}{G}\,,\end{aligned}\right\} \tag{A8}$$

where

$$\sigma_{xy}=\frac{Gb}{2\pi(1-\nu)}\cdot\frac{x(x^2-y^2)}{(x^2+y^2)^2} \tag{A9}$$

$$=\frac{Gb}{2\pi(1-\nu)}\cdot\frac{\cos\alpha\cos 2\alpha}{r}\,. \tag{A10}$$

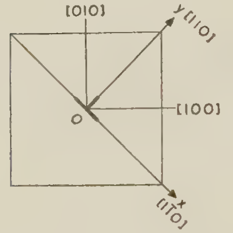

Fig. 8. The coördinate system for an edge dislocation, with xz plane being the slip plane and Oz the dislocation line which is parallel to [001].

Averaging q^2 over a cylinder of radius r coaxial with the dislocation, and then again integrating with respect to r, we obtain

$$\langle\nu-\nu_0\rangle_{\text{Edge}}=\frac{49}{1016}\frac{72}{\pi^2}\lambda^2\left(\frac{e^2Q}{ha^3}\right)^2\frac{1}{\nu_0}\times(\pi a^2c_E')\ln\frac{1}{9\pi a^2c_E'}\,; \tag{A11}$$

here the value 1/7 has been inserted for the Poisson's ratio, and c_E' has the same nature as c_S'. One should note that (A10) gives a contribution having only positive value. This arises from the absence of averaging process over θ. Changing the direction of the magnetic field, contributions having negative values may also be derived for edge dislocations. In any case, with H_0//[100] we get the first moment expression just combining (A6) and (A11), thus yielding (10) in the text.

Squaring (A1) and averaging in a similar way we can find the quadrupolar second moment given as (11) in the text.

Magnetic Properties of the $FeTiO_3$-Fe_2O_3 Solid Solution Series

By Yoshikazu ISHIKAWA
Institute of Science and Technology, Tokyo University

and Syun-iti AKIMOTO
Geophysical Institute, Tokyo University

(Received June 25, 1957)

Magnetic properties of the synthesized solid solution $x\,FeTiO_3\cdot(1-x)Fe_2O_3$ of ilmenite ($FeTiO_3$) and hematite (Fe_2O_3) were investigated in detail for the whole range of $0 \leqq x \leqq 1$. On the experimental side of the study, the most suitable method for preparing the specimen with the largest intensity of magnetization was found. Changes of the Curie point, the estimated intensity of magnetization at 0°K, the Curie constant and the asymptotic paramagnetic Curie point with the composition were presented. It was found that the magnetic properties of the solid solution, $xFeTiO_3\cdot(1-x)Fe_2O_3$, could be divided into three parts, (i) $x=1$, (ii) $1>x\gtrsim 0.5$ and (iii) $0.5>x\geqq 0$: Pure ilmenite ($FeTiO_3$) is antiferromagnetic below 55°K and the specimens for $1>x\gtrsim 0.5$ are very strongly ferromagnetic and for $0.5>x\geqq 0$ they are again antiferromagnetics on which feeble parasitic ferromagnetism is superimposed.

On the theoretical side of the study, these magnetic properties were discussed by using the approximation of molecular field. It was shown that we could explain an outline of the magnetic properties of the solid solution if we assume that the tetravalent Ti ions always occupy one of the two sublattices in the specimens for $1\geqq x\gtrsim 0.5$, while such an ordering of Ti ions and Fe ions is disturbed for $0.5>x\geqq 0$.

§ 1. Introduction

Both hematite (α-Fe_2O_3) and ilmenite ($FeTiO_3$) which are of rhombohedral crystal structure have been considered as antiferromagnetic substances1),2). Below its Néel point of about 950°K, hematite shows a parasitic ferromagnetism with a transition temperature of magnetic susceptibility around 260°K3). Néel proposed an idea that this parasitic ferromagnetism is due to an imperfect compensation of two antiferromagnetic sublattices4). Although many experiments have been carried out on this substance5),6),7), no decisive explanation of the magnetic properties of hematite has not yet been attained. On the other hand, very little work has been done8),9) with respect to the detailed magnetic properties of ilmenite which has recently been found to be antiferromagnetic below 68°K by Bizette and Tsai2). Practically nothing has been known about the spin orientation or its interaction in the antiferromagnetic state.

A systematic investigation of the solid solution of hematite and ilmenite, $xFeTiO_3\cdot(1-x)Fe_2O_3$, was first carried out by Pouillard10), who found hematite and ilmenite form solid solution only for two limited ranges of composition ($1\geqq x\geqq 0.66$ and $0.33\geqq x\geqq 0$), when the specimens are prepared by sintering at 950°C for two hours. Nicholls proposed a phase diagram of hematite and ilmenite by making use of this result11). We have found that, when the specimens are quenched from the sintering temperature higher than 1100°C, it is possible to make the solid solution in the whole range of the composition12).

On the magnetic properties of this solid solution series, Nagata, Akimoto and Uyeda found that certain minerals composed of the solid solution of hematite and ilmenite have very strong ferromagnetism13), sometimes playing a very important role in the magnetic properties of the rocks, especially in the characteristics of the thermoremanent magnetism. For example, the existence of the ilmenite-hematite solid solutions results in the self-reversal of thermoremanent magnetism of some rocks14). Since the ferromagnetism of the ilmenite-hematite solid solution series was discovered, experimental studies on this solid solution series have been rather systematically continued by ourselves and many other investigators for both natural minerals and synthesized specimens[12),15),16)]. But any comprehensive experiments and plausible explanation of the experimental results have not yet been presented up to now.

The characteristics of the magnetic properties of this solid solution series can be summarized into the following three parts, which must be explained consistently when we try to discuss the magnetic properties completely.

a) The ferromagnetism of this ilmenite-solid solution series appears only in the limited region of the composition; that is, the solid solution of $x\mathrm{FeTiO_3}\cdot(1-x)\mathrm{Fe_2O_3}$ is ferromagnetic only for $0.95 \geqq x \gtrsim 0.5$.

b) As for the strong ferromagnetic specimens, the intensity of magnetization increases almost linearly with temperature from near the Curie temperature down to the liquid nitrogen temperature. It has been reported that some compounds of the spinels show the same thermomagnetic characteristics for the very restricted conditions[17),18)].

c) The intensity of magnetization of the ferromagnetic specimen is remarkably affected by heat treatments[19)], indicating that the magnetization of this series has a great correlation with the ordering of cations.

In the experimental part of the present study, the authors will investigate these magnetic properties of the solid solution synthesized with special care of the ordering of cations in the whole range of the composition, and in the theoretical part they will discuss the experimental results as consistently as possible by using the molecular field theory.

Part I. Experimental Studies

§ 2. Preparation of Specimens

The specimens dealt with in the present study were prepared by the usual ceramic method. Pure hematite and ilmenite were prepared in advance by the method described in the previous paper[9)]. Both were ground in an agate mortar to pass a 200 mesh sieve and were mixed in the desired proportion. Then the mixture of pure hematite and ilmenite, sealed in a quartz tube evacuated approximately to 10^{-3} mm mercury, was sintered at high temperatures for a long time.

It is, however, necessary to find the most suitable heat treatment for preparing the specimens perfectly ordered or having the largest intensity of magnetization. Thermomagnetic curves of the specimens prepared by various heat treatments are shown in Fig. 1.

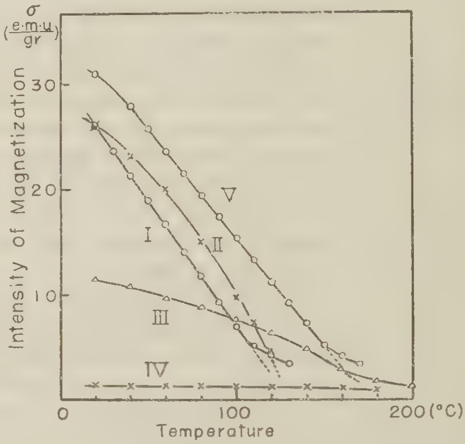

Fig. 1. Intensity of magnetization in a field strength of 8500 Oe vs. temperature of the specimens prepared by various heat treatments.

I. a specimen prepared by quenching from 1200°C after being maintained at this temperature for more than 12 hours.

II. a specimen prepared by quenching from 1200°C after being maintained at this temperature for 6 hours.

III. a specimen prepared by quenching from 1300°C.

IV. a specimen prepared by quenching from 1370°C.

V. a specimen prepared by slow-cooling from 1200°C.

Before heat treatment each specimen had the same original composition of about $0.7\,\mathrm{FeTiO_3}\cdot 0.3\,\mathrm{Fe_2O_3}$. It was found from this experiment that we could obtain the specimen having the largest intensity of magnetization at 80°K when it was quenched from 1200°C after being maintained at this temperature for more than 12 hours. The thermomagnetic curve of this specimen is almost linear down to 80°K. This method of preparation is denoted in the present paper as I hereafter. When, on the other hand, the specimen was quenched from

1200°C after being kept at this temperature for less than six hours, the thermomagnetic curve is convex, the intensity of magnetization at 80°K being fairly smaller than that of the specimen prepared by the method I. Of course, the solid reaction proceeded enough even in this case, the prepared specimen having the same composition and the crystal parameters as that prepared by the method I. This method is denoted as II. The specimen prepared by this method seems to be in the partially ordered state. When the temperature of sintering is higher than 1200°C, the ordering seems to be disturbed by the thermal agitation, intensity of magnetization getting smaller with the elevation of the sintering temperature. It is further remarked that when the sintering temperature was higher than 1300°C some amounts of oxygen might flow into the quartz tube through its wall so that the composition of the specimen deviated from the expected value towards the hematite and some Fe_2TiO_5-$FeTi_2O_5$ solid solution series was also produced[20]. It was also found that we could obtain the homogeneous specimen even when it was prepared by cooling slowly in the furnace from 1200°C. Its thermomagnetic characteristic is, however, not better than that prepared by the method I.

§ 3. X-ray Analysis and Chemical Analysis

X-ray analysis of this ilmenite-hematite solid solution series has already been carried out by one of the authors for both synthesized specimens and natural minerals in the whole range of the solid solution[12]. Those results are reproduced in Fig. 2 and 3, in which the results obtained thereafter are also plotted. The chemical analysis was carried out by Katsura, Dept. of Geochemistry, Tokyo Institute of Technology, for the three main components, FeO, Fe_2O_3 and TiO_2 and the details were described in the previous paper[12].

It was confirmed from the X-ray analysis carried out by a *"Norelco"* X-ray diffractometer that the specimens dealt with here were of sufficiently pure single phase of the rhombohedral crystal structure. Some specimens contained a trace of $FeTi_2O_5$-Fe_2TiO_5 solid solution series, but it was acertained that they had negligible influence on the magnetic properties of the specimens[20]. No other trace such as titanomagnetite, ($y Fe_2TiO_4 \cdot (1-y) Fe_3O_4$) of the cubic structure could be observed at all.

In Fig. 2, the chemical composition of the specimens is plotted on a FeO-Fe_2O_3-TiO_2 ternary diagram and in Fig. 3 the volume V, of the unit cell of the crystal, calculated from the two crystal parameters a_{rh} and α_{rh} of the rhombohedral structure, is plotted against the mol. per cent of $FeTiO_3$. This figure shows that the volume of the unit cell varies linearly with the composition from 100.43Å^3 of α-Fe_2O_3 to 105.22Å^3 of $FeTiO_3$. Hence, the chemical composition of the specimens were determined in the present study from their volume of unit cell determined by X-ray analysis on the assumption that the above empirical linear relation always hold true. Such a method of determination of the composition seems to be more plausible than chemical analysis when the specimen involves

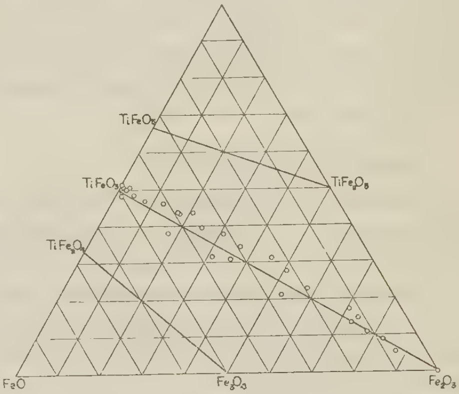

Fig. 2. Chemical composition of the $FeTiO_3$-Fe_2O_3 series specimens represented on a FeO-Fe_2O_3-TiO_2 ternary diagram in mol. per cent.

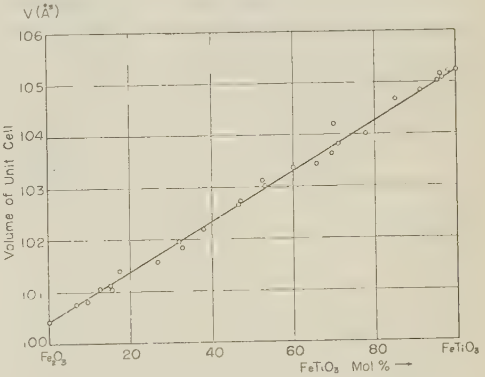

Fig. 3. Volume of unit cell vs. composition of the $FeTiO_3$-Fe_2O_3 solid solution series.

some other impurities of oxides such as $FeTi_2O_5$-Fe_2TiO_5 solid solution series. For some specimens used in this paper, the chemical analysis was also performed and the compositions determined by both methods were found to accord well with each other.

§ 4. Thermomagnetic Measurement

The magnetic properties of ilmenite-hematite solid solution series, $x\mathrm{FeTiO_3}\cdot(1-x)\mathrm{Fe_2O_3}$ can be classified into three groups; that is, i) $x=1$, ii) $1>x\gtrsim 0.5$ and iii) $0.5>x\geqq 0$. Therefore they are discussed separately in the following.

4. 1. *Intensity of Magnetization*

The intensity of magnetization was measured by means of the magnetic balance described elsewhere[9]. The amounts of the specimens used for this measurement were a few milligrams as for the strong ferromagnetic ones. Consequently the largest error is caused from the weighing of specimen, it is, however, estimated to be less than four per cent.

i) $x=1$

Pure ilmenite, being found to be antiferromagnetic at very low temperatures, will be dealt with in the next section (4. 2).

ii) $1>x\gtrsim 0.5$

In Fig. 4 several examples of the thermomagnetic curve down to the liquid nitrogen temperature in a field strength of 8500 Oe are shown. The specimens used are the ones either prepared by the method I described in § 2 or of which magnetization were intensified by an appropriate heat treatment after they were prepared by the method II[19]. The latter is denoted as **h** in the figure. A few specimens of which thermomagnetic curve were extended to the liquid helium temperature in the figure were measured at Research Institute for Iron, Steel and Other Metals, Tôhoku University, for the field strength of 5000 Oe. The field dependence of magnetization of the specimens at 80°K are given in Fig. 5. It is seen in this figure that the magnetization is almost saturated by the field strength of 8500 Oe for the specimens of $x<0.8$, while it is far from saturation at the same field strength for the specimens of $x>0.8$.

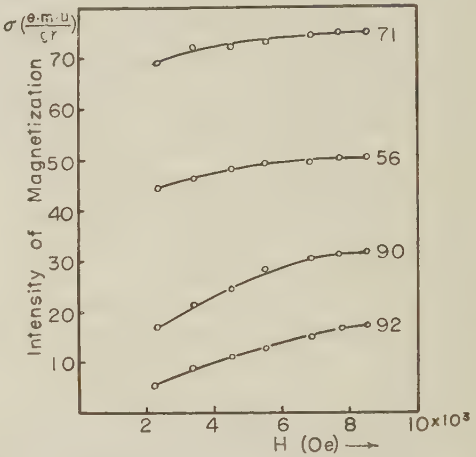

Fig. 5. Intensity of magnetization vs. magnetic field strength at 80°K. Numerals attached to each curve indicate the $FeTiO_3$ mol. per cent.

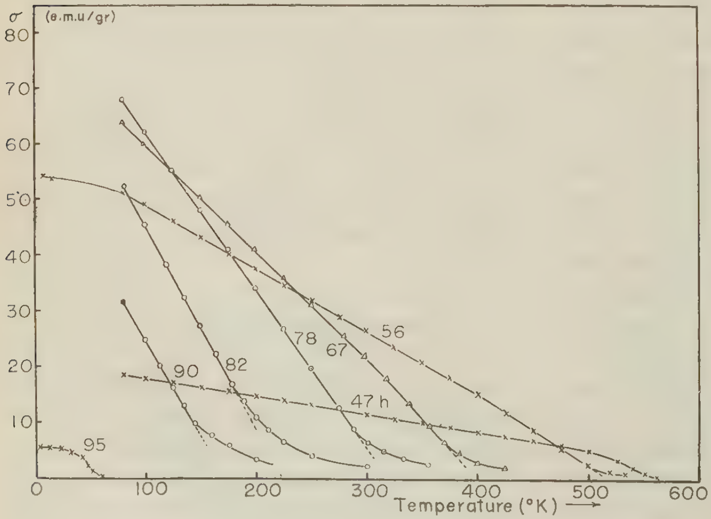

Fig. 4. Intensity of magnetization in a field strength of 8500 Oe vs. temperature for the specimens of $0.95\geqq x\geqq 0.47$. Numerals attached to each curve indicate the $FeTiO_3$ mol. per cent.

As was shown in Fig. 4, it is a remarkable characteristic for the thermomagnetic curve of this solid solution series that magnetization changes almost linearly with temperature to the liquid nitrogen temperature and then approaches to the final value of 0°K with the decreasing slope.

Hence we can not extrapolate the thermomagnetic curve linearly to 0°K in the estimation of the saturation value of magnetization at that temperature. Then, the following procedure was tentatively adopted to obtain the approximate value of the magnetization at 0°K, $\boldsymbol{J}(0)$.

$$\boldsymbol{J}(0)=\frac{\boldsymbol{J}_0+\boldsymbol{J}(80)}{2},$$

where $\boldsymbol{J}(80)$ and $\boldsymbol{J}_0$ indicate respectively the observed value of magnetization at 80°K and the one calculated by assuming that the linear character of thermomagnetic curve can be extrapolated to 0°K without any modification.

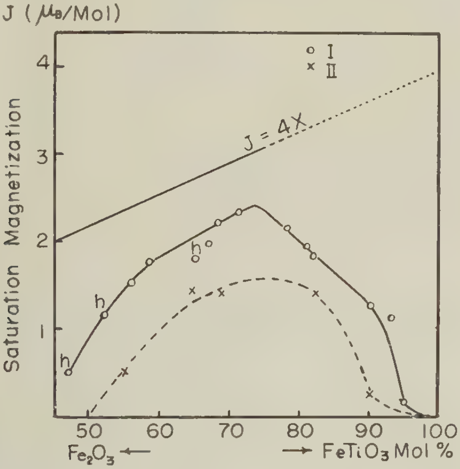

Fig. 6. Estimated saturation magnetization at 0°K vs. composition for the specimens of $1>x\geqq 0.47$. The solid straight line indicates the theoretical value.
○ : the specimens prepared by the method I.
× : the specimens prepared by the method II.
h : the specimen of which magnetization was intensified by heat treatment after being prepared by the method II.

Fig. 6 shows the dependence of the estimated value of the saturation magnetization at 0°K upon the composition of the solid solution series. In this figure the intensity of magnetization is expressed by the Bohr magneton number per one molecule of $x\mathrm{FeTiO_3}\cdot(1-x)\mathrm{Fe_2O_3}$. Although such an estimation as mentioned above includes a fairly large error for the specimens of $1>x>0.8$, the general tendency that the magnetization attains to the largest value around $x=0.75$ and decreases on both sides of the composition seems to be true. In the figure the magetization of the specimens prepared by the method II is also plotted for comparison. The above-mentioned general tendency remains unchanged even in this case.

iii) $0.5>x\geqq 0$

All specimens in this region are feeble ferromagnetics when they are quenched from any temperature higher than 1100°C. The thermomagnetic curve down to the liquid nitrogen temperature are given in Fig. 7 and the intensity of magnetization at 80°K for a field strength of 9350 Oe is plotted in Fig. 8 against the composition of the specimen. It is clearly seen in these figures that the

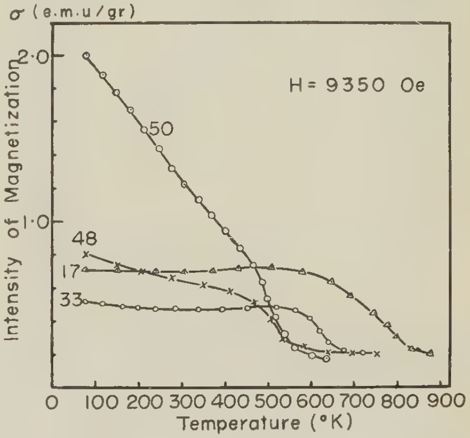

Fig. 7. Intensity of magnetization in a field strength of 9350 Oe vs. temperature for the specimens of $0.5>x>0$. Numerals attached to each curve indicate the FeTiO₃ mol. per cent.

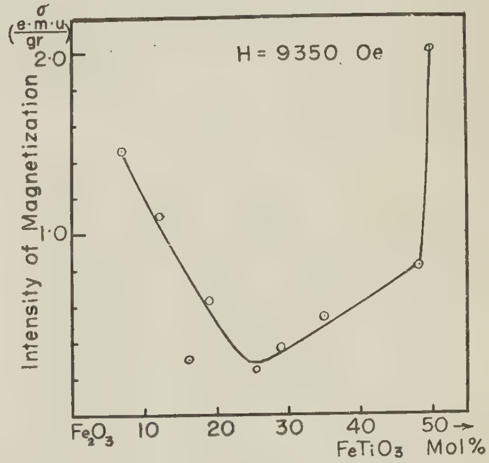

Fig. 8. Intensity of magnetization in a field strength of 9350 Oe at 80°K vs. composition for the specimens of $0.5>x>0$.

magnetic properties of the solid solution series change with their composition very abruptly when x approaches to 0.5. It must be noticed in Fig. 7 that the thermomagnetic curves of the specimen for $x=0.50$ and $x=0.48$ differ one another remarkably in their general modes; the thermomagnetic curve of the specimen of $x=0.50$ is distinguished in a large temperature coefficient, $\partial J/\partial T$, from that of $x=0.48$. It must be further noted that, as to the specimens of x greater than 0.07, a discontinuous change in magnetization at the lower temperatures as Morin found in α-Fe_2O_3[3] was not observed.

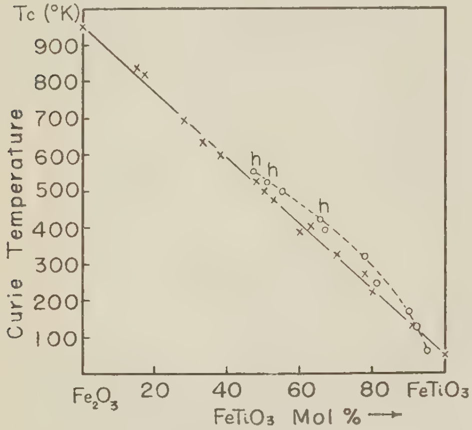

Fig. 9. Variation of Curie temperature with composition in the $FeTiO_3$-Fe_2O_3 series.

×: the specimens prepared by the method II.

○: the specimens prepared by the method I or of which magnetization was intensified by heat treatment after being prepared by the method II.

We plotted the Curie point of the specimens against their compositions in Fig. 9, where it was found that the Curie point of the specimens with the weak magnetization (those for $x<0.5$ or those prepared by the method II) changes almost linearly from 950°K of α-Fe_2O_3 to 55°K of $FeTiO_3$, but as for the specimens of which magnetization was intensified the Curie point deviated distinctly from this line towards the higher temperature side. These facts will be discussed in detail in the theoretical considerations of the second part of this paper.

4. 2. *Magnetic Susceptibilities*

Change in the magnetic susceptibility with temperature was also measured by the magnetic balance. The specimens of 100~200 milligram in their weight were used in this case. The specimens for $0.5>x\geq 0$ were measured in the atmospheric pressure, while for $1.0\geq x\geq 0.5$ in the state sealed into a quartz tube evacuated below 10^{-3} mm mercury.

In Fig. 10, the change in the reciprocal magnetic susceptibility with temperature is given. In this figure it must be noted first of all that pure ilmenite is antiferromagnetic below 55°K as has been reported by Bizette and Tsai[2], but its Néel point is lower than that of their specimen. The pure ilmenite specimen used in the present study has the very high electrical resistivity ($10^6\,\Omega$-cm at the room temperature) and is expected to have no trace of Fe^{3+}. This was also confirmed by the chemical analysis. This measurement at the very low temperatures was also carried out at Research Institute for Iron, Steel and Other Metals, Tôhoku University.

The reciprocal magnetic susceptibility versus temperature curve ($1/\chi-T$ curve) of the specimens for $x<0.5$ shows a particular mode which can be interpreted as the simple superposition of the parasitic ferromagnetism upon the antiferromagnetism proper to this sub-

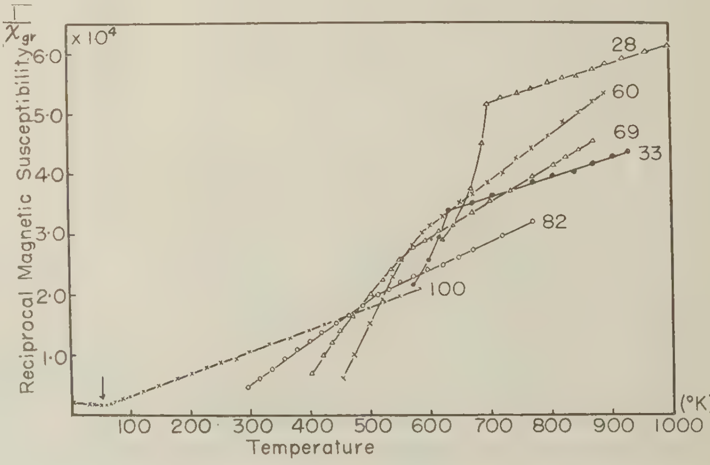

Fig. 10. Reciprocal magnetic susceptibility vs. temperature. Numerals attached to each curve indicate the $FeTiO_3$ mol. per cent.

stance. On the other hand the $1/\chi-T$ curve for the specimen around $x=0.5$ shows a mode unique to the ferrimagnetic substances: a concavity towards the temperature axis is clearly seen in the curve. It must be further noted that when x approaches 1, the $1/\chi-T$ curve approaches to the straight line which is distinguished from that of the ordinary ferrimagnetics.

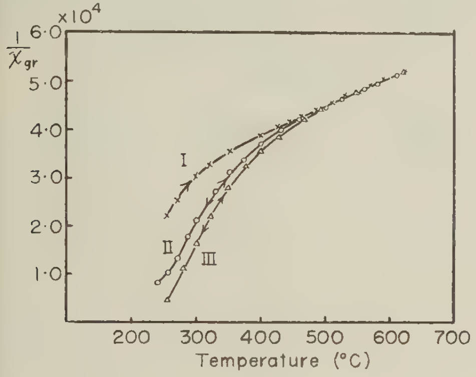

Fig. 11. Reciprocal magnetic susceptibility vs. temperature for the specimen of $x=0.5$.

We showed in Fig. 11 the change in the reciprocal magnetic susceptibility with temperature of the specimen for $x=0.5$ in detail. The specimen originally prepared by the method I has the very weak magnetization. When it is heated up above its Curie point, the reciprocal magnetic susceptibility follows the curve I, but in the cooling process it follows the curve II. This shows the magetization was intensified appreciably by cooling under the magnetic field. The $1/\chi-T$ curve of the specimen in re-heating and re-cooling process coincides well with the initial cooling curve. Furthermore, we could make this specimen strongly ferromagnetic by the heat treatment described in another paper[19]. The $1/\chi-T$ curve of the specimen of which magnetization was intensified in this way follows the curve III. It may be worthwhile to note that in any cases the magnetic susceptibilities coincide well at high temperatures within the experimental errors. Hence, we may need not pay too much attention in the measurement of magnetic susceptibility by what method the specimens were prepared.

We could find that the $1/\chi-T$ curve for all the specimens obeys the Curie-Weiss' law, $\chi=C_M/T-\Theta$, quite well at high temperatures. The values of C_M and Θ were determined by means of the method of least squares, their variations with composition of the solid solution series being given in Fig. 12 and Fig. 13. The cross marks in these figures are the

values determined by using the following equation,

$$\frac{1}{\chi}=\frac{T-\Theta}{C_M}-\frac{\sigma}{T-\theta}\,.$$

It is suggested in Fig. 12, by taking the sign of Θ into consideration, that there are ferromagnetic coupling in the specimens for $1>x>0.55$ and when the composition approaches to 0.5 antiferromagnetic coupling comes to predominate. The latter result is very consistent with other experimental results. However, we can also find that the value of C_M decreases and the value of Θ increases in holding its positive sign as the composition change from $x=1$ to $x=0.5$. This fact can not be explained by such a simple theory as will be stated in the second part of the present paper.

Part II. Theoretical Considerations

§ 5. Super Exchange Interactions in the Rhombohedral Structure

Before we discuss the magnetic properties of the solid solution series, it is necessary to understand fully the configuration of cations and the exchange interaction between them in the rhombohedral sesquioxide. This has been recently discussed by Li[21] and Iida[22].

In the rhombohedral sesquioxide the cations form a hexagonal lattices but they deviates slightly from the hexagonal lattice points towards the direction of arrows illustrated in Fig. 14. As we can see in the figure the cation sites can be divided into four sublattices; A_1, A_2, B_1 and B_2. Such cation pairs along C axis as A_1-B_2 or B_1-A_2 form the pseudo-molecules.

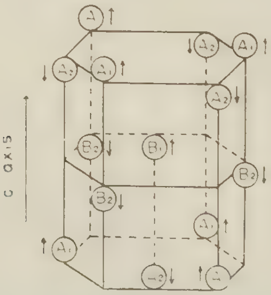

Fig. 14. Cation lattice in a rhombohedral sesquioxide. The cations deviate from the hexagonal sites towards the direction of arrows.

Then the exchange interaction between these cations can be classified as is given in Table I. In the third column of the table, the number of the nearest neighbour having the same kind of interaction is given. The angles between metal-oxygen-metal tabulated in the last column were calculated by Iida for α-Fe$_2$O$_3$. As this angles show, Γ_a and Γ_b; the interactions between the cations on different layers are expected to be stronger than Γ_c, i.e. those between the cations on the same layer. This is because the overlapping of electrons of cations and oxygen is larger for Γ_a and Γ_b than for Γ_c. Hence, the magnetic lattice might be chiefly determined by these interactions. It must be further noticed that Γ_a and Γ_b have the same sign for α-Fe$_2$O$_3$ but different for Cr$_2$O$_3$. Li proposed that Γ_d, the interaction between cations of the pseudo-molecule plays also an important role on the construction of magnetic lattice, while Iida has omitted it as the secondary effect. We also disregard this interaction in the present paper.

Table I. The configurations of Me–O–Me with close contacts between Me and O. The angle ∠Me O Me is calculated for αFe$_2$O$_3$. n is the number of the nearest neighbour having the same kind of interaction.

Exchange interaction	Cation sites	n	∠Me O Me
Γ_a	$A_i\ B_i$	6	132°41′
Γ_b	$A_i\ B_j (i\neq j)$	3	116°59′
Γ_c	$A_i\ A_j$ $B_i\ B_j$	3	94°20′
Γ_d	$A_j\ B_i$ (pseudo molecule)	1	88°23′

§ 6. Cation Distribution in Hexagonal Lattice

In order to understand the magnetic properties of the solid solution series, we must know how the cations distribute among four sublattices described in § 5. It has recently been confirmed by both X-ray* and neutron analysis* that the crystal structure of the ferromagnetic specimen in the solid solution series keeps the same space group $R\overline{3}$ as pure ilmenite[23]. In other words we could detect a kind of super structure of Ti ions and Fe ions, where the layers involving Ti ions selectively alternate along *C*-axis with the layers involving only Fe ions. Accordingly we can assume with sufficient plausibility that Ti ions occupy only two sublattices B_1 and B_2 in our rhombohedral structure for the ferromagnetic specimen which we denote hereafter as the ordered specimen. Generally speaking, there are four possible configurations of Fe^{2+}, Fe^{3+} and Ti^{4+} ions among four sublattices and the number of occupation of these ions on each sublattice is given in Table II for the solid solution of $x FeTiO_3 \cdot (1-x) Fe_2O_3$.

---

* The results of the X-ray analysis for a single crystal of the ferromagnetic specimen of the FeTiO$_3$-Fe$_2$O$_3$ solid solution series will be published separately in near future.

In this table, the configuration I and II correspond to the cases when each Fe^{2+} and Ti^{4+} ions occupy the one of the four sublattices preferentially; that is, A_1 and B_1 for configuration I and A_1 and B_2 for configuration II. But in the configuration III, Fe^{2+} and Fe^{3+} distribute at random among A_1 and A_2 sublattices and Ti^{4+} and Fe^{3+} among B_1 and B_2 sublattices. Configuration IV is the case when all ions distribute at random among the cation sites, corresponding to the disordered state.

Table II. Possible distributions of Fe^{2+}, Fe^{3+} and Ti^{4+} ions among four sublattices and the number of the occupation of these ions on each sublattice in $x TiFeO_3 \cdot (1-x) Fe_2O_3$ solid solution series.

	I	II	III	IV
A_1	$Fe^{2+}\ \frac{1}{2}$	$Fe^{2+}\ \frac{1}{2}$	$Fe^{2+}\frac{x}{2}\ Fe^{3+}\frac{(1-x)}{2}$	$Fe^{2+}\frac{x}{4}\ Ti^{4+}\frac{x}{4}\ Fe^{3+}\frac{(1-x)}{2}$
A_2	$Fe^{2+}\left(x-\frac{1}{2}\right)Fe^{3+}(1-x)$	$Fe^{2+}\left(x-\frac{1}{2}\right)Fe^{3+}(1-x)$	〃	〃
B_1	$Ti^{4+}\ \frac{1}{2}$	$Ti^{4+}\left(x-\frac{1}{2}\right)Fe^{3+}(1-x)$	$Ti^{4+}\frac{x}{2}\ Fe^{3+}\frac{(1-x)}{2}$	〃
B_2	$Ti^{4+}\left(x-\frac{1}{2}\right)Fe^{3+}(1-x)$	$Ti^{4+}\ \frac{1}{2}$	〃	〃

In pure ilmenite Fe^{2+} ions always occupy the A sublattice, so the configuration such as Fe^{2+} ions enter into the B sublattice seems to be unnatural for the ordered specimens. Besides, the simple consideration of the magnetic properties excludes this configuration as will be stated in the next paragraph. Consequently such a configuration was omitted for the ordered structure from the outset.

It is very difficult to know which of these three configurations I, II and III is the most stable and is realized in the ordered specimens, because it can be determined only by the careful X-ray or neutron diffraction studies. In the present stage, we know nothing about it, so we calculated the electrostatic energy of these three configurations to see which is the more stable. The calculation was carried out for the specimen of $x=0.5$ where the superstructure within the layer as well as along *C*-axis can be established.

In Fig. 15, the super lattices established for the configuration I and II are shown, and in the bottom of the figure, the calculated gains of the electrostatic energy by forming the superstructure are presented. $E^{(1)}$ is the value calculated by considering only the nearest neighbour interaction, while in the case of $E^{(2)}$ the interaction is considered up to the second nearest neighbour. In these calculations the energy for the disordered state is taken null and the unit is arbitrary. As the Coulomb force is very slow to converge, we must consider the interaction between the more remote neighbour to obtain the more accurate value of the energy. We can see, however, from these two calculations that the energy difference between these two configurations is getting less when we consider the interaction more completely. In other words it is expected that the configuration I and II are realized with an almost equal probability. Consequently, the configuration III seems to be the most probable for the ordered specimens so long as we consider the electrostatic energy alone, since the configuration III may be regarded as the average state of the configuration I and II. Hence, in the following discussions we always assume this configuration for the ordered state.

---

§ 7. Simple Explanation of the Magnetic Properties of the $FeTiO_3$-Fe_2O_3 Solid Solution Series

In this paragraph, we will discuss briefly an outline of the magnetic properties of the solid solution series. The more detailed discussion is stated in the next paragraph.

i) *Antiferromagnetism of ilmenite* ($FeTiO_3$)

We have already confirmed in § 4 that ilmenite is antiferromagnetic below 55°K. This temperature is a little lower than that of ilmenite measured by Bizette and Tsai. Considering that their specimen is a natural mineral, this discrepancy may be due to the presence of an impurity in their specimen. Shomate reported a marked hump on the heat capacity versus temperature curve at 58°K for synthesized ilmenite[24]. If we suppose this temperature corresponds to the Néel point, our Néel temperature agrees well with it.

In order to understand the magnetic structure of antiferromagnetic ilmenite, it is very important to know the valency of Ti ions. We have found through the study of the electrical conduction of the $FeTiO_3$-Fe_2O_3 solid solution series it is more plausible to assume that Ti ions is always tetravalent in the solid solution[25]. So we assumed in the following discussion Ti^{4+} ions play no part on the magnetic coupling.

Accordingly, we can consider the two different magnetic structures for the antiferromagnetic ilmenite which are given in Fig. 16 schematically.

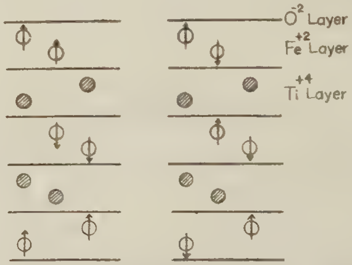

Fig. 16. Schematic illustrations of two possible antiferromagnetic structure in ilmenite.

We can explain the outline of the magnetic properties of the solid solution by using either of these models.

ii) $1>x\gtrsim 0.5$: *ferromagnetic region*

In this region, the ordering of Fe and Ti ions established for pure ilmenite is retained. So, the cation configuration is assumed to be the case III. If we put another assumption for the specimens of $0.75>x>0.5$ that the interaction Γ_a and Γ_b are negative and their strengthes are fairly large compared with Γ_c, the magnetic moment on each layer is orientated in the same direction, coupling antiferromagnetically between neighbouring layer. Consequently, the saturation magnetization of the solid solution, $x FeTiO_3\cdot(1-x) Fe_2O_3$ at 0°K can be given for this region of x by

$$J=x\cdot J_{Fe^{2+}}=4x$$

where J is the magnetization per one molecule of the solid solution expressed by the number of Bohr magnetons. In Fig. 6 this value is drawn by a solid line. Though the experimental values are deviated from this line, this configuration may be the most plausible, because the discrepancy becomes larger when we assume the other configurations.

The decrease in the magnetization for $x>0.75$ may be attributed to the following reason. So long as the magnetic ions in B layers are few and the interaction between A and B layer is weak, the magnetic moments on the A layer are orientated antiparallel with each other by the interaction within the layer and they can not align in the same direction as is assumed in the above consideration. Consequently, the total magnetization decreases with the increase of the number of ions coupled antiferromagnetically on the A layer, tending to zero for pure ilmenite.

It may be very probable to suppose that the specimens are not completely ordered* since they were prepared by quenching from high temperatures. The theoretical value of the magnetization for $0.75>x>0.5$ can be approached more closely the experimental value when we consider this imperfect ordering.

iii) $0.5>x\geqq 0$: *antiferromagnetic region*

When the concentration of $FeTiO_3$ is less than 50 mol. per cent, the state that Fe^{2+} and Ti^{4+} distribute at random between A and B lattices is assumed to be more stable. Consequently these two sublattices become equivalent, the magnetic structure being antiferromagnetic as a whole. The reciprocal magnetic susceptibility versus temperature curve which was given in Fig. 10 clearly shows this character at high temperatures. It is, however, impossible that these two sublattices become completely equivalent, so the parasitic ferromagnetism appears owing to an uncompensation of magnetization between two sublattices. When the composition approaches to $x=0.5$, the tendency that Fe^{2+} ions concentrate on A layers and Ti^{4+} ions B layers begins to appear, resulting in the abrupt increase of the parasitic ferromagnetism around $x=0.5$.

It has already been shown in the experimental part of the present paper and in another paper[19)] that such an ordering of Ti^{4+} and Fe^{2+} ions could be either established or disturbed by the appropriate heat treatments especially for the specimen of x around 0.5. The mechanism of the order-disorder transformation of this substance, however, is so complicated that it will be discussed elsewhere in near future.

§ 8. Detailed Discussion

In the above paragraph we have proposed a model which can explain the outline of the magnetic properties of the solid solution series. In this paragraph we shall discuss them more in detail by using the molecular field theory and examine whether such an approximation can be applied successfully to the interpretation of the magnetic properties of this rhombohedral solid solution series in the same manner as has been done for many ferrites[26)].

Since we have assumed in the previous paragraph that the cations distribute at random within each layer, the molecular field coefficient in the structure is reduced to α and γ which correspond respectively to the interaction within a layer and between layers, being expressed by the following equations,

$$\begin{aligned}\alpha&=2(3\Gamma_c)/Ng^2\mu_B^2\\ \gamma&=2(6\Gamma_a+3\Gamma_b)/Ng^2\mu_B^2\,.\end{aligned}\qquad(8.1)$$

Then, the molecular field acting on each magnetic ion on different layer becomes

$$\begin{aligned}\vec{h}_{IA}&=(1-x)\gamma_{I\,II}\vec{J}_{IIB}+x\alpha_{I\,I}\vec{J}_{IA}+(1-x)\alpha_{I\,II}\vec{J}_{IIA}\\ \vec{h}_{IIA}&=(1-x)\gamma_{II\,II}\vec{J}_{IIB}+x\alpha_{II\,I}\vec{J}_{IA}+(1-x)\alpha_{II\,II}\vec{J}_{IIA}\\ \vec{h}_{IIB}&=(1-x)\alpha_{II\,II}\vec{J}_{IIB}+x\gamma_{II\,I}\vec{J}_{IA}+(1-x)\gamma_{II\,II}\vec{J}_{IIA},\end{aligned}\qquad(8.2)$$

where $\vec{h}_{IA}$, $\vec{h}_{IIA}$ and $\vec{h}_{IIB}$ indicate the molecular field acting on a Fe^{2+} ion on the A sublattice, that on Fe^{3+} ion on the A sublattice and that on Fe^{3+} ion the B sublattice respectively. $\gamma_{I\,II}$, $\alpha_{I\,I}\cdots$ indicate the molecular field coefficient between Fe^{2+} (I) and Fe^{3+} (II) ions, Fe^{2+} (I) and Fe^{2+} (I) ions$\cdots$. $\vec{J}_{IA}$ and $\vec{J}_{IIA}$ are the magnetic moment per gram ion of Fe^{2+} and Fe^{3+} on the A sublattice, and $\vec{J}_{\mathrm{IIB}}$ is that of Fe^{3+} on the B sublattice. The magnetic moment J at any temperature T is given by

---

* This was also expected from the neutron diffraction analysis. (Private Communication from Dr. G. Shirane)

$$\vec{J}_{\mathrm{IA}}(T)=\vec{J}_{\mathrm{IA}}(0)\,B_J(\vec{H}+\vec{h}_{\mathrm{IA}}/kT)\,. \tag{8.3}$$

i) *The Curie point*

We have found in § 4 that the Curie points of the series vary almost linearly from the Curie point of α-$\mathrm{Fe_2O_3}$ to that of $\mathrm{FeTiO_3}$ when the magnetization is weak or the ordering is not complete, whereas some deviation from this straight line was seen when the magnetization becomes large. In this section we show that such a characteristics can be derived from the above theory.

The Curie temperature of the solid solution is determined from the following equation

$$\begin{vmatrix} x\alpha_{\mathrm{I\,I}}-T/C(x) & (1-x)\alpha_{\mathrm{I\,II}} & (1-x)\gamma_{\mathrm{I\,II}} \\ x\alpha_{\mathrm{I\,II}} & (1-x)\alpha_{\mathrm{II\,II}}-T/C(x) & (1-x)\gamma_{\mathrm{II\,II}} \\ x\gamma_{\mathrm{I\,II}} & (1-x)\gamma_{\mathrm{II\,II}} & (1-x)\alpha_{\mathrm{II\,II}}-T/C(x) \end{vmatrix}=0, \tag{8.4}$$

where $C(x)$ is the Curie constant per gram ion of the solid solution of $x\mathrm{FeTiO_3}\cdot(1-x)\ \mathrm{Fe_2O_3}$. In special cases for $x=1(\mathrm{FeTiO_3})$, and $x=0(\mathrm{Fe_2O_3})$, the Curie temperatures are reduced from eq. (8.4) as follows,

$$\begin{aligned} T_{\mathrm{FeTiO_3}}&=C(1)\,\alpha_{\mathrm{I\,I}} \\ T_{\mathrm{Fe_2O_3}}&=C(0)\,(\alpha_{\mathrm{II\,II}}+\gamma_{\mathrm{II\,II}})\,. \end{aligned} \tag{8.5}$$

In order to solve the eq. (8.4) for general case, we neglect the quadratic terms of α because α is very small compared with γ. The Curie point of the specimen for any x is given by a root of the following equation.

$$\begin{aligned} \left(\frac{T}{C(x)}\right)^3-\left(\frac{T}{C(x)}\right)^2[\alpha_{\mathrm{I\,I}}x+2(1-x)\alpha_{\mathrm{II\,II}}]-\left(\frac{T}{C(x)}\right)[(1-x)\,x\gamma^2_{\mathrm{I\,II}}+(1-x)^2\,\gamma^2_{\mathrm{II\,II}}] \\ -x(1-x)^2[2\alpha_{\mathrm{I\,II}}\,\gamma_{\mathrm{I\,II}}\,\gamma_{\mathrm{II\,II}}-\alpha_{\mathrm{II\,II}}\,\gamma^2_{\mathrm{I\,II}}-\alpha_{\mathrm{I\,I}}\,\gamma^2_{\mathrm{II\,II}}]=0\,. \end{aligned} \tag{8.6}$$

The last term of the equation is expected to be very small and is also neglected. Then T/C is given by

$$\begin{aligned} \frac{T}{C(x)}&=\frac{1}{2}\,[\alpha_{\mathrm{I\,I}}x+2(1-x)\,\alpha_{\mathrm{II\,II}}]+\sqrt{(1-x)x\,\gamma^2_{\mathrm{I\,II}}+(1-x)^2\,\gamma^2_{\mathrm{II\,II}}} \\ &\therefore\ \frac{1}{2}\,T_{\mathrm{TiFeO_3}}/C(1)\times x+T_{\mathrm{Fe_2O_3}}/C(0)\times(1-x)+\bar{\gamma}[\sqrt{1-x}-(1-x)]\,. \end{aligned} \tag{8.7}$$

On the other hand, in the disordered state, A and B sublattices becomes equivalent and the molecular fields $\vec{h}_{\mathrm{I}}$ and $\vec{h}_{\mathrm{II}}$ are reduced as follows by ignoring the distinction of A and B in eq. (8.2).

$$\begin{aligned} \vec{h}_{\mathrm{I}}&=\frac{x}{2}\,(\alpha_{\mathrm{I\,I}}+\gamma_{\mathrm{I\,I}})\,\vec{J}_{\mathrm{I}}+(1-x)(\alpha_{\mathrm{I\,II}}+\gamma_{\mathrm{I\,II}})\,\vec{J}_{\mathrm{II}}\,, \\ \vec{h}_{\mathrm{II}}&=\frac{x}{2}\,(\alpha_{\mathrm{I\,II}}+\gamma_{\mathrm{I\,II}}\vec{J}_{\mathrm{I}}+(1-x)(\alpha_{\mathrm{II\,II}}+\gamma_{\mathrm{II\,II}})\vec{J}_{\mathrm{II}}\,. \end{aligned} \tag{8.8}$$

Then the Curie temperature is determined from the following equation

$$\begin{aligned} \left(\frac{T}{C(x)}\right)^2-\left(\frac{T}{C(x)}\right)\left[\frac{x}{2}\,(\alpha_{\mathrm{I\,I}}+\gamma_{\mathrm{I\,I}})+(1-x)\,(\alpha_{\mathrm{II\,II}}+\gamma_{\mathrm{II\,II}})\right] \\ +\left[(\alpha_{\mathrm{I\,II}}+\gamma_{\mathrm{I\,II}})^2-(\alpha_{\mathrm{I\,I}}+\gamma_{\mathrm{I\,I}})\,(\alpha_{\mathrm{II\,II}}+\gamma_{\mathrm{II\,II}})\right]\frac{x(1-x)}{2}=0\,. \end{aligned} \tag{8.9}$$

The last term is also neglected in the same reason as in eq. (8.6), since it is expected that $(\alpha_{\mathrm{I\,II}}+\gamma_{\mathrm{I\,II}})$ may be the mean value of $\alpha_{\mathrm{I\,I}}+\gamma_{\mathrm{I\,I}}$ and $\alpha_{\mathrm{II\,II}}+\gamma_{\mathrm{II\,II}}$. Thus, the Curie temperature for the disordered state is finally expressed by

$$T/C(x)=\frac{x}{2}(T_{\mathrm{FeTiO_3}}/C(1)+\gamma_{\mathrm{II}})+(1-x)\,T_{\mathrm{Fe_2O_3}}/C(0). \tag{8.10}$$

The difference of the Curie temperature for the ordered and disordered state of the same composition is

$$(T/C)_{\mathrm{order}}-(T/C)_{\mathrm{disorder}}=\sqrt{(1-x)\,x\,\gamma^2_{\mathrm{I\,II}}+(1-x)^2\gamma^2_{\mathrm{II\,II}}}-\left[\frac{x}{2}\gamma_{\mathrm{I\,I}}+(1-x)\gamma_{\mathrm{II\,II}}\right]. \tag{8.11}$$

In order to compare this theory with the experimental results, we plotted in Fig. 17 the value of the Curie temperature divided by the Curie constant $C(x)$, $T_c/C(x)$ against the composition. As for $C(x)$ we used rather theoretical value obtained from $C(x)=xC(1)+(1-x)C(0)$, where $C(0)$ and $C(1)$ are the atomic Curie constant for Fe^{2+} and Fe^{3+} ions, being 3.00 and 4.38 respectively. These values are calculated from the assumption that the spin for Fe^{2+} ions is $j=4/2$ and for Fe^{3+} ions is $j=5/2$.

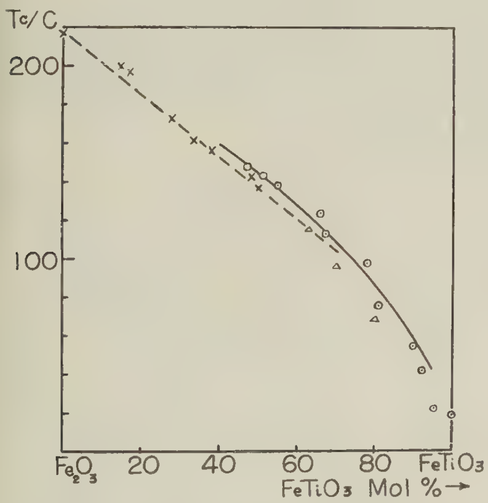

Fig. 17. Variation of the reduced Curie temperature $T_c/C(x)$ with composition in the $FeTiO_3$-Fe_2O_3 series.

⊙: ordered specimen.

△: partially ordered specimen.

×: disordered specimen.

—: theoretical value for the ordered case.

---: theoretical value for the disordered case.

In the figure cross marks indicate the Curie temperature of the disordered specimens, while triangle marks and circles show that of partially or nearly completely ordered specimens. On the other hand, the solid line represents the theoretical curve calculated from eq. (8.7) by estimating $\bar{\gamma}=150$ and the broken line was calculated from eq. (8.10) by estimating $\gamma_{\mathrm{II}}=98$. These estimated values seem not to be unreasonable, because it can be inferred from eq. (8.5) that $\gamma_{\mathrm{II\,II}}+\alpha_{\mathrm{II\,II}}=216$ and furthermore $\gamma_{\mathrm{I\,II}}$ or $\gamma_{\mathrm{I\,I}}$ are expected to be smaller than $\gamma_{\mathrm{II\,II}}$. As we can see in the figure, the agreement is fairly well. The linear decrease of the Curie temperature of the specimens prepared by the method II with composition from that of hematite to ilmenite may be only apparent, since we can not expect any linear relation between the Curie temperature and the composition from the present theory.

Besides we may expect from these considerations that the magnitude of superexchange interactions in this rhombohedral structure is given by the following order,

$$\mathrm{Fe^{3+}{-}O{-}Fe^{3+}>Fe^{3+}{-}O{-}Fe^{2+}>Fe^{2+}{-}O{-}Fe^{2+}}.$$

This is also expected from the mechanism of the superexchange interaction theoretically.

It may safely be said that the number of the interaction between Fe^{2+} and Fe^{3+} increases and that between Fe^{2+} and Fe^{2+} decreases as the cation configuration changes from disordered state to ordered state. Accordingly as was shown in the figure, it was expected that the Curie temperature of the ordered specimen is higher than that of the disordered specimen only for $x<0.75$ provided that we adopt the above-estimated values for $\bar{\gamma}$ and $\gamma_{\mathrm{I\,I}}$. But it was found from the experimental results which was shown in Fig. 9 that the increase of the Curie temperature attains to the largest value around $x=0.75$. This discrepancy may become smaller if we take the configuration I or II for the ordered state in place of III and adopt the experimental value for $C(x)$.

ii) *Magnetization*

In this section we try to explain the general mode of the thermomagnetic curve and the magnetization at 0°K by the present theory.

For this purpose, we simplify the expression of eq. (8.2) a little more by assuming that the magnetization of all ions on the same sublattice changes with the same temperature coefficient; that is, $\vec{J}_{IA}=n\vec{J}_{IIA}$ for any temperature, where $n=4/5$ in our case.

Then eq. (8.2) can be reduced to

$$\begin{aligned}\vec{h}_A&=[xn\alpha_{I\,I}+(1-x)\alpha_{I\,II}]\vec{J}_A+(1-x)\gamma_{I\,II}\vec{J}_B\\&=\alpha'\vec{J}_A+(1-x)\gamma\vec{J}_B\,,\qquad(8.12)\\\vec{h}_B&=[xn\gamma_{I\,II}+(1-x)\gamma_{II\,II}]\vec{J}_A+(1-x)\alpha_{II\,II}\vec{J}_B\\&=\gamma'\vec{J}_A+(1-x)\alpha\vec{J}_B\,.\end{aligned}$$

This equation corresponds to that for the case when one kind of magnetic ions distribute on A and B sublattices with the ratio of $1:(1-x)$. This was treated by Néel in detail[26]. So we can adopt his results if the assumption made above is permitted. According to his theory, the thermomagnetic curve takes very different modes as the values of α, α', γ and γ' change relatively. When they are in some restricted range which he denoted as **R**, the thermomagnetic curve becomes linear as is found in our specimens. The type **R** corresponds to the case when the interaction within the A layer α, α' is not so weak compared with that of ions between the neighbouring layer and they are all negative. In this case the magnetization on the A layer does not saturate even at 0°K, while that on the B layer saturates, total magnetization changing linearly with temperature.

This model seems to be able to be applied to our case, because the interaction between the layer is diluted by concentration of non magnetic ions only on the B sublattice. Then the magnetization on the A sublattice is expected not to be saturated, while that of B sublattice is saturated. Consequently the total magnetization of the specimens must take the smaller values than in the case when the magnetization is saturated on both the sublattices. The deviation of the observed value of magnetization from the theoretical curve which was seen in Fig. 6 for the specimens of $0.75>x>0.5$ may be partially attributed to this effect.

When we calculate the total magnetic moment J at 0°K mathematically by following Néel's procedure, it becomes for **R** type

$$J=(1-x)\left(\frac{|\gamma|+|\gamma'|-2|\alpha|}{2|\alpha|}\right)J_{AII}\,.\qquad(8.13)$$

This value can not be fitted to the observed value for $0.75>x>0.5$ even though we choose any proper value for γ, γ' and α, indicating that the magnetization on the A sublattice seems to be more saturated than is expected from the theory. This fact suggests that, though we assumed in the above consideration that the superexchange interaction within the layer was negative, there exists some force to align the magnetic moment parallel. Existence of such a force is also expected from the measurement of magnetic susceptibility.

iii) *Magnetic Susceptibility*

If the above molecular field approximation can be applied to the magnetic susceptibility above the Curie temperature, it must obey the following equation rather than the simple Curie-Weiss' law

$$\frac{1}{\chi}=\frac{T-\Theta}{C}-\frac{\sigma}{T-\theta}\,.\qquad(8.14)$$

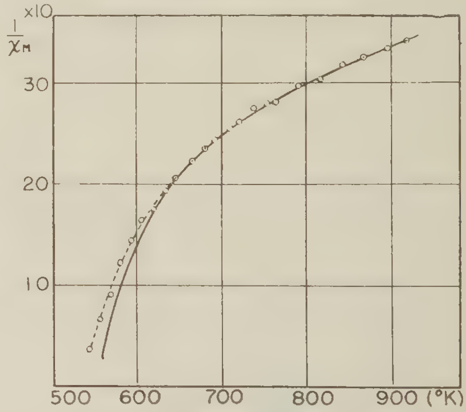

Fig. 18. Theoretical curve for $1/\chi_M=(T+854)/4.61-17733/(T-496)$ and the experimental values for the specimen of $x=0.5$. (the case III in Fig. 11)

We showed in Fig. 18 that this equation can be fitted well to the observed values for the specimen of $x=0.5$. The values of Θ and C determined from this equation are also plotted in Fig. 12 and Fig. 13. When x becomes larger than 0.7, however, it is found that this equation can not be adapted to the observed curve. Therefore, it is clear that the above model is still unsatisfactory for explaining the magnetic properties of the solid solutions $x\text{FeTiO}_3\cdot(1-x)\text{Fe}_2\text{O}_3$ over the whole range of x.

Furthermore, the positive value of Θ (that is the positive interaction) for the specimens of $1>x>0.5$ can not be expected from the above model where we assumed all interactions to be negative. The decrease of the Curie constant or the atomic moment with the decrease of x, which was shown in Fig. 13, is much more unexplainable. Such a deviation of C from the theoretical value is generally attributed to the decrease of the ionic character of ions as has been done for some cobaltite[27]. But such a situation can not be expected for the present solid solution series, because we could not find any extraordinary change of the lattice parameters and the electrical conductivity for the specimen of $1>x>0.5$, which would be expected if the covalent character should appear only in this region.

It must be noticed that in the case of the solid solution of $NiTiO_3$ and Fe_2O_3, which is also ferromagnetic and has the same characteristics of the thermomagnetic curve and the magnetization at 0°K as that of the present solid solution series[28], we have not observed any anomalous change for Θ and C. Hence, such an anomalous character as was stated above may be, if really exists, due partially to the instability of the compound or the presence of Fe^{2+} ions whose orbital moment is not quenched. Because in case of the $NiTiO_3$–Fe_2O_3 solid solution series, the compound is stable and orbital moment seems to be quenched.

§ 9. Conclusion

Magnetic properties of the synthesized solid solution of $x\mathrm{FeTiO_3}\cdot(1-x)\mathrm{Fe_2O_3}$ have been examined in detail both experimentally and theoretically for the whole range of $0\geqq x\geqq 1$. The general conclusions obtained may be summarized as follows:

1). We have found that the specimens having the largest intensity of magnetization (or perfectly ordered) can be prepared by quenching the mixture of ilmenite and hematite in a given ratio from 1200°C after being maintained at this temperature for more than 12 hours. The magnetic properties of ilmenite–hematite solid solution series $x\mathrm{FeTiO_3}\cdot(1-x)\mathrm{Fe_2O_3}$ can be classified into three groups; i) $x=1$, ii) $1>x\gtrsim 0.5$, and iii) $0.5>x\geqq 0$. As for the pure ilmenite, we have found that it is antiferromagnetic below 55°K. The specimens for $1>x\gtrsim 0.5$ are strongly ferromagnetic. Estimated intensity of magnetization at 0°K increases as the composition x becomes large from 0.5 to 0.75 and reaches maximum around $x=0.75$, then decreasing towards pure ilmenite. The specimens for $0.5>x\geqq 0$ are again antiferromagnetic on which feeble parasitic ferromagnetism is superimposed. Curie temperature of the specimens with a weak magnetization (the specimens of $x<0.5$ and those imperfectly ordered for $1>x\gtrsim 0.5$) changes almost linearly from 950°K of α-Fe_2O_3 to 55°K of $FeTiO_3$. But, as for the specimens having a large intensity of magnetization, the Curie temperature deviated distinctly from this straight line towards the higher temperature side. Dependence of the Curie constant C_M and the asymptotic paramagnetic Curie temperature Θ, which were determined from the reciprocal magnetic susceptibility versus temperature curve, upon the composition has also been examined. We have found, for the specimens of $1>x>0.5$, the anomalous decrease and increase on the value of C_M and Θ respectively.

2) These experimental results were discussed by using the approximation of molecular field. It was shown that we could explain an outline of the magnetic properties of the soild solution provided that the tetravalent Ti ions always occupy preferentially one of the two sublattices in the specimen for $1\geqq x\gtrsim 0.5$, while such an ordering of Ti and Fe ions is disturbed for $0.5>x\geqq 0$. However, we have also found in detailed study that the simple molecular field theory can not explain all the magnetic properties consistently.

Since the present theory stands on many assumptions, they must be verified by the further precise experiments.

Acknowledgement

The authors wish to express their hearty thanks to Profs. T. Nagata and S. Sawada for their kind encouragement throughout the course of the present study. Their sincere thanks are also due to Dr. T. Katsura for his chemical analysis, to Drs. S. Maeda and I. Tsubokawa for their kindness of measuring the magnetization at the liquid helium temperature, to Drs. S. Iida and S. Uyeda for their fruitful discussions and comments and especially to Mr. Kondho for his analysis of the magnetic susceptibility versus temperature curve and other useful suggestions.

Radiative Collisions between Molecular and Electron Beams
III. Angular Momentum Distribution of OH* Radicals Liberated from Alcohol Molecules

By Tadao HORIE, Masamoto OTSUKA
Faculty of Science, Osaka University
and Takayuki NAGURA
Institute of Physics, South College, Osaka University

(Received June 29, 1957)

The light induced when a homogeneous electron beam (500–700 eV) intersects normally a localized jet of methyl, ethyl, or n-propyl alcohol vapor in a vacuum of 10^{-4} mmHg has been found to be almost entirely due to the emissions from the fragments H*, CH* and, OH*. The angular momentum distributions of the OH* radicals split from alcohol molecules of the respective species have been measured by the molecular spectrophotometric method. They all differ notably from that previously found for OH* from H_2O, that is, the first maximum appears near the rotational quantum number 7 and the second maximum is entirely absent except for OH* from CH_3OH. Qualitative discussions are also given to the multiple fragmentation by electron impact of these alcohol molecules.

§ 1. Introduction

Molecular dissociation due to electron impact is usually a consequence of excitation or ionization of some electronic state of the molecule. Transitions from the ground state of the neutral molecule to some excited or ionized state are governed by the Franck-Condon principle. The energy involved in the dissociation is related to the relative situation of the upper-state potential energy surface to the ground state one. Let E_V be the vertical excitation or ionization potential to raise the molecule from the neutral ground state to a certain unstable state without changing the internuclear distances in the interior of the molecule, and let E_D be the energy of the dissociation limit of the upper state above the ground state of the neutral molecule. Then the total excess energy, E_V-E_D, will be partitioned among various degrees of freedom of the fragments formed by dissociation, being in part converted into the mutual kinetic energy with which the fragments separate from one another.

When the parent molecule is diatomic, the dissociation process is usually treated as follows. For instance, let us consider the reaction $XY+e\rightarrow X^{+}+Y+2e$. Then the kinetic energy possessed by the ion, $E(X^+)$, can be expressed by the following equation, for the conservation laws of energy and momentum,

$$E_V-E_D=E(X^+)M_{XY}/M_Y\ ,$$

where M_{XY} and M_Y are the masses of the parent molecule and the neutral atom formed along with the ion, respectively. On the other hand, as far as the translational energy of fragment ions is concerned, there has been a well established method of observation[1)2)]. The energy, $E(X^+)$, can be measured by employing a plane parallel retardation field in front of the ion-collector plate in a mass spectrometer and recording the ion current as a function of retarding potential. The first derivative of this curve with respect to the voltage scale gives the distribution of translational energies among the fragment ions produced in the dissociation process.

When the parent molecule is polyatomic, however, no satisfactory method can be used to determine how the total excess energy will be distributed among the fragments, especially when multiple fragmentation takes place. In general, it will be transformed not only into translational energies but also into rotational and vibrational energies of the fragment atoms, ions, and radicals according to the conservation laws of energy, linear momentum, and angular momentum. A measurement of the angular momentum distribution of fragment radicals would be a valuable addition to the knowledge of the kinetics of fragmentation by electron impact of polyatomic molecule.

Molecular spectro-photometric studies of the angular momentum distribution of diatomic free radicals split from polyatomic molecules by a single electron collision have been in progress at our laboratory for more than ten years. The program was initiated with the intention of investigating the fundamental processes involved in the so-called abnormal rotation of OH which was first observed in 1934 by O. Oldenberg[3] in an electrical discharge through H_2O. In the preceding papers[4][5][6], studies of the OH^* radicals split by electron impact from water and hydrogen peroxide have been reported in detail. In the case of H_2O the angular momentum distribution curve has double maxima near the rotational quantum numbers 5 and 17, while in the case of H_2O_2 it has a single maximum near the rotational quantum number 20. Putting it in other terms, electron impact of H_2O molecules leads to a swarm of OH^* radicals with rotational energies corresponding to the rotational temperature of 14,000°K, while electron bombardment of H_2O_2 molecules results in a swarm of OH^* radicals with a little higher energies of rotation corresponding to the rotational temperature of 20,100°K. With the view of having a further insight into the manner in which the angular momentum distribution for OH^* depends upon the structure of the parent molecule, the present experiment has been carried out with CH_3OH, C_2H_5OH and $n-C_3H_7OH$.

§ 2. Experimental Procedure

The light induced when a beam of electrons intersects normally a localized jet of vapor of methyl, ethyl, and n-propyl alcohol was observed. The beam of electrons was supplied from an electron gun provided with a focusing solenoid producing a coaxial magnetic field. The electron gun, which was specially designed to suit our own purpose of making molecular collision experiments, produces in a horizontal direction a collimated electron beam with nearly homogeneous velocities for electrons of energies ranging from 20 to 1,000 eV. Under the optimum condition of operation, it is possible to raise the beam intensity up to 50 mA or more, but in the present experiment the gun was operated within the limits of the beam intensity from 20 to 30 mA and of the electron energy from 500 to 700 eV. After vacuum distillations of each of the alcohol samples had been repeated several times at the dry ice temperature, the vapor was allowed to enter a source chamber and then to jet into a vacuum chamber through an image and a source slit of a molecular beam projector.

The vacuum chamber was beforehand evacuated down to a pressure of 10^{-5} mmHg or less, and then a beam of alcohol molecules of the respective species was projected into it through the image slit, and at the same time a homogeneous electron beam was fired across the localized jet of vapor. Immediately after having traversed a short distance of 10 mm or so, the molecular beam was condensed on a surface of a liquid air trap to prevent the background pressure within the chamber from being deteriorated. However, the hydrogen gas produced by decomposition of alcohol molecules at the intersection of the two beams and the stray beams from the image slit caused the background pressure to rise up to 10^{-4} mmHg.

The light from the glow appearing at the intersection of the two beams was inspected with the help of an ordinary quartz prism spectrograph with a small dispersion which covers the whole range of wave-lengths from λλ 2,000 to 8,000 within a span of 77 mm on a photographic plate. In order to make photographic photometry measurements for the OH (0,0) band near λ 3064, a Littrow-type quartz prism spectrograph with one 60° and one 30° prism (dispersion, 5.5 Å/mm near λ 3000) was used together with a recording microphotometer provided with a phototube and a string electrometer.

The light excited by the passage of electrons with energies of 500 eV or more across a jet of vapor of any species of alcohol is almost entirely due to the hydrogen Balmer series, the OH band near λ 3064, and the CH bands near λλ 3900 and 4300 as shown in Fig. 1, the C_I line at λ 2478 being too faint to be shown in the same figure. Especially when exposures of long duration were made, the negative system of N_2^+ was also detected, whereas any band of N_2 did not appear at

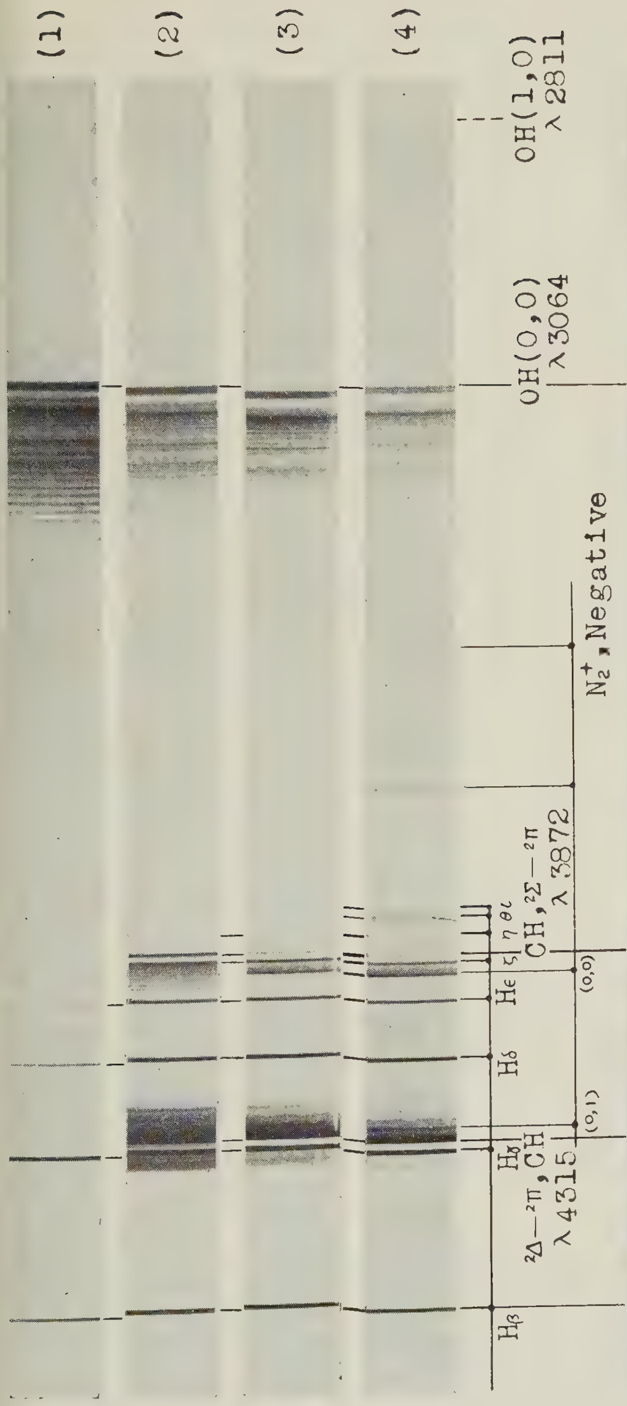

Fig. 1. Electron-impact spectra; (1) H_2O, (2) CH_3OH, (3) C_2H_5OH, and (4) n-C_3H_7OH.

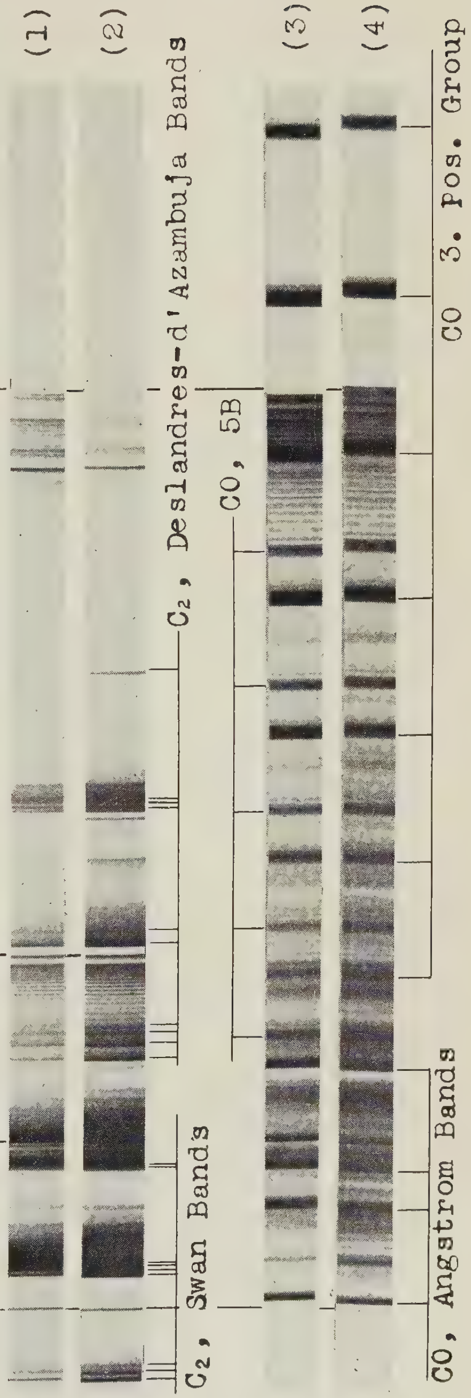

Fig. 2. Discharge spectra; condensed discharge through (1) CH_3OH and (2) n-C_3H_7OH, uncondesed discharge through (3) CH_3OH and (4) n-C_3H_7OH.

all. The (0,0) and (0,1) bands of this system near λλ 3914 and 4278 are in appearance more intensive than would be expected from weak intensities of the other bands of the same system, since they are much enhanced by their superpositions with the CH bands near λλ 3900 and 4300, respectively.

As a result of several tests on the purification procedure of the samples and on the background pressure in the collision chamber, it looks likely that these bands of the N_2^+ negative system are not due to impurities contained in the samples, but entirely due to the residual air in the observation chamber. Such a presumption is in good accordance with the recent experiment performed by C. Y. Fan[7] on the optical emission induced by the passage of a monoenergetic beam of particles through an observation chamber containing a rarefied air sample ($10^{-7}-10^{-5}$ mmHg), in which it has been shown that the first and the second positive systems of N_2 are practically the only emissions in the spectrum excited by 23 eV electrons, but their intensity is negligible compared with the negative system of N_2^+ in the spectra excited by 500 eV electrons and 20 keV protons.

In order to show how simple are the electron-impact spectra for these alcohol molecules, some examples of complicated spectra for the same molecules excited in electrical discharges are presented in Fig. 2. In a condensed discharge through CH_3OH or n-C_3H_7OH vapor, the Swan and the Deslandres-d'Azambuja bands system of C_2 are much stronger than the line of H_β and the bands of CH and OH. In an uncondensed discharge through the same vapor, the spectra are almost entirely due to the Ångstrom, the 3 Pos. Group and the 5 B bands of CO. Furthermore, the C_I line at λ 2478 appears very strongly in a condensed discharge, but does not at all in an uncondensed discharge. On comparison with the electron-impact spectra it is seen that various kinds of secondary processes must be considered to take place in electrical discharges. For instance, the fact that the C_2 bands come out with strong intensities even in a condensed discharge through CH_3OH may be accounted for only by some recombination reactions among fragment carbon atoms which may occur in the interior of the gas or at the side wall of the discharge tube.

§3. Experimental Results and Discussion

In Fig. 1 are compared the electron-impact spectra for CH_3OH, C_2H_5OH, and n-C_3H_7OH with that for H_2O. In the case of H_2O, the light is entirely due to the hydrogen Balmer series and the OH band near λ 3064. In the other cases, it contains the bands of CH near λλ 3900 and 4300 into the bargain. In the former the Balmer series extends only up to the member H_ε at λ 3970, while in the latter even the higher member H_η at λ 3835 can be easily recognized, and further the line of H_ι at λ 3770 is also detectable especially on the original plates taken with C_2H_5OH and n-C_3H_7OH. Furthermore, it looks likely that the tail of the OH band extends towards longer wavelength with decreasing number of hydrogen atoms contained in the parent molecule varying from C_2H_5OH to H_2O. The line C_I at λ 2478 could not be observed unless exposures of exceedingly long duration were made.

When bombarded by an incident electron with such an energy as high as 500 eV or so, if an alcohol molecule were split directly into fragments of different species of H, CH, and OH at a single stroke, the abundance ratio among these fragments would be 2:1:1 for CH_3OH, 3:2:1 for C_2H_5OH and 4:3:1 for n-C_3H_7OH, respectively. If so, when the intensity of the OH band is taken as a standard, the intensity of the CH bands would be expected to increase with increasing number of carbon atoms within the parent molecule. Actually, however, a lowering in intensity is found, e.g., for the band near λ 3900 on going from CH_3OH to C_2H_5OH. Such a discrepancy between the prediction from the simple rupture of the bonds and the observed intensity of the CH bands must be attributed to much more complicated processes of dissociation of the alcohol molecules.

Mass spectrometric investigations have already been made of the products of ionization resulting from electron collisions in several of the simpler alcohols. Methyl and ethyl alcohols were studied by C. S. Cummings, II and W. Bleakney[8], n- and iso-propyl alcohols by T. Kambara[9]. According to the observed relative abundances for electron energy of 70 volts, the greater number of the fragment ions from, for example, CH_3OH are of the species of CH_3OH^+, CH_2OH^+, HCO^+, and CH_3^+, their approximate percentages being estimated as 19.1, 33.6, 25.7, and 12.3, respectively. The formation of these ions except the first must result in the liberation of the neutral fragments H and OH. If any of these fragments have electronic excitational energies, the following processes can be considered to take place,

$$CH_3OH + e \rightarrow CH_2OH^+ + H^* + 2e\,, \qquad (1)$$

$$CH_3OH + e \rightarrow HCO^+ + H_2 + H^* + 2e\,, \quad (2)$$

and

$$CH_3OH + e \rightarrow CH_3^+ + OH^* + 2e\,, \qquad (3)$$

where the asterisk means the excitation of electronic state. The strong emission from the CH* radical, however, must be attributed to another kind of dissociation process of CH_3OH, which will be discussed as follows.

In order to account for the double maxima in the angular momentum distribution curve for OH* from H_2O, the following two processes were proposed in the previous paper[5)],

$$H_2O + e \rightarrow OH^* + H + e\,,$$

and

$$H_2O + e \rightarrow OH^* + H^* + e\,.$$

The former involves only the excitation of the O (2*p*) electron, while the latter the simultaneous excitation of both the O (2p) and the H (1*s*) electrons making a pair bond with each other before dissociation. The former process contributes to the second maximum, and the latter not only to the first maximum but also to the emission of the Balmer lines. In the case of CH_3OH also, let us make a proposal which is in line with that made in H_2O, namely —

$$CH_3OH + e \rightarrow OH^* + CH_3 + e \qquad (4)$$

and

$$CH_3OH + e \rightarrow OH^* + CH_3^* + e\,. \qquad (5)$$

The free methyl radical in its ground state has been proved theoretically by J. W. Linnett and A. J. Poë[10)] to be nonplanar and further by T. Itoh, K. Ohno and M. Kotani[11)] to have the most stable configuration of a pyramidal structure with the angle of 80° between the line C—H and the axis of symmetry. An attempt to obtain the absorption spectrum of the free CH_3 radical has recently been made by G. Herzberg and J. Shoosmith[12)] by means of the flash photolysis technique using $Hg(CH_3)_2$ as the parent compound. They have succeeded in finding diffuse absorption bands of the Rydberg type in the vacuum ultraviolet region and shown that these bands are unambiguously due to the free methyl radical. The former of the two processes newly proposed here, (4), results in a free methyl radical in its stable ground state. However, when a methyl radical is excited up to some unstable electronic state in the latter, (5), it may spontaneously decompose into a CH* radical and hydrogen atoms as, for instance,

$$CH_3OH + e \rightarrow OH^* + CH^* + H^* + H + e. \quad (5')$$

The observed strong bands of CH are likely due to the CH* radicals produced in reaction processes of this kind.

On the other hand, the OH* radicals are liberated in the processes (3), (4), and (5′). In (3) and (4), the parent molecule dissociates into two pieces with nearly equal masses and with a variety of internal degrees of freedom. In these processes as well as in the multiple fragmentation, (5′), only a small fraction of the total excess energy, $E_V - E_D$, will be converted into the rotational energy of the OH* radical. According to the mass spectrometric investigations cited above of the fragment ions from methyl, ethyl, and propyl alcohol, the more complicated the parent molecule is, the more different kinds of processes of dissociation into pieces must be considered to take place.

In Fig. 3 there are presented the results of photographic photometry measurements for the rotational lines of the Q_1 branch in the (0,0) band emitted from the OH* radicals split from methyl, ethyl, and n-propyl alcohol molecules, respectively. The previous result for H_2O and the Maxwell-Boltzmann distribution for 2,800°K are also shown in the same figure for the sake of comparison. In every one of these alcohol molecules the first maximum shifts towards a little higher rotational quantum number near 7, as compared with the case of H_2O, and moreover the second maximum is quite flat in CH_3OH and entirely absent in both C_2H_5OH and n-C_3H_7OH. The distribution of rotational energies among OH* radicals is in all cases quite similar to the distribution calculated for the rotational temperature of 2,800°K. It is true some traces of the second maximum is still retained in the simplest molecule of alcohols, CH_3OH, but in C_2H_5OH and n-C_3H_7OH the number of degrees of freedom among which the total excess energy will be partitioned is so great that any energy of abnormal rotation is not likely given to the OH* radicals splitting from these molecules.

In 1938 a study was made by H. Wakeshima[13] of intensity distributions in the OH (0,0) band excited in an electrical discharge through H_2O, CH_3OH, and C_2H_5OH, in which no appreciable variation was pointed out. Now that a great difference has been found to exist between the electron-impact and the discharge spectra, even for the same alcohol, it goes without saying that his result must not be considered as contradictory to ours that reveals a remarkable difference between the angular momentum distribution for OH* from H_2O and that for OH* from several of the simpler alcohols, in the most fundamental process of excitation by electron impact.

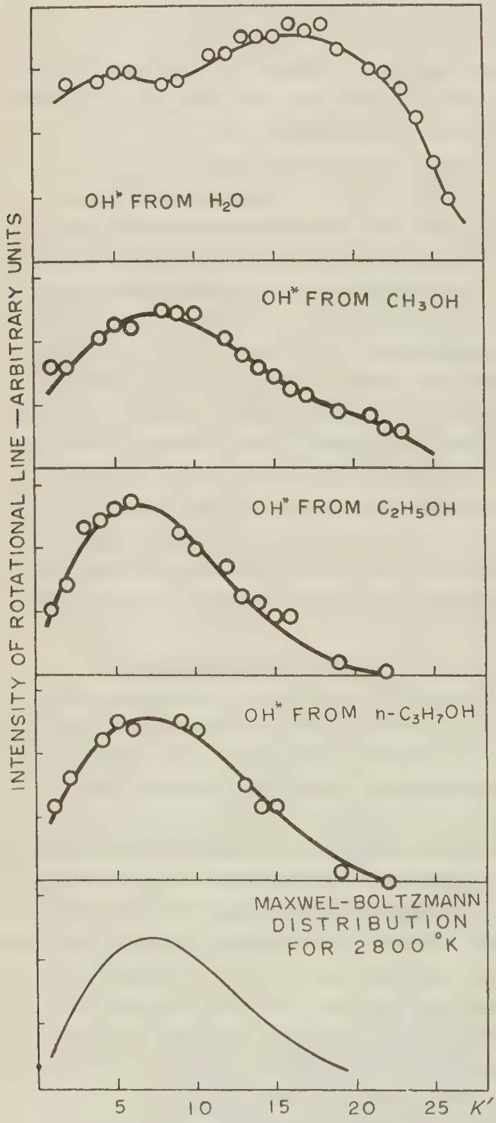

Fig. 3. The rotational intensity distributions for OH* from CH_3OH, C_2H_5OH and n-C_3H_7OH in comparison with that for OH* from H_2O and with the Maxwell-Boltzmann distribution for 2,800°K.

§ 4. Acknowledgments

The authors wish to express their sincere thanks to Dr. Herbert P. Broida of the National Bureau of Standards for his interest in the preceding papers and for his kind encouragements throughout the course of this series of works. The authors are also obliged to Prof. C. A. Coulson of the University of Oxford and Prof. K. Niira of the Tokyo Institute of Technology for valuable suggestions on the structure of water type molecules containing OH within themselves. They also would like to express their hearty thanks to Prof. T. Asada for placing various experimental facilities at their disposal.

Nuclear Quadrupole Resonance of Antimony Isotopes in Solids

By Shizuko OGAWA*

Department of Physics, Faculty of Science, Ochanomizu University, Tokyo

(Received July 5, 1957)

Measurements of nuclear quadrupole resonances of antimony isotopes in solids have been made at a relative accuracy of about one part in 10^6. Detectors are superregenerative oscillators. Relative accuracy was achieved by measurement of two or three resonance frequencies in a very short time. For antimony trichloride the results were almost in agreement with Wang's data, but the resonant frequency ν_3 of the Sb^{123} isotope, was higher about 2.5 kc. This implies that the cedecipole coupling constant might not have an order of magnitude which leads to a definitely measurable amount. In antimony oxide the simultaneous measurement was more easy, since it has a small asymmetry parameter. In this case, the deviation of resonance frequencies from a multiple relation is very small. These results are discussed in terms of cedecipole interaction and thermal vibration.

§ 1. Introduction

The first indication of the existence of nuclear electric cedecipole interaction was given by Wang through the experiment of nuclear quadrupole resonances of antimony isotopes[1]. Antimony consists of two isotopes, Sb^{121} and Sb^{123}, with relative abundances of 57.2% and 42.7%, respectively. The isotope Sb^{123}, having a spin of 7/2, gives rise three nuclear quadrupole resonances, whereas the isotope Sb^{121}, having a spin of 5/2, has two resonances. The frequencies of each resonances depend upon two quantities, i.e., nuclear quadrupole coupling constant eQq and asymmetry parameter of field gradient tensor η. Wang measured three resonance frequencies of Sb^{123} in $SbBr_3$ with a great deal of care at 0.4°C, and found that the frequency of the third resonance, calculated from eQq and η, which were obtained from the measured frequencies of the first and the second resonances, showed a small disagreement with the measured one. He attributed this small discrepancy to nuclear cedecipole interaction. In his experiment the amount of the discrepancy was only 2 kc, but the width of the resonance line was about 12 kc and the temperature dependence of the line was about 7~17 kc/degree. He also measured $SbCl_3$ and Sb_2S_3 in single crystals. Descrepancies of measured and calculated ν_3 frequencies range from nearly zero to 4 kc. The present work aims at a similar measurement of nuclear quadrupole resonances of antimony isotopes in Sb_2O_3, where the resonance line is more sharp and the dependency of the frequency upon temperature is smaller. The resonances of antimony isotopes in $SbCl_3$ studied by Wang were also measured for comparison.

§ 2. Experimental Procedure and Apparatus

In order to compare the frequencies of nuclear quadrupole resonances to an accuracy of about 0.001 percent, it is necessary that the center of the resonance line be determined accurately and that the temperature of the sample be kept constant during a series of measurements.

a) Apparatus

Two types of superregenerative oscillator were used. The first oscillator was a push pull feed back type with *LC* tuning circuit. It is responsible to a frequency range between 20 and 90 Mc, with two similar circuits cover the lower and higher range. The circuit diagram is shown in Fig. 1. The second oscillator had a transmission line tuned circuit similar to one reported by Kojima et al.[2] The frequency range was between 90 and 200 Mc. In order to measure three resonance frequencies of Sb^{123} three oscillators were used corresponding to their resonance frequencies. By use of a long sample three oscillator coils could be arranged linearly as shown in Fig. 2. If the coils have been coupled more closely, the oscillators would interacted with each other. Exact simultaneous operations were avoided on account of pulling phenomena of oscillations. Therefore, the three oscillators were operated in turn. A block diagram of the complete system is given in the same figure. Thus three frequencies were measured in a time of about a few minutes.

---

* This experiment was done at the laboratory of the Physics Department, Tokyo University of Education.

b) Method to Determine the Center of the Line

Generally simple regenerative spectrometers are adequate for studying line shapes. Such spectrometers were tested at the beginning of this experiment. However, because of the high sensitivity, superregenerative spectrometer were used for all measurements. The superregenenerative spectrometer gives many signals resulting from the side bands separated by the quenching frequency. These signals have various shapes owing to their different phases which depend on the frequency and amplitude of the quenching oscillator[3]. Moreover the resonance shape displayed on the cathod ray oscilloscope is asymmetric to the direction of sweep, since it receives some distortion from the finite pass band of the amplifier. The center of the resonance line was determined by superposing the two patterns at sinusoidal sweep as shown in Fig. 3. The phase of sweep was adjusted by receiving a sharp marker signal from a test oscillator. When the frequency of a line was measured, the signal from the test oscillator was superimposed on the resonance line.

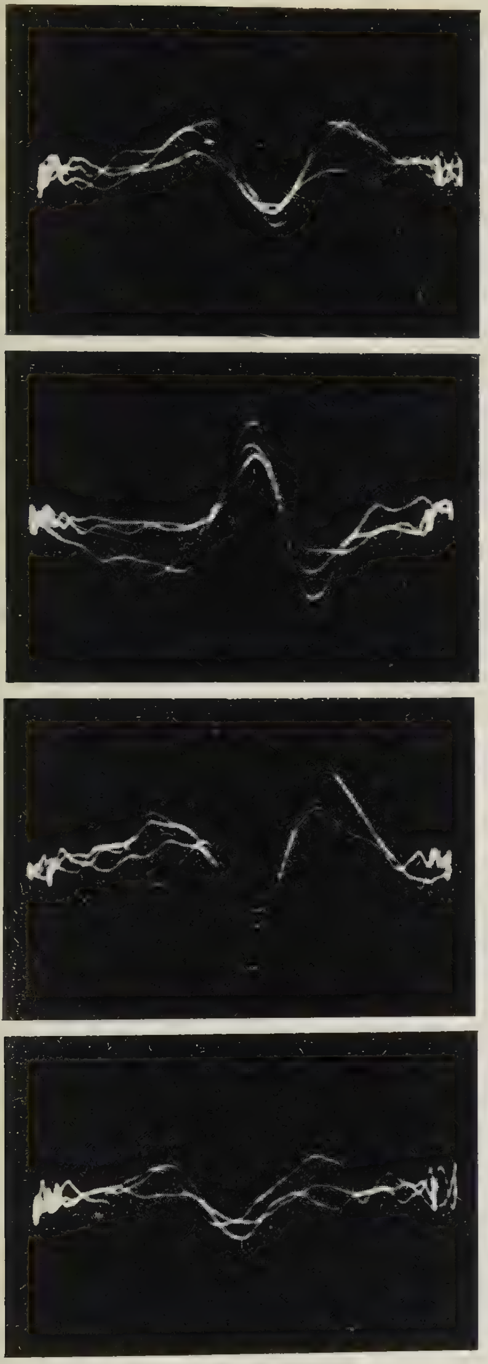
Preliminary adjustment of marker frequency of test oscillator to the center of the line was carried out to be consistent for all the shapes of three or four side bands of superregenerative oscillator.

c) Method to measure the three frequencies at the same temperature

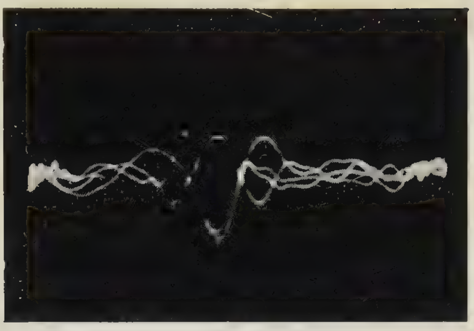
It is often experienced that the temperature of a sample rises during a measurement by its absorption of radio frequency power. Therefore, to keep a sample at a constant temperature, it is not sufficient even if a thermostat is used. To avoid the rise of temperature the oscillation level must be kept low and the necessary measurements must be carried out in a very short time at the beginning of operation. Indeed, the third resonance frequency of Sb^{123} in $SbCl_3$ was observed to change 0.01 percent during five minutes from the time of switch on of oscillator operation at some condition. Thus two or three frequencies are measured almost simultaneously by a suitable arrangement of the apparatus. Accurate measurements were obtained by changing the switch of supply voltage, and by varying the quenching power as shown in Fig. 2. Measurements were repeated many times.

d) Measurement of Frequencies

The test oscillator used had a frequency range between 10 and 15 Mc. Its frequency



(a)



(b)

Fig. 3. A series of resonance absorptions of side bands (a) and marker signal (b) viewed on oscilloscope.

was stabilized to about one part in 10^5. Soon after adjustment to the center of resonance lines its frequency was measured accurately beating with the higher harmonics of a precission frequency meter, having a working range between 1 and 2 Mc and an accuracy of one cycle. The frequency meter was always calibrated against the standard frequency of 4 Mc from *JJY*. Thus measured frequency has a accuracy of about 0.0001 percent of resonance frequency.

§ 3. Results and Discussion

a) Sb_2O_3

The resonance frequencies of Sb^{121} and Sb^{123} of Sb_2O_3 were measured by Barnes and Bray at room temperature and liquid air temperature[4]. We also measured these frequencies at room temperature. The temperature dependency is about -3×10^{-5} Mc/deg. at all frequencies which are very small compared to $SbCl_3$ and its other compounds. This small temperature variation of resonance frequencies increases the accuracy of the measurement. Signal to noise ratio was five to ten for all the resonances, which is better signal to noise ratio than other Sb compounds. The line widths were about 8 kc on oscilloscope measurements. The asymmetry parameter was almost equal to zero. A signal of one frequency from test oscillator could be used to measure all resonance frequencies of one isotope. Therefore it is very convenient to measure resonance frequencies relative to one another. Plots of ν_1 and ν_3 relative to ν_2 are expected almost to coinside with the line inclined 45°. Resonance frequencies are shown in Table I.

Table I. The resonance frequencies of Sb in Sb_2O_3.

Isotope	T°C	ν_1	ν_2	ν_3 (Mc/sec.)
Sb^{123}	16.8±0.5	50.20608	100.41144	150.61572
Sb^{121}	〃	82.70832	165.41928	—

The averaged values of frequency differences from multiple relation are obtained over all measured values supposing that they do not depend upon temperature in this small region. Errors are weighted mean of mean square deviation in every measurement at each temperature. The deviation from multiple ratio was obtained which was comparable to the experimental error of measured frequencies.

From resonance frequencies of Sb^{123}, the asymmetry parameter η and the cedecipole coupling constant eMm was calculated. For $I=3/2$, the energy level has an exact solution but for $I=5/2$ the energy level are obtained from an expansion in powers of η^2. In Sb_2O_3 the asymmetry factor is very small, therefore it is sufficient to use terms of the order of η^2. The nuclear cedecipole term which is the next term to be considered in the electric interaction of nucleus with surrounding electrons will be zero unless nuclear spin $I \geqq 2$ and the electron configuration has an angular momentum, such as, d or f orbitals. For $I=7/2$, and 5/2 the resonance frequencies will be deduced from the equation of the energy levels[1].

$$I=7/2 \quad \nu_1=\frac{1}{14}eQq\left(1+\frac{109}{30}\eta^2\right)-\frac{1}{32}eMm\,,$$

$$\nu_2=\frac{2}{14}eQq\left(1+\frac{17}{30}\eta^2\right)-\frac{5}{224}eMm\,,$$

$$\nu_3=\frac{3}{14}eQq\left(1-\frac{1}{10}\eta^2\right)+\frac{5}{112}eMm\,.$$

$$I=5/2 \quad \nu_1=\frac{3}{20}eQq\left(1-\frac{59}{54}\eta^2\right)-\frac{5}{64}eMm\,,$$

$$\nu_2=\frac{3}{10}eQq\left(1-\frac{11}{54}\eta^2\right)+\frac{1}{16}eMm\,.$$

With the values of the asymmetry parameter of Sb^{123} the cedecipole coupling constant and quadrupole coupling constant of Sb^{121} were calculated. Table II indicates these calculate values and the frequency differences in kc/sec

b) **$SbCl_3$**

Sb^{123} in $SbCl_3$ has three frequencies ν_1, ν_2 and ν_3 of about 37 Mc, 68Mc and 103 Mc respectively. Simultaneous measurement were carried out for the three frequencie ν_1, ν_2, and ν_3 in a temperature range betwee 17 and 20°C. The observed frequencies ν and ν_3 are plotted against ν_2, which has th smallest temperature dependence in these

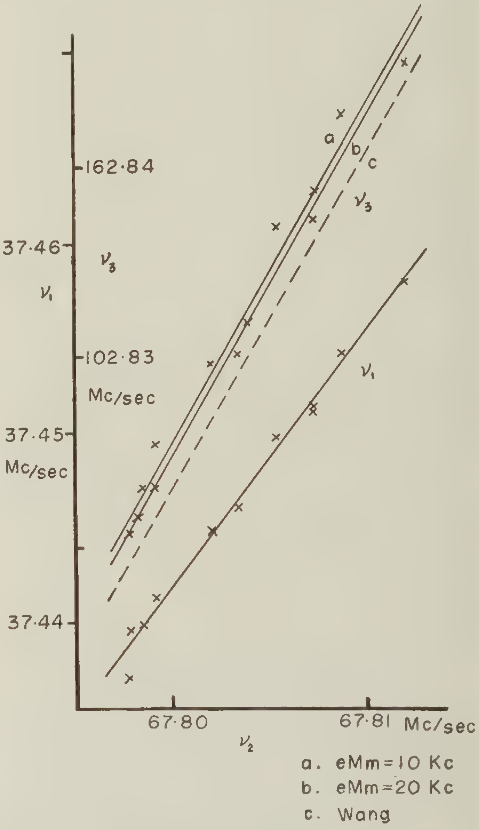


Fig. 4. Resonance frequencies ν_1 and ν_3 vs. ν_2 in $SbCl_3$.

Table II.

Isotope	$\nu_1-\nu_2/2$ (kc/sec.)	$\nu_1-\nu_3/3$ (kc/sec)	η	$\|eQq\|$ (kc/sec.)	$\|eMm\|$ (kc/sec.)
Sb^{123}	0.36±0.74	0.84±0.84	0.0006±0.001	702877.3±0.5	18±10

Table III. The resonance frequencies of Sb in $SbCl_3$.

Isotope	T°C	ν_1	ν_2	ν_3	ν_3 cal (Mc/sec.)
Sb^{123}	19.4±0.5	37.4449	67.8022	102.8283	102.8285
Sb^{121}	〃	58.1925	112.6443	—	

three frequencies, as shown in Fig. 4. Wang has measured these frequencies at the two temperatures of 0.8 and 30.07°C. The results which were extrapolated from Wang's data to our temperature range are shown in Fig. 4 with a broken line. On the resonance ν_1, the present result agrees well with Wang's data. On the other hand for the resonance ν_3, however, the present values are higher than his value by about 2.5 kc. The frequencies at 18°C, estimated from the points on the figure, are summarized in Table III. The temperature was measured with a thermocouple. Since the frequencies ν_1 and ν_3 were measured relative to ν_2, the error of temperature did not affect the discussion. The resonance frequencies of Sb^{121} was also measured. In this case the measured values agree with Wang's data. The resonance lines of Sb^{121} have better signal to noise ratio than those of Sb^{123}. $\nu_{3\mathrm{cal.}}$ is calculated from measured frequencies of ν_1 and ν_2 under the assumption that the resonance frequencies are depend upon the quadrupole coupling constant and the field asymmetry parameter. In this calculation the energy level equations which were described with the terms of eQq and η to the order of η^8 1) were used. Indicated lines in Fig. 4 are calculated under assumption that $SbCl_3$ has a cedecipole coupling constant of the order of about 10 kc and 20 kc and has sign opposite to the electric quadrupole interaction.

c) Discussion

The valence electrons of the antimony isotopes are in *5p* orbitals which may be hybridized with *5d* orbitals. The hybridization factor of configuration will depend upon their bonding angles. In $SbCl_3$ bond length and angles have been investigated by microwave experiment and $Sb-Cl=2.325\pm0.005$ Å, $Cl-Sb-Cl=99.5\pm0.5°$.5) In Sb_2O_3 these values are also obtained which is about 2.22 Å and $O-Sb-O\sim100°$, respectively6). In this respect, they seemed to be hybridized with similar configurations. By Wang's data $SbCl_3$ has a cedecipole interaction to be many times larger than our results, which lead the value of 10 kc at the most. It seems very difficult to deduce an accurate value of cedecipole interaction factor in this experimental accuracy.

The atoms Sb and O in crystal of Sb_2O_3 are arranged as shown in Fig. 5.6) Sb atom has three bonds to the three oxygen atoms with the same bond length and lies on one of the body diagonals of cubic lattice, thus the asymmetry parameter will vanish.

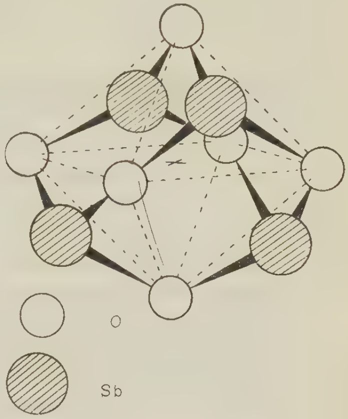

Fig. 5. Molecular structure of antimony oxide.

In consideration for cedecipole interaction, calculated results introduce small asymmetry factor of about 0.0006, which could not be distinguish from zero within the limits of experimental error. It is consistent with the consideration of crystal structure. This small value of η, if it exists, would be ascribed to the thermal vibration of molecule. The effect of the thermal vibraiton of molecule on asymmetry parameter has been studied by H. Bayer.7) Accurate measurements at the different temperatures would be favourable, but at other temperature differing from the room temperature, it would be very difficult.

Acknowledgements

The author wishes to thank to Professor Shoji Kojima, University of Education, for the encouragement and the guidance through this experiment. She also indebted to Miss Kiyoe Kato for cooperation in measurements. The present work was supported by the Scientific Research Expenditure of the Ministry of Education.

Oscillations of Electron Cloud in External Fields

By Masao SUMI
Electrical Communication Laboratory, Tokyo

(Received May 10, 1957)

The collective behavior of density fluctuations in a purely electronic cloud which is not neutralized by positive ions is analysed under the influence of external electromagnetic fields. In an equilibrium state the electrostatic space charge force is counter-balanced by the external fields and it gives rise to the mean drift flow of electronic cloud accompanying with the oscillations similar to those in the usual plasma. The classical description lead to the dispersion relation, which involves additional terms due to the drift velocity of electron flow. The effect of this drift velocity on the frequency shift is briefly discussed.

§ 1. Introduction

The collective behavior of the electrons in an electron gas has since been analyzed and developed in a number of papers[1)2)], where the "electron gas" is usually assumed to be neutralized by the positive charge of ions distributed over the volume considered. There are sometimes the cases that the positive ions are eliminated or of absence in the electron clouds or beams*. Even in such a purely electronic cloud there have been observed plasma-like oscillations when external fields confine the assembly of electrons appropriately[3)]. These plasma-like oscillations may be qualitatively illustrated as follows: let us consider a simple case where external electric and magnetic fields counter-balance the electrostatic space-charge forces of electron clouds. Then it will give rise to the steady drift flow in this clouds. When we observe on a sliding frame of reference with the velocity of the drift flow, the external and space-charge forces vanish in the clouds and there remains the density fluctuations of electrons, bringing about the plasma-like collective oscillations as usual. Back to the laboratory frame of reference the drift flow of electrons will reappear which affects these plasma-like oscillations, resulting in the shift of oscillating frequency. We shall deal with these situations first in the classical theory of density fluctuations and next in the quantum-mechanical theory of collective descriptions.

In the simple classical treatment of section 2, the velocity of individual electron will be devided into the steady component of drift flow and the fluctuating component. Then we shall find by the method of the Fourier decomposition of density fluctuations[1)] that the latter component brings about the plasma-like oscillations and the former the corresponding shift of frequency.

In section 3, we shall give a more precise dispersion relation by the quantum-mechanical description, which is equivalent to the general method by Bohm and Pines[2)], and by Tomonaga[4)]. The center-of-mass coordinate and momentum conjugate to each other for the electron assembly will be introduced, while internal coordinates and momenta will simply be obtained for the system with a sufficiently large number of electrons. The Hamiltonian for the system will be decomposed into a part representing the center-of-mass motion and an internal part describing an internal motion of electron assembly, the latter of which leads to the plasma-like oscillations and accordingly to the dispersion relation by the method of usual collective descriptions[2)4)5)].

---

* For instance, in the interaction space of magnetrons or in an electron beam of vacuum tubes, there remains almost purely electronic cloud or beams.

The effect of drift flow on the dispersion relation will be considered in section 4, but for the present we shall have to restrict ourselves to give rather formal discussions.

§ 2. Classical Treatment of Oscillatory Behavior

We shall first treat classically an aggregate of electrons under the influence of external electric and magnetic fields. Coulomb repulsive forces between electrons will provide an electrostatic space-charge force, as an average, and a fluctuating force caused by the density fluctuation. It will be shown that a macroscopically steady state is attained, when the repulsive space-charge force is counterbalanced by the external electromagnetic forces. Then the assembly of electrons will exhibit a flow with a steady drift velocity.

If we ride on a frame of reference which moves with the same velocity as that of drift flow, we might no more observe the drift flow of electron gas, since net forces acting on the electrons vanish on the average in this frame of reference. This means that the external electromagnetic fields play as similar an effective role to cancel out the repulsive space-charge forces in this case as positive ions do in the case of usual neutralized plasma.

Then it would be seen that the density fluctuation causes the collective oscillations as if the electron cloud would be the usual plasma. If we go back to the frame of reference fixed on the laboratory, the frequency shift of oscillations would be expected to appear due to the drift flow of electron cloud. These situations will be clarified in the following analysis.

The particle density of point electrons in a box of unit volume is expressed as:

$$\rho(\boldsymbol{x})=\sum_{j=1}^{N}\delta(\boldsymbol{x}-\boldsymbol{x}_j) \tag{2.1}$$

where N is the number density: $N=\int\rho(\boldsymbol{x})d\boldsymbol{x}$.

Splitting $\rho(\boldsymbol{x})$ into Fourier components,

$$\rho(\boldsymbol{x})=\sum_{j,k}e^{i\boldsymbol{k}(\boldsymbol{x}-\boldsymbol{x}_j)}=\sum_{k}\rho_k e^{i\boldsymbol{k}\boldsymbol{x}}\,, \tag{2.2}$$

$$\rho_k=\sum_j e^{-i\boldsymbol{k}\boldsymbol{x}_j}\,. \tag{2.3}$$

Note that ρ_0 represents the mean electron density N and the ρ_k with $k\neq 0$ the density fluctuations.

The equation of motion of the j-th electron is described by

$$\ddot{\boldsymbol{x}}_j=\dot{\boldsymbol{v}}_j=-\frac{e}{m}[\boldsymbol{E}(\boldsymbol{x}_j)+\boldsymbol{v}_j\times\boldsymbol{B}(\boldsymbol{x}_j)]\,, \tag{2.4}$$

the dot denoting the time derivative. MKS rationalized unit is used throughout this paper. $\boldsymbol{E}$ is devided into static and fluctuating parts: static part consists of two parts, i. e., one due to the mean charge distribution of electrons $\boldsymbol{E}_0$ and the other due to the external agency $\boldsymbol{E}_{ext}$; the fluctuating part $\boldsymbol{E}_1$ is due to the density fluctuations of electron charge. Hence the total electric field becomes

$$\boldsymbol{E}=\boldsymbol{E}_{ext}+\boldsymbol{E}_0+\boldsymbol{E}_1\,. \tag{2.5}$$

Denoting the electric potential by $\varphi(\boldsymbol{x})$,

$$\begin{aligned}\nabla^2\varphi(\boldsymbol{x})&=\frac{e}{\varepsilon_0}\rho(\boldsymbol{x})\\&=\frac{e}{\varepsilon_0}\Big(\rho_0+\sum_{k\neq0}\rho_k e^{i\boldsymbol{k}\boldsymbol{x}}\Big)\,.\end{aligned} \tag{2.6}$$

Hereafter the summation over k implies not to include the term of $k=0$. Also splitting $\varphi(\boldsymbol{x})$ into two parts

$$\nabla^2\varphi_0(\boldsymbol{x})=\frac{e}{\varepsilon_0}\rho_0\,, \tag{2.7}$$

$$\nabla^2\varphi_1(\boldsymbol{x})=\frac{e}{\varepsilon_0}\sum_k\rho_k e^{i\boldsymbol{k}\boldsymbol{x}}\,, \tag{2.8}$$

then we get

$$\varphi_1(\boldsymbol{x})=-\frac{e}{\varepsilon_0}\sum_k\frac{\rho_k}{k^2}e^{i\boldsymbol{k}\boldsymbol{x}}\,, \tag{2.9}$$

and

$$\boldsymbol{E}_0(\boldsymbol{x})=-\nabla\varphi_0(\boldsymbol{x})\,, \tag{2.10}$$

$$\boldsymbol{E}_1(\boldsymbol{x})=-\nabla\varphi_1(\boldsymbol{x})=\frac{ei}{\varepsilon_0}\sum_k\frac{\boldsymbol{k}}{k^2}\rho_k e^{i\boldsymbol{k}\boldsymbol{x}}. \tag{2.11}$$

We can regard (2.4) as the equation of motion of a specified electron in a small volume element located at $\boldsymbol{x}$. It may be written as

$$\begin{aligned}\dot{\boldsymbol{v}}_j=-\frac{e}{m}\,\boldsymbol{E}_1(\boldsymbol{x}_j)-\frac{e}{m}&\\ \times[\boldsymbol{E}_0(\boldsymbol{x}_j)+\boldsymbol{E}_{ext}(\boldsymbol{x}_j)+\boldsymbol{v}_j\times\boldsymbol{B}(\boldsymbol{x}_j)]\,.&\end{aligned} \tag{2.12}$$

If we take an average of Eq. (2.12) over all particles in the volume element, assuming reasonably $\boldsymbol{B}_0$, $\boldsymbol{E}_{ext}$ and $\boldsymbol{B}$ to be uniform over this volume element, we can drop out the first term in the righthand side and obtain in the following macroscopic equation of motion,

$$\dot{\boldsymbol{v}}_0=-\frac{e}{m}[\boldsymbol{E}_0(\boldsymbol{x})+\boldsymbol{E}_{ext}(\boldsymbol{x})+\boldsymbol{v}_0\times\boldsymbol{B}(\boldsymbol{x})]\ . \qquad (2.13)$$

As a macroscopically steady state is reached, $\dot{\boldsymbol{v}}_0=0$. The relation that the righthand side of Eq. (2.13) is put equal to zero yields a function of $\boldsymbol{x}$, $\boldsymbol{v}_0(\boldsymbol{x})$, which represents the drift velocity of electron cloud.

Putting

$$\boldsymbol{v}_j=\boldsymbol{v}_0+\boldsymbol{v}_{1j}\ ,$$

then

$$\dot{\boldsymbol{v}}_j=\dot{\boldsymbol{v}}_0+\dot{\boldsymbol{v}}_{1j}=\dot{\boldsymbol{v}}_{1j}\ . \qquad (2.14)$$

Hence Eq. (2.12) becomes

$$\dot{\boldsymbol{v}}_{1j}=-\frac{e^2i}{m\varepsilon_0}\sum_{j',k}\frac{\boldsymbol{k}}{k^2}e^{i\boldsymbol{k}(\boldsymbol{x}_j-\boldsymbol{x}_{j'})}-\frac{e}{m}\boldsymbol{v}_{1j}\times\boldsymbol{B}(\boldsymbol{x}_j). \qquad (2.15)$$

Now differentiation of (2.3) gives

$$\dot{\rho}_k=-i\sum_j(\boldsymbol{k}\boldsymbol{v}_j)e^{-i\boldsymbol{k}\boldsymbol{x}_j}\ , \qquad (2.16)$$

$$\ddot{\rho}_k=-\sum_j[(\boldsymbol{k}\boldsymbol{v}_j)^2+i\boldsymbol{k}\dot{\boldsymbol{v}}_j]e^{-i\boldsymbol{k}\boldsymbol{x}_j}\ . \qquad (2.17)$$

By the use of (2.15) and the random phase approximation, (2.17) becomes

$$\ddot{\rho}_k+\sum\left[\left(\frac{Ne^2}{m\varepsilon_0}\right)+(\boldsymbol{k}\boldsymbol{v}_j)^2-\frac{ie}{m}(\boldsymbol{k}\cdot\boldsymbol{v}_{1j}\times\boldsymbol{B})\right]e^{-i\boldsymbol{k}\boldsymbol{x}_j}=0. \qquad (2.18)$$

Furthermore assuming the random distribution of $\boldsymbol{v}_{1j}$ and averaging over all electrons, we see that the third term in the bracket of the last equation is cancelled out, because the magnetic field gives the gyromagnetic motion to the electron but does not alter the magnitude of electron speed. Then we get

$$\ddot{\rho}_k+[\omega_p{}^2+(\boldsymbol{k}\boldsymbol{v}_0)^2+\langle(\boldsymbol{k}\boldsymbol{v}_{1j})^2\rangle]\rho_k=0\ , \qquad (2.19)$$

where $\omega_p{}^2=Ne^2/m\varepsilon_0$ and the bracket $\langle\ \rangle$ means the average concerned. We find this equation indicates the oscillatory behavior of the density fluctuations, the frequency of which is given by the relation

$$\omega^2=\omega_p{}^2+(\boldsymbol{k}\boldsymbol{v}_0)^2+\langle(\boldsymbol{k}\boldsymbol{v}_{1j})^2\rangle. \qquad (2.20)$$

The second term in the right hand side represents the frequency shift due to the drift velocity which confirms the qualitative illustration mentioned previously. The third term is due to the usual thermal agitations.

If we separate the density fluctuations ρ_k into two parts, i. e., the collective and individual components, we shall obtain also in this case the more refined dispersion relation, as was shown by Pines and Bohm. But we shall stop here the classical treatment and in the next section we shall reconfirm the effects of drift flow by means of the quantum-mechanical treatment.

§ 3. Quantum-mechanical Descriptions

In the previous section we have discussed in a classical description the effect of external fields to the density fluctuations of purely electronic cloud. This section will present the more precise description of our problems by quantum-mechanical methods.

We start with a system containing N electrons in a box of unit volume affected by the external electric and magnetic fields, which is represented by the potential φ_e and $\boldsymbol{A}_e$. This system can be described by a Hamiltonian of the form

$$H=\frac{1}{2m}\sum_j[\boldsymbol{p}^{(j)}+e\boldsymbol{A}_e(\boldsymbol{x}^{(j)})]^2$$
$$+\frac{e^2}{2\varepsilon_0}\sum_{\substack{i,j,k\\ i\neq j,k\neq 0}}\frac{e^{i\boldsymbol{k}(\boldsymbol{x}^{(i)}-\boldsymbol{x}^{(j)})}}{k^2}$$
$$-e\sum_j[\varphi_0(\boldsymbol{x}^{(j)})+\varphi_e(\boldsymbol{x}^{(j)})]$$

where φ_0 corresponds to the potential due to the uniform distribution of electronic charge, satisfying the equation $\nabla_j{}^2\varphi_0(\boldsymbol{x}^{(j)})=e/\varepsilon_0$. It is well known this Hamiltonian is equivalently transformed by introducing the longitudinal vector potential $\boldsymbol{A}(\boldsymbol{x})$ and electric field intensity $\boldsymbol{E}(\boldsymbol{x})$, which is expressed by

$$H=\frac{1}{2m}\sum[\boldsymbol{p}^{(j)}+e\boldsymbol{A}_e(\boldsymbol{x}^{(j)})+e\boldsymbol{A}(\boldsymbol{x}^{(j)})]$$
$$+\frac{\varepsilon_0}{2}\int\boldsymbol{E}^2(\boldsymbol{x})d\boldsymbol{x}-e\sum[\varphi_0(\boldsymbol{x}^{(j)})+\varphi_e(\boldsymbol{x}^{(j)})]\ , \qquad (3.1)$$

together with a subsidiary condition restricting allowable state vectors

$$\Omega\Phi\equiv\left[div\boldsymbol{E}(\boldsymbol{x})+e\sum_{j=1}^{N}\delta(\boldsymbol{x}-\boldsymbol{x}^{(k)})\right]\Phi=0\ . \qquad (3.2)$$

Now we consider a motion of a center-of-mass coordinate of this system. Defining a center-of-mass coordinate by

$$\boldsymbol{x}_0=\frac{1}{N}\sum_{j=1}^{N}\boldsymbol{x}^{(j)}\ , \qquad (3.3)$$

a center-of-mass momentum conjugate to this quantity can be introduced by the relation for each component

$$p_{0x}=\frac{iNm}{\hbar}[T, x_0], \text{ etc.}, \tag{3.4}$$

where T is the kinetic energy of this system, $(1/2m)\sum_{j=1}^{N}\boldsymbol{p}^{(j)2}$. Hence we get

$$\boldsymbol{p}_0=\sum_{j=1}^{N}\boldsymbol{p}^{(j)}. \tag{3.5}$$

Clearly in this case

$$[p_{0x}, x_0]=-i\hbar, \text{ etc.}, \tag{3.6}$$

hold.

Internal coordinates $\boldsymbol{x}_j$ must satisfy the relations

$$[p_{0x}, x_j]=0, \text{ etc.},$$

which is fulfiled by putting

$$\boldsymbol{x}_j=\boldsymbol{x}^{(j)}-\boldsymbol{x}_0 . \tag{3.7}$$

As internal momenta conjugate to these we take

$$\boldsymbol{p}_j=\boldsymbol{p}^{(j)}-\frac{1}{N}\boldsymbol{p}_0 . \tag{3.8}$$

Then

$$[p_{jx}, x_j]=-\left(1-\frac{1}{N}\right)i\hbar\approx-i\hbar, \text{ etc.}, \tag{3.9}$$

for $N\gg1$, which shows that the internal momenta defined by (3.8) are sufficient approximations for large N. Clearly we get

$$[p_{jx}, x_0]=0, \text{ etc.}, \tag{3.10}$$

and

$$\sum_{j=1}^{N}\boldsymbol{p}_j=0 . \tag{3.11}$$

Thus we can write for $N\gg1$,

$$\boldsymbol{x}^{(j)}=\boldsymbol{x}_j+\boldsymbol{x}_0 ,$$

$$\boldsymbol{p}^{(j)}=\boldsymbol{p}_j+\frac{1}{N}\boldsymbol{p}_0 . \tag{3.12}$$

Insertion of (3.12) into the Hamiltonian (3.1) leads

$$H=H_c+H_0 , \tag{3.13}$$

$$H_c=\frac{1}{2Nm}[\boldsymbol{p}_0+Ne\boldsymbol{A}_e(\boldsymbol{x}_0)]^2-Ne[\varphi_0(\boldsymbol{x}_0)+\varphi_e(\boldsymbol{x}_0)] , \tag{3.14}$$

$$H_0=\frac{1}{2m}\sum_j\boldsymbol{p}_j^2+\frac{e}{2m}\sum_j\Big[\Big\{\boldsymbol{p}_j+\frac{1}{N}\boldsymbol{p}_0+e\boldsymbol{A}_e(\boldsymbol{x}_0)\Big\}\times\boldsymbol{A}(\boldsymbol{x}_0+\boldsymbol{x}_j)+\boldsymbol{A}(\boldsymbol{x}_0+\boldsymbol{x}_j)\times\Big\{\boldsymbol{p}_j+\frac{1}{N}\boldsymbol{p}_0+eA_e(\boldsymbol{x}_0)\Big\}\Big]+\frac{e^2}{2m}\sum_j\boldsymbol{A}^2(\boldsymbol{x}_0+\boldsymbol{x}_j)+\frac{\varepsilon_0}{2}\int\boldsymbol{E}^2d\boldsymbol{x} , \tag{3.15}$$

here consideration are taken into account that static fields are regarded as uniform in the volume concerned, so that $\boldsymbol{A}_e$, φ_0 and φ_e are functions of $\boldsymbol{x}_0$ only. The Hamiltonian H_c represents the center-of-mass motion in the external fields, while H_0 yields the internal motion of electronic cloud affected by the external fields.

The total Hamiltonian H determines the motion of state vector of the system by the Schroedinger equation

$$H\Phi=i\hbar\frac{\partial}{\partial t}\Phi . \tag{3.16}$$

By making a unitary transformation $\Phi=U_c\Psi$,

$$U_c=\exp\left[-\frac{i}{\hbar}H_ct\right], \tag{3.17}$$

the equation satisfied by the new state vector Ψ becomes

$$U_c^{-1}H_0U_c\Psi\equiv\mathscr{H}_0\Psi=i\hbar\frac{\partial}{\partial t}\Psi . \tag{3.18}$$

The motion of center-of-mass coordinates is represented by

$$i\hbar\frac{d}{dt}x_0^*=[x_0^*, H_c]=e^{(i/\hbar)H_ct}[x_0, H_c]e^{(-i/\hbar)H_ct},$$

and for the other components, so that

$$\boldsymbol{v}_0^*=\dot{\boldsymbol{x}}_0^*=\frac{1}{Nm}(\boldsymbol{p}_0+Ne\boldsymbol{A}_e)^*$$

and

$$i\hbar\dot{v}_{0x}^*=[v_{0x}^*, H_c] , \text{ etc.}$$

Hence a condition for the steady motion of *c-m*-coordinates corresponds to $[v_{0x}, H_c]=0$, etc.; i. e.,

$$[p_{0x}+NeA_{ex}, H_c]=0, \text{ etc.} \tag{3.19}$$

Returning to the original Hamiltonian (3.1) and applying the unitary transformation

$$U=\exp\left[-\frac{1}{\hbar}\sum_{j,k>k_c}\frac{e}{k\sqrt{\varepsilon_0}}q_ke^{i\boldsymbol{kx}^{(j)}}\right]$$

to it, we see that (3.15) is equivalently replaced by H_0' as follows,

$$H_0'=\frac{1}{2m}\sum_j\boldsymbol{p}_j^2+\frac{e}{2m\sqrt{\varepsilon_0}}\sum_{\substack{j\\k<k_c}}\left[\left(\boldsymbol{p}_j+\frac{\boldsymbol{p}_0}{N}+e\boldsymbol{A}_e\right)q_k\varepsilon_ke^{i\boldsymbol{k}(\boldsymbol{x}_0+\boldsymbol{x}_j)}+q_k\varepsilon_ke^{i\boldsymbol{k}(\boldsymbol{x}_0+\boldsymbol{x}_j)}\left(\boldsymbol{p}_j+\frac{\boldsymbol{p}_0}{N}+e\boldsymbol{A}_e\right)\right]$$
$$-\frac{1}{2}\sum_{k<k_c}p_kp_{-k}+\frac{e^2}{2\varepsilon_0}\sum_{\substack{j,j'\\k>k_c}}\frac{e^{i\boldsymbol{k}(\boldsymbol{x}_j-\boldsymbol{x}_{j'})}}{k^2}+\frac{e^2}{2m\varepsilon_0}\sum_{\substack{j\\k,l<k_c}}\varepsilon_k\varepsilon_lq_kq_le^{i(\boldsymbol{k}+\boldsymbol{l})(\boldsymbol{x}_0+\boldsymbol{x}_j)} \tag{3.20}$$

where q_k and p_k are Fourier amplitudes of $\boldsymbol{A}$ and $\boldsymbol{E}$,

$$\boldsymbol{A}(\boldsymbol{x})=\frac{1}{\sqrt{\varepsilon_0}}\sum_k q_k\varepsilon_k e^{i\boldsymbol{kx}}, \tag{3.21}$$

$$\boldsymbol{E}(\boldsymbol{x})=\frac{1}{\sqrt{\varepsilon_0}}\sum_k p_{-k}\varepsilon_k e^{i\boldsymbol{kx}}, \tag{3.22}$$

$$[p_k, q_{k'}]=-i\hbar\delta_{kk'},\ [p_k, p_{k'}]=[q_k, q_{k'}]=0\ . \tag{3.23}$$

Subsidiary conditions becomes

$$\Omega\Psi\equiv\left[p_{-k}-i\left(\frac{e}{k\sqrt{\varepsilon_0}}\right)\sum_j e^{i\boldsymbol{kx}^{(j)}}\right]\Psi=0\ , \tag{3.24}$$

for $k<k_c$, where k_c is the usual maximum wave vector beyond which we cannot expect the collective description of oscillations.

Now the transformed Hamiltonian $\mathscr{H}_0=U_c^{-1}H_0\,U_c$ can be written as

$$\begin{aligned}\mathscr{H}_0=&\frac{1}{2m}\sum_j \boldsymbol{p}_j^2\\&+\frac{e}{m\sqrt{\varepsilon_0}}\sum_{\substack{j\\k<k_c}}\varepsilon_k q_k\left\{\boldsymbol{p}_j-\frac{\hbar\boldsymbol{k}}{2}+\frac{1}{N}\left(\boldsymbol{p}_0+Ne\boldsymbol{A}_e-\frac{\hbar\boldsymbol{k}}{2}\right)\right\}e^{i\boldsymbol{k}\{\boldsymbol{x}_0+(1/Nm)(\boldsymbol{p}_0+N_e\boldsymbol{A}_e+\hbar\boldsymbol{k}/2)t\}}e^{i\boldsymbol{kx}_j}\\&+\frac{e^2}{2m\varepsilon_0}\sum_{\substack{j\\k,l<k_c}}\varepsilon_k\varepsilon_l q_k q_l e^{i(\boldsymbol{k}+\boldsymbol{l})\,[\boldsymbol{x}_0+(1/Nm)\{\boldsymbol{p}_0+Ne\boldsymbol{A}_e+(\hbar/2)(\boldsymbol{k}+\boldsymbol{l})\}t}e^{i(\boldsymbol{k}+\boldsymbol{l})\boldsymbol{x}_j}\\&-\frac{1}{2}\sum_{k<k_c}p_k p_{-k}-\frac{Ne^2}{2m\varepsilon_0}\sum_{k<k_c}q_k q_{-k}+\frac{e^2}{2\varepsilon_0}\sum_{\substack{j,j'\\k>k_c}}\frac{e^{i\boldsymbol{k}(\boldsymbol{x}_j-\boldsymbol{x}_{j'})}}{k^2}\ .\end{aligned} \tag{3.25}$$

Here use has been made of the condition for steady flow (3.19). In (3.25) the third term can be neglected by random phase approximation and the last term which represents the short range screening interaction between electrons may also be dropped out as we are not concerned here with it. Thus it becomes.

$$\mathscr{H}_0=\mathscr{H}_p+\mathscr{H}_f+\mathscr{H}_i \tag{3.26}$$

$$\mathscr{H}_p=\frac{1}{2m}\sum_j \boldsymbol{p}_j^2, \tag{3.27}$$

$$\mathscr{H}_f=-\frac{1}{2}\sum_{k<k_c}(p_k p_{-k}+\omega_p^2 q_k q_{-k}), \tag{3.28}$$

$$\mathscr{H}_i=\frac{e}{m\sqrt{\varepsilon_0}}\sum_{j,k}\varepsilon_k q_k \boldsymbol{P}_j^- e^{i\boldsymbol{k}(\boldsymbol{x}_0+(1/m)\boldsymbol{P}_0^+t)}e^{i\boldsymbol{kx}_j}\ , \tag{3.29}$$

where

$$\boldsymbol{P}_j^\pm=\boldsymbol{p}_j\pm\frac{\hbar\boldsymbol{k}}{2}+\frac{1}{N}\left(\boldsymbol{p}_0+Ne\boldsymbol{A}_e\pm\frac{\hbar\boldsymbol{k}}{2}\right), \tag{3.30}$$

$$\boldsymbol{P}_0^\pm=\frac{1}{N}\left(\boldsymbol{p}_0+Ne\boldsymbol{A}_e\pm\frac{\hbar\boldsymbol{k}}{2}\right). \tag{3.31}$$

We introduce creation and destruction operators a_k^* and a_k,

$$\begin{aligned}q_k&=(\hbar/2\omega)^{1/2}(a_k-a_{-k}^*)\ ,\\p_k&=i(\hbar\omega/2)^{1/2}(a_k^*+a_{-k})\ ,\end{aligned} \tag{3.32}$$

where

$$[a_k, a_{k'}^*]=\delta_{kk'}, \quad \text{other commutaters vanish.}$$

Then we have

$$\begin{aligned}\mathscr{H}_f&=\sum\left(\frac{\hbar\omega}{2}\right)(a_k^*a_k+a_ka_k^*)+\sum\left(\frac{\hbar}{2\omega}\right)(\omega_p^2-\omega^2)(a_k^*a_k+a_ka_k^*-a_ka_{-k}-a_k^*a_{-k}^*)\\&=\mathscr{H}_h+\mathscr{H}_{anh}\,,\end{aligned} \tag{3.33}$$

$$\mathscr{H}_i=\frac{e}{m}\left(\frac{\hbar}{2\omega\varepsilon_0}\right)^{1/2}\sum\left[\varepsilon_k\boldsymbol{P}_j^-a_ke^{i\boldsymbol{k}(\boldsymbol{x}_0+(1/m)P_0^+t)}e^{i\boldsymbol{k}\boldsymbol{x}_j}+e^{-i\boldsymbol{k}(\boldsymbol{x}_0+(1/m)\boldsymbol{P}_0^-t)}e^{-i\boldsymbol{k}\boldsymbol{x}_j}a_k^*\varepsilon_k\boldsymbol{P}_j^-\right]. \tag{3.34}$$

In (3.33) $\mathscr{H}_h$ and $\mathscr{H}_{anh}$ represents harmonic and anharmonic parts of the oscillating field, respectively.

Next we pass to the interaction representation with unperturbed Hamiltonian $\mathscr{H}_p+\mathscr{H}_h$ by means of the U-transformation

$$U_0=\exp\left[-(i/\hbar)(\mathscr{H}_p+\mathscr{H}_h)t\right].$$

Hence

$$\Psi=U_0\psi\,,$$

$$i\hbar\frac{\partial}{\partial t}\psi=U_0^{-1}(\mathscr{H}_i+\mathscr{H}_{anh})U_0\psi=(\mathrm{H}_i+\mathrm{H}_{anh})\psi\,. \tag{3.35}$$

$$\mathrm{H}_i=\frac{\partial}{m}\left(\frac{\hbar}{2\omega\varepsilon_0}\right)\sum_{j,k}\left[\varepsilon_k\boldsymbol{P}_j^-a_ke^{-i\omega t}\cdot e^{i(k/m)\boldsymbol{P}_j^-t}\cdot e^{ik(x_0+x_j)}+e^{-ik(x_0+x_j)}e^{-i(k/m)\boldsymbol{P}_j^-t}a_k^*e^{i\omega t}\varepsilon_k\boldsymbol{P}_j^-\right], \tag{3.36}$$

$$\mathrm{H}_{anh}=\frac{\hbar}{4\omega}(\omega_p^2-\omega^2)\sum\left[a_k^*a_k+a_ka_k^*-a_ka_{-k}e^{-i[\omega(k)+\omega(-k)]t}-a_k^*a_{-k}^*e^{i[\omega(k)+\omega(-k)]t}\right]. \tag{3.37}$$

If we can cancel out the interaction terms by a suitable transformation, the representation corresponds to the system consisting of the bare electrons without interaction and collective oscillations.

If we make the transformation given by

$$\psi=e^{iS/\hbar}\cdot\phi\,,\quad S=-\int_{-\infty}^{t}\mathrm{H}_i(t')dt'\,, \tag{3.38}$$

the wave equation for ϕ becomes

$$i\hbar\frac{\partial}{\partial t}\phi=\left\{\mathrm{H}_{anh}+\frac{i}{2\hbar}[\mathrm{H}_i, S]\right\}\phi\,, \tag{3.39}$$

to the approximation retaining only quadratic terms in the field variables. $i/2\hbar[\mathrm{H}_i, S]$ involves terms respresenting the residual interaction of electrons through virtual collective field, which include the self-action of individual electrons. The remaining terms combined with the H_{anh} provides the anharmonic part of collective oscillations. The residual parts of electron-electron interaction can be written as

$$\mathrm{H}_{r.p.}=-\frac{e^2}{4m^2\omega\varepsilon_0}\sum\left[\frac{(\varepsilon_k\boldsymbol{P}_j^-)(\varepsilon_k\boldsymbol{P}_{j'}^+)}{\omega-(\boldsymbol{k}/m)\boldsymbol{P}_j^+}e^{ik(x_j-x_{j'})}+e^{ik(x_j-x_{j'})}\frac{(\varepsilon_k\boldsymbol{P}_j^-)(\varepsilon_k\boldsymbol{P}_{j'}^+)}{\omega-(\boldsymbol{k}/m)\boldsymbol{P}_j^+}\right]. \tag{3.40}$$

This term may be negligible also in this case in comparison with the screening interaction according to Bohm and Pines.

The elimination of anharmonic collective oscillations leads us to the dispersion relation as follows:

$$\frac{e^2}{m\varepsilon_0}\sum_j \frac{1}{\left(\omega-\frac{\boldsymbol{k}}{m}\boldsymbol{P}_j^-\right)\left(\omega-\frac{\boldsymbol{k}}{m}\boldsymbol{P}_j^+\right)}=1\,, \tag{3.41}$$

which becomes for $N\gg 1$,

$$\frac{e^2}{m\varepsilon_0}\sum_j \frac{1}{\left[\omega-\frac{\boldsymbol{k}}{m}\left\{\boldsymbol{p}_j+\frac{1}{N}(\boldsymbol{p}_0+Ne\boldsymbol{A}_e)\right\}\right]^2-\left(\frac{\hbar k^2}{2m}\right)^2}=1\,. \tag{3.42}$$

While the self-action term becomes

$$H_{\text{self}}=-\frac{e^2}{4m\varepsilon_0\omega^2}\sum_j\left[\frac{(\varepsilon_k\boldsymbol{P}_j^-)^2}{\omega-\frac{\boldsymbol{k}}{m}\boldsymbol{P}_j^-}+\frac{(\varepsilon_k\boldsymbol{P}_j^+)^2}{\omega-\frac{\boldsymbol{k}}{m}\boldsymbol{P}_j^+}\right]. \tag{3.43}$$

Neglecting the terms of $\hbar k$, $\boldsymbol{P}_j^+\approx\boldsymbol{P}_j^-=\boldsymbol{P}_j$ and assuming $|\boldsymbol{k}\boldsymbol{P}_j/m\omega|\ll 1$,

$$H_{\text{self}}\approx-\frac{N'}{3N}\sum_j\frac{\boldsymbol{P}_j^2}{2m}\,, \tag{3.44}$$

where

$$N'=\frac{k_c^3}{6\pi^2}\,. \tag{3.45}$$

This self-action can be reflected into the original kinetic energy which gives the effective mass as usual:

$$\frac{1}{2mN}(\boldsymbol{p}_0+Ne\boldsymbol{A}_e)^2+\frac{1}{2m}\sum\boldsymbol{p}_j^2+H_{\text{self}}\approx\frac{3N-N'}{3N}\sum\frac{\boldsymbol{P}_j^2}{2m}\equiv\sum\frac{\boldsymbol{P}_j^2}{2m^*}\,, \tag{3.46}$$

so that

$$m^*=[3N/(3N-N')]m\,. \tag{3.47}$$

Finally the new subsidiary conditions which is obtained after the transformation reduces to, for $k<k_c$,

$$\left[\sum_j\frac{\omega^2}{\omega^2-\left(\frac{\boldsymbol{k}}{m}\boldsymbol{P}_j^-\right)^2}e^{i\boldsymbol{k}(\boldsymbol{x}_0+\boldsymbol{x}_j)}\right]\phi=0\,, \tag{3.48}$$

where the dispersion relation (3.41) has been taken into account.

§ 5. Discussions

If we donote $\boldsymbol{p}_j/m=\boldsymbol{v}_j$ and $(\boldsymbol{p}_0+Ne\boldsymbol{A}_e)/Nm=\boldsymbol{v}_0$ in the dispersion relation (3.41), the approximation for small k such that $|\boldsymbol{k}\boldsymbol{v}_j/\omega|\ll 1$ and $|\boldsymbol{k}\boldsymbol{v}_0/\omega|\ll 1$ gives the following relation as

$$\omega^2=\omega_p^2\left[1+2\frac{(\boldsymbol{k}\boldsymbol{v}_0)}{\omega}+3\frac{(\boldsymbol{k}\boldsymbol{v}_0)^2}{\omega^2}+3\frac{\langle(\boldsymbol{k}\boldsymbol{v}_j)^2\rangle}{\omega^2}+\left(\frac{\hbar k^2}{2m\omega}\right)^2+\cdots\right], \tag{4.1}$$

where assumption of the isotropic distribution is made for $\boldsymbol{v}_j$.
Hence

$$\omega\approx\omega_p\left[1+\frac{(\boldsymbol{k}\boldsymbol{v}_0)}{\omega_p}+\frac{(\boldsymbol{k}\boldsymbol{v}_0)^2}{\omega_p^2}+\frac{3\langle(\boldsymbol{k}\boldsymbol{v}_j)^2\rangle}{2\omega_p^2}+\frac{1}{2}\left(\frac{\hbar k^2}{2m\omega_p}\right)\right]^2. \tag{4.2}$$

The terms containing $\boldsymbol{v}_0$ represent the effect of drift velocity of the electron cloud. If the magnitude of $\boldsymbol{v}_0$ is much smaller than that for the mean velocity of thermal agitations, the effect of drift velocity would be negligible and (4.2) reduces to the dispersion relation for the usual plasma. In some cases the magnitude of the drift velocity would be expected much greater than that of the mean velocity for thermal electrons*. Then the drift velocity has the main effect on the dispersion for the collective oscillations.

In practical cases, however, it is a rather complicated problem that with what wave vector $\boldsymbol{k}$ the wave would be excited which satisfies given initial and boundary conditions. Accordingly it is difficult to give the quantitative estimation for this effect, but we must content ourselves for the present with the qualitative or formal discussions of the problem.

If the excited wave travels towards one direction, the term $(\boldsymbol{k}\boldsymbol{v}_0)/\omega_p$ contributes to the frequency shift and the sign of this contribution is dependent on whether the direction of the wave vector is the same or opposite to the drift velocity. If the standing wave is excited, the term $(\boldsymbol{k}\boldsymbol{v}_0)/\omega_p$ vanishes and $(\boldsymbol{k}\boldsymbol{v}_0)^2/\omega_p{}^2$ yields the main contribution.

Note that in (4.2) we must replace the effective mass m^* expressed in (3.47) for the electron mass m, except in $\omega_p{}^2=Ne^2/m\varepsilon_0$; hence $\boldsymbol{v}_j$ and $\boldsymbol{v}_0$ should also be replaced by $\boldsymbol{v}_j{}^*=\boldsymbol{p}_j/m^*$ and $\boldsymbol{v}_0{}^*=(\boldsymbol{p}_0+NeA_e)/m^*$ respectively. In the usual electron gas N' would be small compared with N so that the effect of these replacements would not be remarkable.

---

* For example, the drift velocity of electrons in an interaction space of magnetron is nearly expressed as $v_0=E/B$. For typical values of applied voltage 1000 volts over 2 mm and magnetic flux 1000 Gauss, $v_0\sim5\times10^6$ m/sec. This is much greater than the thermal speed of electron, $v_T\sim2\times10^5$ m/sec for the electron temperature of 1000°K or 6×10^5 m/sec for that of 10000°K.

The Scattering of light from Metal Aventurine Surface and Their Statistical Models

By Hirosi HASUNUMA and Jiro NARA

Department of Applied Physics, Faculty of Engineering, University, of Tokyo

(Received June 22, 1957)

The scattered light from Cr-plated aventurine surfaces were measured by a goniophotometer. The results were analysed assuming that the surfaces are covered by randomly distributed small facets and the scattered light consists of ones reflected regularly by the facets. It is concluded that the inclinations of the facets are distributed by Gaussian process, the r.m.s. values of them lying between 4° to 10°. The results were compared with the theoretical one calculated by the equi-inclination model.

§ 1. Introduction

The angular distributions of scattered light $I(\alpha, \varphi)$ from matt surfaces are dependent on the profile of the surfaces, where α and φ indicate the angle of incidence and the angle of view respectively (Fig. 1). The experimental results obtained until now may be summarised as follows:

1) At any setting of α, the relation of log I to $(\varphi-\alpha)$ are nearly linear or quadric as the roughness of the surfaces are small or large respectively.

2) The intensity of specular reflection increases as α increases, the rate of increases being much larger than that expected by the simple application of the Fresnel's formula.

There are two methods for the theoretical treatments of the problem, the one being the approximation based on the geometrical optics and the other based on the wave optics. The former may fit to rougher surfaces and the later to finer surfaces.

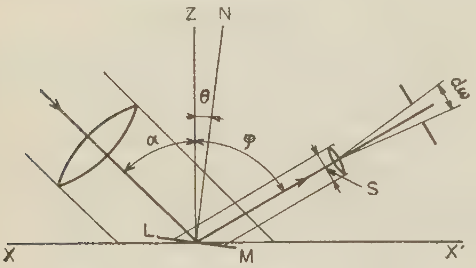

Fig. 1. Reflection by a facet.

We[1] analysed the scattered light from surfaces whose r.m.s. roughness h being smaller than $0.5\,\mu$, by a wave optical method. It was assumed that the height z of any point of the surface is a statistical quantity following the Ornstein-Uhlenbeck process. The surfaces are then represented by two constants h and β. Here $1/\beta$ has the dimention of "length" and indicates the range of the extents of the autocorrelation of z. The critical angle of sheen and curves of diffuse reflection are explained by assuming some adequate values for $1/\beta$, which is about $10\,\mu$ for the surfaces $h=0.2\,\mu$.

The Kirchhoff's diffraction theory tells us that the half-value width of a zeroth order diffraction pattern is inversely proportional to the slit width and is approximately 1° for a slit of $30\,\mu$ width. The geometrical approximation of scattering, then, may be sufficient for the much rougher surfaces than we have treated.

Kappler and Schricker[2] analysed the scattered light from matt glass surfaces by a geometrical approximation. The surfaces are assumed as consisted of small facets which may be set at any angle to mean surface. The intensity of light which is received at any angle is considered to be proportional to the Fresnel's coefficient besides the area of the facets suitably directed. Their analysis reveals that for matt glass surfaces, prepared by lapping with #150 to 500 abressives, the geometrical models are well fitted and the distribution of the inclination of facets is Gaussian. For finer surfaces prepared by #2000 powder, these approximation are insufficient.

Tanaka[3] measured the reflection charactoristics of matt glass surfaces using polarized light and got a result similar to that of Kappler and Schrlicker's.

In the following paper, we have measured the scattering of light from metal aventurine surfaces and analysed them by geometrical approximations which are believed sufficient for our purpose. The mean inclination of the facets obtained by the analysis are compared with the one calculated from profilo-curves by the Katto's[4] methods.

§ 2. The Theory of the Analysis

The intensity of scattered light was measured by a goniophotometer. Figs. 1 and 2 give the schematical arrangement of the apparatus. Sufficiently large area of the test surface is illuminated uniformly by a parallel beam of light, the angle of incidence being α. The light scattered to the direction φ is received by a photomultiplier tube. The solid angular aperture of the receiver $d\omega$ is limited by a diaphragm situated at the focal plane of a lens whose effective area is s_0. The apertures of the optical systems and the area of test pieces are carefully selected so that the reflected flux are always limited by the area s_0 throughout the experiments.

It was assumed that the beam of light is reflected regularly by facets LM whose normal inclining θ, where $\theta=(\alpha+\varphi)/2$. I_0 is the flux density of the incident beam, and $R(\alpha+\theta)$, the coeficient of reflection of the metal. $\Phi(\theta)d\theta$ is the probability density of existence of the facets, i.e., the sum of the projection upon XX' of all facets having the inclination θ, divided by the area of XX'.

The intensity of reflection is given by the following consideration. The intensity of illumination of the surface LM is $I_0\cos(\alpha+\theta)$

The area of the surface which reflects the light to the direction φ passing the aperture s_0 is $\Phi(\theta)s_0 d\theta/\cos\varphi\cos\theta$. The solid angular range of the direction of facets which reflects light flux involved in the cone $d\omega$, is $d\omega/4\cos(\alpha+\theta)$. The distribution of facets is considered constant for small angle of $d\omega$. Multiplying these factors, the intensity of the received light is given by;

$$I(\alpha+2\theta)=\frac{I_0 R(\alpha+\theta)s_0\Phi(\theta)}{4\cos(\alpha+2\theta)\cos\theta}d\omega \qquad (1)$$

If $R(\alpha+\theta)$ is known, we can calculate $\Phi(\theta)$ from the observed intensity $I(\alpha+2\theta)$ by (1). That is the case of transparent materials as reported by Kappler and Schricker or Tanaka. Although the coefficient of reflection of metals are unknown, it can be approximated as constant for small angle of incidence.

If we put

$$R(\alpha-\theta)=\text{const.} \quad \text{for} \quad \alpha-\theta\leqq 20° \qquad (2)$$

assuming

$$\Phi(\theta)=\Phi(-\theta)\ .$$

$$I(\alpha-2\theta)=\frac{I_0 R(\alpha-\theta)\,s_0\Phi(\theta)}{4\cos(\alpha-2\theta)\cos\theta}d\omega \qquad (3)$$

$$R(\alpha+\theta)=\frac{I(\alpha+2\theta)\cos(\alpha+2\theta)}{I(\alpha-2\theta)\cos(\alpha-2\theta)}R(\alpha-\theta) \qquad (4)$$

we can calculate $R(\alpha+\theta)$ successively from the experimental data by (4) and then $\Phi(\theta)$ by (1) numerically.

§ 3. Apparatus and Results of Measurements

a) Goniophotometer. The goniophotometer used is given in Fig. 2. The angular aperture of both the incident and the reflected beam

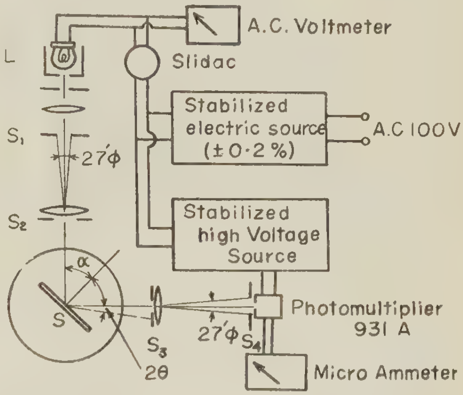

Fig. 2. The apparatus.

Table I. The Results

* The powder marked "A" are alundum and "S", carborandum.

are 27′. The aperture of the incident and the receiving lens are 50 mm and 10 mm respectively.

b) Test pieces. The test pieces were Cr-plated aventurine surfaces. Brass plates were roughened by liquid horning and electro-polished, then electroplated by Ni and finally by Cr. The details of the processes were listed in the 2nd to 4th columns of the Table I.

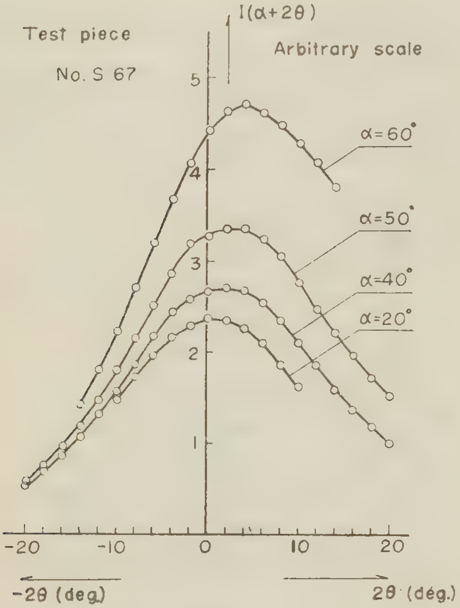

Fig. 3. Distributions of scattered light.

c) Measurments and calculations. A series of reflection curves were obtained on each plates, namely, the intensities of scattered light I against θ were measured, the angle of incidence α being fixed at 20°, 25°, 30°, 40°, 50° and 60° on each plates. Some examples are given in Fig. 3.

$R(\alpha+\theta)$ were calculated successively by the formula (2) and (4), Fig. 4 is a result of calculation, where curves (a) and (b) are the $R(\alpha+\theta)$ taken separately for the reversed directions of the same plate whose distribution of inclination is expected symmetrical. Their differences may be due to the accumulated errors of the calculation which are apt to occur by the successive application of (4). For the calculation of $\Phi(\theta)$ we used the mean of the tw curves. It is shown from Fig. 4 that the as sumption (2) is reasonable. The R-curves fo different test pieces are similar. Fig. 5 the $\Phi(\theta)$ of a sample calculated separatel for each incident angle α using a common R curves. All the curves coincide perfectly wit each other.

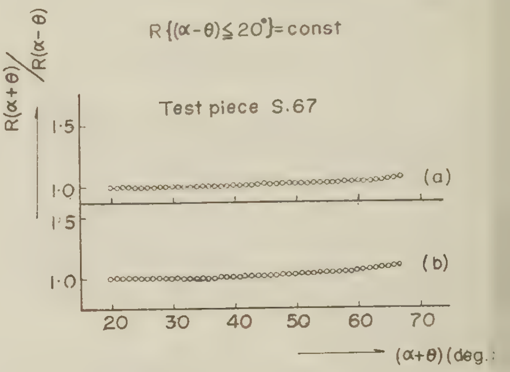

Fig. 4. Reflectivity of a Cr- plated surface (No. S 67).

Examples of the $\Phi(\theta)$ curves of the tes pieces averaged over α are given in Fig. 6 then R-curves being calculated separetely fo each plates.

The distribution of the inclination of facet are then approximated by Gaussian Process i.e.,

$$\Phi(\theta)=\Phi_0 e^{-\theta^2/2\gamma^2} \qquad (5$$

γ being the r.m.s. inclination. The 5th column of the Table I give the values of γ..

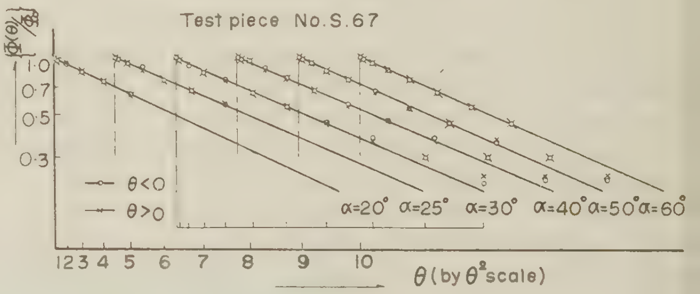

Fig. 5. Distribution of inclinations of facets. (No. S 67)

§ 4. The Analysis of the Profilocurves o the Surfaces

Katto[4] analysed profilocurves of randon surfaces and concluded that they can be re presented by a model named the equi-inclination profile with the Gaussian distribution It is assumed that the boundary of the sur ace consists of straight lines inclined by a onstant angle θ_0 and the height of the vertex f the triangle is a random function of aussian process. (Fig. 7)

If a straight line drawn parallel to the orizon at z, cut the profile at A_1B_1, A_2B_2, $\cdots A_nB_n$, in the unit length of the mean urface, the sum of these length $\sum_{i=1}^{n} A_iB_i$ ivided by unit length is the probability $P(z)$ hat the height of a point on the surface is higher than a definite value of z.

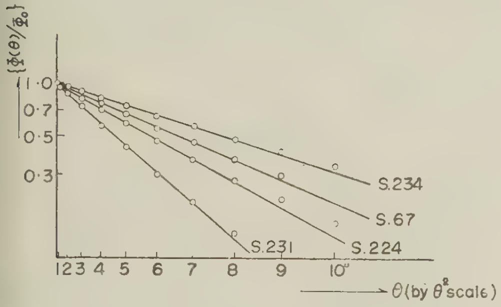

Fig. 6. Distribution of the inclination of facets.

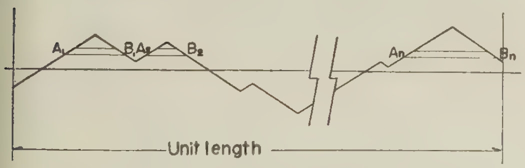

Fig. 7. Katto's equi-inclination profile.

The probability density $\Phi(z)dz$ is the increase of $P(z)$, i.e.,

$$\Phi(z)\Delta z = P(z+\Delta z) - P(z)$$
$$= 2n(z)\cot\theta_0\Delta z \qquad (6)$$

where $n(z)$ is the number of cut in the unit length.

The distribution of z is considered Gaussian

$$\Phi(z) = \frac{1}{\sqrt{2\pi}\,h}\exp\left\{-\frac{1}{2}\left(\frac{z}{h}\right)^2\right\} \qquad (7)$$

h being the r.m.s. roughness of the furface. If n_0 indicate the number of cut by the mean ine ($z=0$),

$$2n_0\cot\theta_0\Delta z = \Phi_0\Delta z = \frac{1}{\sqrt{2\pi}\cdot h}\Delta z$$

or

$$\tan\theta_0 = 2\sqrt{2\pi}\,n_0h \qquad (8)$$

and

$$h = \frac{\Delta z}{\sqrt{2\pi}}\,\frac{\sum_{-\infty}^{\infty} n(z)}{n_0} \qquad (9)$$

We have proceeded the analysis of our profilocurves*, the vertical and the horizontal magnifications being 5000× and 100× respectively. Cares were taken to get a profile as accurate as possible. We had tested several types of profilograph as it was found that some one do not record the detailed structure of surfaces missing small peaks, and selected a optical lever type profilograph designed by Yamamoto.

The main inclination and the r.m.s. roughness, calculated from the record of 600 mm length (corresponding the 6 mm of the real surfaces) by the equation (8) and (9), are given on the 6th and 8th column of the Table I.

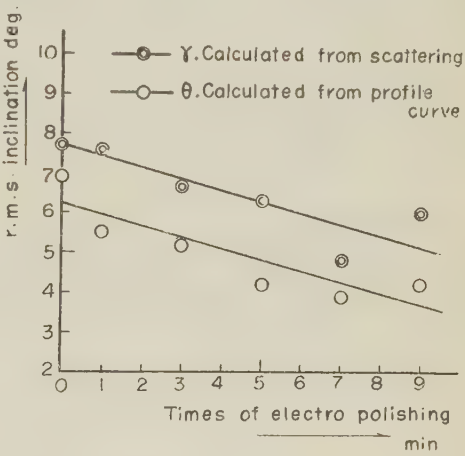

Fig. 8. Decrease of inclination by Electro-polishing.

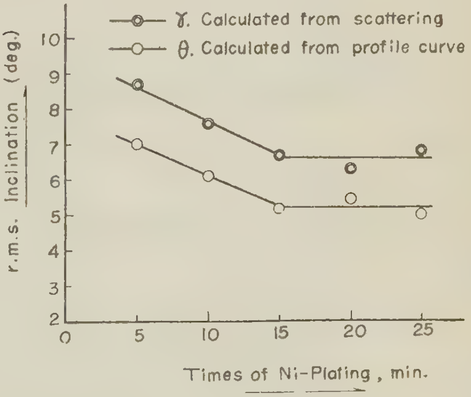

Fig. 9. Decrease of inclination by Ni-plating.

The 7th column of the Table I is the r.m.s. roughness of the surfaces measured by a Kosth's profilometer which measures the r.m.s. value of the roughness directly.

---

* We are indebted to Miss Iwasaki for these curves.

The mean inclination γ and θ_0 plotted against the time of electropolishing and the time of Ni-electroplating are given in Fig. 8 and Fig. 9. It is shown that the mean inclination reduces as the time of electropolishing increases and seems to reduce and saturate as the time of Ni-plating increases. No such relations observed between the times and the roughness heights.

The inclination γ calculated by optical method is always lower than θ_0 obtained by the Katto's method. This discrepancy may be attributed to the approximate nature of the latter model which assumes the sharply pointed vertex whereas that of the real surfaces are rounded.

§ 5. Conclusions

1) The scattering of light by metal aventurine surface whose r.m.s. roughness ranged 1,5 μ to 2 μ may be treated on the bases of the geometrial optics.
